Clinical prediction rules that combine patient history with physical exam findings have been developed to identify those at low risk of injury for whom specific radiographic and laboratory studies may not be necessary. The NEXUS C-spine rule is a sensitive, easily applicable rule that was validated for adults and children, although the younger population was smaller (see Table 72-7). Several clinical prediction rules have been developed to identify children at low risk of traumatic brain injury (Table 72-10). Another clinical prediction rule has been developed to identify children at very low risk of clinically-important intra-abdominal injuries following blunt trauma (Table 72-11). Although this rule has a negative predictive value of 99.9%, it needs to be externally validated before widespread implementation.

Psychological and Social Support

Serious multisystem trauma may result in significant long-term psychological and social difficulties for the child and family, particularly when there is a major head injury. Like adults, children are at risk for depressive symptoms and posttraumatic stress disorder. Caregivers face persistent stress and have been noted to have more psychological symptoms. Psychological and social support, during the resuscitation period and afterwards, is extremely important. Parents often prefer to be offered the choice to be present during resuscitations. A member of the resuscitation team should be made responsible for answering the family's questions and supporting them in the trauma room.

72.1 Care of Abrasions and Minor Lacerations

Joanna S. Cohen and Bruce L. Klein

LACERATIONS AND CUTS

Lacerations are tears of the skin caused by blunt or shearing forces. A cut (or a stab), in contrast, is an injury inflicted by a sharp object. Although distinguishing between the two can be important for forensic purposes, their evaluation and management are similar. In this chapter, lacerations include cuts and stabs.

Epidemiology

More than half of the 12 million wounds treated annually in U.S. EDs are lacerations. Approximately 30% occur in children younger than 18 yr. Approximately 2% of pediatric office visits are related to wound management.

Evaluation

The history should include the mechanism of injury, the amount of force, and the time the injury occurred. The mechanism helps determine whether there may be foreign material in the wound, which would increase the risk for infection. Particularly in children, it is essential to determine whether the injury was inflicted intentionally. If nonaccidental trauma is suspected, state or local child protective services agency should be notified. The type of force causing the laceration also influences the risk of infection, as a significant crush injury is more likely to become infected than a shearing one. Blunt injury, such as bumping the head, is a common cause of lacerations in children and is less likely to become infected. Theoretically, the amount of bacteria in the wound should increase exponentially with the time from injury to repair; however, the length of time that results in a clinically significant increase in wound infection is unclear. Older wounds may require delayed primary closure or healing by secondary intention. The patient or parent should be asked about any special host factors that may predispose to infection or impede healing, such as diabetes, malnutrition, obesity, and steroid therapy, as well as immunization status, with particular attention to tetanus administration.

On exam, the provider should note the size and depth of the wound, as well as any associated vascular, neurologic, tendon, or other tissue injury. The laceration's location also is important with regard to both the risk for infection and the cosmetic outcome. Compared with lacerations in adults, those in children occur more commonly on the face and scalp and less commonly on the upper extremities. Because the face and scalp are more vascular, wounds located there are less likely to become infected. Lacerations overlying joints are more likely to develop wider scars as a result of tension during healing.

Treatment

The goals of treatment are to establish hemostasis, minimize the risk of infection, restore skin and underlying tissue integrity, and produce the most functionally and cosmetically acceptable result possible. Complications of wounds, including infection, hypertrophic scar formation, and functional limitation occur in 8% of children.

Any significant bleeding must be controlled (with external pressure usually) before a thorough evaluation of the wound can occur. *If there is a skin flap, it should be returned to its original position before application of pressure.* A tourniquet may need to be applied if bleeding cannot be controlled with direct pressure. Clothing over the injury should be removed to minimize wound contamination. Jewelry encircling an injured extremity should be removed to prevent the jewelry from forming a constricting band when the extremity swells.

It is best to administer a local anesthetic early, before exploration and more meticulous cleansing of the wound. This anesthetic can be applied topically (e.g., lidocaine, epinephrine, and tetracaine gel) or infiltrated locally or as a regional nerve block (e.g., lidocaine or bupivacaine), depending on the location of the laceration and the complexity of the repair. Pain from lidocaine infusion can be reduced by buffering the lidocaine with sodium bicarbonate. Sometimes

nonpharmacologic or additional pharmacologic methods of analgesia and anxiolysis are required for a young, frightened, or uncooperative child. The wound should be examined under proper light to enable identification of foreign bodies or damage to vessels, nerves, or tendons.

Many lacerations, especially heavily contaminated ones, benefit from irrigation, with either water or sterile saline, to reduce the risk of infection. It is important to recognize that many traumatic lacerations treated in the ED or office are only minimally contaminated, containing less than 10^2 bacterial colonies. In fact, in one of the few human studies on irrigation, irrigation did not decrease the infection rate of minimally contaminated scalp or facial lacerations in patients who presented to an ED within 6 hr of injury. Another concern is that higher-pressure irrigation may actually increase tissue damage, making the wound and adjacent tissue more susceptible to infection and delaying healing. These caveats notwithstanding, irrigation has benefits, although which technique to use—that is, which device, what size syringe, what size needle, which solution, how much volume, how much pressure—remains to be determined. These features may vary for different types of lacerations. In heavily contaminated wounds, the benefit of higher-pressure irrigation likely outweighs the harm of tissue damage. For heavily contaminated lacerations, a typical recommendation is to use a 35- to 65-mL syringe attached to a plastic splatter shield, or a 19-gauge needle if a splatter shield is unavailable, and to irrigate with approximately 100 mL of solution per centimeter of wound. Conversely, for relatively clean wounds, lower-pressure irrigation minimizes tissue damage, which may be more important for outcome than any decrease in bacterial clearance that may ensue. Debridement of devitalized tissue with higher-pressure irrigation, scrubbing, or surgical excision can also be necessary in certain cases, such as crush injuries.

Most lacerations seen in the pediatric ED or office should be closed primarily. Contraindications to primary closure (e.g., certain bite wounds) do exist (see Chapter 724). Although it is commonly accepted that the time from injury to repair should be as brief as possible to minimize the risk of infection, there is no universally accepted guideline as to what length of time is too long for primary wound closure. Also, this length of time varies for different types of lacerations. A prudent recommendation is that higher-risk wounds should be closed within 6 hr at most after the injury but that some low-risk wounds (e.g., clean facial lacerations) may be closed as late as 12-24 hr.

Many lacerations can be closed with simple, interrupted, 4-0, 5-0, or 6-0, nonabsorbable sutures. For lacerations under tension, horizontal or vertical mattress sutures, which provide added strength and may evert the wound edges better, can be used instead. For lacerations in cosmetically significant areas, a running intradermal stitch may produce a less conspicuous, more aesthetic scar than simple or mattress skin sutures, which can leave unattractive track marks. Deeper lacerations may need repair with an absorbable dermal and/or fascial layer. Other complex lacerations, such as those involving the ear, eyelid, nose, lip, tongue, genitalia, or fingertip, sometimes require more advanced techniques as well as subspecialty consultation.

Staples, topical skin adhesives, and surgical tape are acceptable alternatives to sutures, depending on the laceration's location and the healthcare provider's preference. Staples are particularly useful for lacerations of the scalp, where the appearance of the scar tends to be less important. Topical skin adhesives (octylcyanoacrylates or butylcyanoacrylates) are ideal for linear, relatively superficial lacerations with easily approximated edges that are not under tension. They are particularly good for lacerations located in areas where suture track marks are especially undesirable, or in situations where resources are constrained.

Maintaining a warm, moist, wound environment following repair accelerates wound healing without increasing the risk of infection. A topical antimicrobial ointment (e.g., bacitracin or a bacitracin, neomycin, and polymyxin B combination) and conventional gauze dressing provide such an environment and reduce the infection rate. Compared with conventional dressings, occlusive dressings (hydrocolloids, hydrogels, polyurethane films) may be better at accelerating healing, reducing infection, and decreasing pain but are more expensive. Occlusive dressings that adhere (hydrocolloids or polyurethane films) are impractical for lacerations with protruding sutures. If the laceration overlies or is near a joint, splinting helps limit mobility and can speed healing and minimize dehiscence.

For most routine lacerations evaluated in the ED or office that are repaired early and meticulously, prophylactic systemic antibiotics are unnecessary because they do not decrease the rate of infection. Antibiotic prophylaxis is or may be indicated for human and many animal bites, for open fractures and joints, and for grossly contaminated wounds, as well as for wounds in patients who are immunosuppressed or have prosthetic devices. Tetanus prophylaxis should be administered, if indicated, according to Centers for Disease Control and Prevention guidelines (see Chapter 211).

ABRASIONS

An *abrasion* is a scrape to the epidermis, and sometimes the dermis, that is usually caused by friction of the skin against a rough surface. "Road rash" is a colloquial term for abrasions that result from friction of the skin against pavement. Motor vehicle collisions with pedestrians and cycling accidents are common causes of road rash in children. Road rash can be extensive, involving multiple areas on the body. These abrasions also can be deep, and they often contain embedded debris. A "rug burn" is an abrasion sustained by sliding across a carpet. Some abrasions display specific patterns and are called *imprint abrasions*. Ligature marks are a type of imprint abrasion caused by a rope or cord that has been tied around a part of the body and has rubbed against the skin. These injuries should alert the clinician to the likelihood of nonaccidental (including self-inflicted) trauma.

Treatment

All abrasions should be cleansed thoroughly, and any debris or foreign material removed. If debris is not removed, abnormal skin pigmentation, known as post-traumatic tattooing, can occur and can be difficult to treat. A nonadherent occlusive dressing or a topical antibiotic and conventional dressing should be applied. Tetanus prophylaxis should be administered, if indicated (see Chapter 211). Large and/or deep abrasions that have not healed in a few weeks require consultation with a plastic surgeon for more advanced care.

Chapter 73

Altitude-Associated Illness in Children (Acute Mountain Sickness)

Susan Niermeyer and Michael Yaron

High-altitude illness represents a spectrum of clinical entities with neurologic and pulmonary manifestations that overlap in their presentations and share common elements of pathophysiology. **Acute mountain sickness (AMS)** is the relatively benign and self-limited presentation, whereas **high-altitude pulmonary edema (HAPE)** and **high-altitude cerebral edema (HACE)** represent the potentially

life-threatening manifestations. Children are at risk of developing these conditions as they travel to high mountainous locations with their families pursuing outdoor recreation, tourism, or relocation to high-altitude communities.

In 1987, it was estimated that more than 1 million visitors of all ages travelled annually to the remote high mountain ranges of Asia, Africa, and South America, and approximately 35 million visitors travelled annually to high-altitude recreation areas in the western United States; today these numbers are likely to be underestimations. Given the large number of families travelling to high-altitude mountain locations worldwide and the potential for 25% of those travelling to even moderate altitudes to develop altitude-related symptoms, this has become a significant public health issue. Significant morbidity among children travelling with their families to high altitude locations warrants improved education of the populations at risk and the clinicians who care for them.

ETIOLOGY

Definitions

The altitude threshold where clinical illness may begin to occur is 1,500 meters (~4,900 ft). At this altitude a mild impairment in oxygen transport begins, yet altitude illness is relatively rare until higher elevations are reached. Children with underlying medical problems that impair oxygen transport may be predisposed to developing altitude illness at these lower levels. At moderate high altitude, 2,500-3,500 meters (~8,000-11,500 feet) arterial oxygen saturation (Sa_{O_2}) is generally well maintained; however, mild tissue hypoxia may occur as a result of low arterial oxygen partial pressure (Pa_{O_2}) and altitude illness becomes common after rapid ascent over 2,500 m. This is the altitude range that most people visit and the elevation of many popular ski resorts in the United States, thus the most common range to find the greatest number of altitude illness cases. Very high altitude, 3,500-5,500 meters (~11,500-18,000 feet) is associated with the most serious altitude illness, as Sa_{O_2} falls below 90%. Here saturations fall on the steep portion of the oxyhemoglobin dissociation curve, and marked desaturation may occur with relatively small increases in altitude. At these heights severe hypoxemia is seen with sleep, exercise and illness. HAPE and HACE are most common in this environment. *Extreme high altitude,* above 5,500 meters (~18,000 feet) generally results in severe altitude illness during acute ascent without supplemental oxygen. Acclimatization at intermediate altitudes is required to reach extreme altitudes. Complete acclimatization is not possible, and long visits in this range result in progressive deterioration.

Environmental Considerations

The partial pressure of oxygen (pO_2) in the atmosphere decreases logarithmically as geographic altitude rises, but oxygen remains a constant 20.93% of the barometric pressure. The degree of hypoxia is related to the geographic altitude and the local variability of barometric pressure. The shape of the earth is slightly flat at the poles and bulging at the equator. The atmospheric envelope that surrounds the earth has a similar shape; thus the barometric pressure and the relative altitude are lower at higher latitudes than at the equator. The atmospheric envelope also develops seasonal variations in its local thickness, resulting in barometric pressures that are lower and relative altitudes that are higher during the winter season. Local weather can also have a significant effect on barometric pressure from day to day. A strong low-pressure front can reduce the barometric pressure 10-20 mm Hg and result in a significant temporary increase (150-500 m) in relative altitude.

GENERAL EFFECTS OF HYPOBARIC HYPOXIA

Arterial oxygen saturation falls with increasing altitude, eventually triggering central chemoreceptor responses to produce hyperventilation in an attempt to normalize oxygen saturation; relative hypoventilation exacerbates the hypoxemia of high-altitude exposure. During sleep, periodic breathing associated with high-altitude exposure may result in periods of apnea, causing further arterial oxygen desaturation. Fluid homeostasis often shifts at altitude, resulting in a generalized fluid retention and redistribution into intracellular and interstitial spaces manifested by peripheral edema, decreased urinary output, and impaired gas exchange.

Acclimatization

Gradual ascents allowing for acclimatization over several weeks have allowed successful summiting of many of the world's highest peaks without supplemental oxygen. Without this gradual approach, rapid exposure to extreme altitude results in loss of consciousness and asphyxia in a matter of minutes. Children may acclimatize at least as well if not better than adults when comparing heart rate and arterial saturation of children 7-9 yr of age to their parents during a slow ascent.

Some of the responses to hypoxia are mediated at the molecular level by hypoxia inducible factor (HIF). This transcriptional activator orchestrates the expression of hundreds of genes in response to both acute and chronic hypoxic conditions. Acclimatization begins at the altitude that causes the oxygen saturation of arterial blood to fall below sea level values. Most healthy, unacclimatized visitors to high altitude will not experience a significant drop in oxygen saturation ($Sa_{O_2} < 90\%$) until they reach elevations above 8,000 feet. Children with preexisting conditions that reduce oxygen transport may have altitude intolerance and hypoxic stress at lower levels. Of particular importance are both acute and chronic cardiac and respiratory illnesses. An individual's inherent ability to acclimatize is also important. Some acclimatize easily without developing clinical symptoms, others may transiently develop AMS during acclimatization, and a few have marked reactions to altitude exposure, fail to acclimatize, and develop severe altitude illness. Previous successful acclimatization may be predictive of future responses for adults in similar conditions but may not be the case for children.

The most important response to acute hypoxia is an increase in minute ventilation. Peripheral chemoreceptors in the carotid bodies respond to hypoxia by signaling the respiratory control center in the medulla to increase ventilation. This decreases alveolar carbon dioxide partial pressure resulting in a corresponding increase of alveolar oxygen tension and arterial oxygenation. This increased ventilation known as the **hypoxic ventilatory response (HVR)**, varies in magnitude among individuals, may be genetically predetermined, and is related to the ability to acclimatize. A low HVR and relative hypoventilation are implicated in the pathogenesis of both AMS and HAPE, whereas a strong HVR enhances acclimatization. As ventilation increases, a respiratory alkalosis occurs, exerting negative feedback on central respiratory control, limiting further ventilation increase. The kidneys excrete bicarbonate in an effort to compensate for the alkalosis. As the pH normalizes, ventilation rises slowly, reaching a maximum after 4-7 days. *This process is enhanced by acetazolamide, which induces a bicarbonate diuresis.*

Increased sympathetic activity and catecholamine release on ascent result in elevation of heart rate, blood pressure, cardiac output, and venous tone. Except at extreme altitudes, acclimatization results in the resting heart rate gradually returning to near sea level values. *Resting relative tachycardia is evidence of poor acclimatization.*

Hematopoietic acclimatization consists of an increase in hemoglobin and the number of red blood cells and increase in 2,3-diphosphoglycerate. After acute ascent, an early increase of up to 15% occurs in hemoglobin concentration primarily from fluid shifting into the extravascular space. Acclimatization leads to an increase in plasma volume and total blood volume. Erythropoietin is secreted in a HIF-mediated response to hypoxemia within hours of ascent, stimulating the production of new red blood cells, which begin to appear in the circulation in 4 or 5 days. Hypoxemia also increase 2,3-diphosphoglycerate, resulting in a rightward shift of the oxyhemoglobin dissociation curve, favoring release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the oxyhemoglobin dissociation curve caused by the respiratory alkalosis from hyperventilation. The result is a net null change in the oxyhemoglobin curve and an increase in oxygen-hemoglobin binding in the lung, raising Sa_{O_2}. Climbers at extreme altitude respond with marked hyperventilation, alkalosis and leftward shift; this leftward shift favors oxygen loading in a hypoxic environment and increases Sa_{O_2}. Some

individuals with mutant hemoglobin and high oxygen-hemoglobin affinity have been found to acclimatize more efficiently at moderate altitudes than their normal counterparts.

ACUTE MOUNTAIN SICKNESS

Epidemiology and Risk Factors

The incidence of high-altitude illness depends on several variables including the rate of ascent, previous altitude exposure, and individual genetic susceptibility. Sleeping altitude, final altitude reached, and duration of stay at altitude are also clear risk factors for AMS development. AMS is very common with rapid ascent. Climbers around the world who ascend quickly (1 or 2 days) from sea level to altitudes of 14,000-20,000 feet have a very high incidence of AMS (27-83%). The rapid ascent profile associated with air travel to high altitude locations also results in high AMS attack rates. Trekkers who fly into the Khumbu region to explore the Mt. Everest area have a higher incidence of AMS (47%) compared with those who walk (23%). Skiers who visit resorts in the western United States from sea level generally fly or drive to the region but sleep at relatively moderate altitudes (6,300-9,700 ft). Among this population, AMS occurs in approximately 25%.

Children have the same incidence of AMS as adults. Individual (genetic) susceptibility for the development of AMS plays a significant role in risk assessment. Most individuals with previous histories of AMS after acute ascent are likely to experience similar symptoms with repeated visits to altitude. While anecdotal clinical experience supports this concept in children, limited data exist regarding recurrent AMS in children. Gender does not affect the incidence of AMS.

Pathophysiology

The symptoms of AMS develop several hours after arrival at high altitude, whereas the development of HAPE and HACE generally requires several days of altitude exposure. Because hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness, but rather the initiating factor.

The clinical manifestations of AMS/HACE are primarily the result of central nervous system dysfunction caused by hemodynamic mechanical factors and biochemical mediators of permeability. The central nervous system (CNS) vasodilatory response to hypoxemia causes an increase in cerebral blood flow and volume. Significant elevation of brain volume is observed in moderate to severe AMS and HACE but has not been demonstrated in mild AMS. Hypoxic alteration of CNS vascular autoregulation and hypertension from exercise may increase pressure transmission to the brain's capillary beds resulting in transcapillary leakage and vasogenic edema. HIF-mediated vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation may increase permeability. Both mechanical and biochemical activation of the trigeminovascular system have been proposed as the cause of high-altitude headache, the primary symptom of AMS. While vasogenic edema has been implicated in severe AMS and HACE, magnetic resonance imaging (MRI) reveals signal changes in subjects with and without clinical AMS.

Many of the responses to hypoxia and altitude exposure occur both in individuals who develop symptoms and those who remain free of AMS. To address the discrepancy in symptomatic illness, the "tight fit" hypothesis was proposed. This theory suggests that the development of AMS/HACE is the result of a lack of intracranial space to accommodate increasing volume from brain swelling and edema that develop at altitude. The adequacy of the intracranial and intraspinal space to buffer changes in brain and cerebrospinal fluid (CSF) volume is the central concept. Buffering occurs as the intracranial CSF is displaced via the foramen magnum into the space available in the spinal canal, followed by increased CSF absorption and decreased CSF production. Individuals with less CSF buffering capacity have less compliance and are hypothesized to become more symptomatic (develop AMS).

Diagnosis

In adults, the symptoms of mild AMS are similar to those of a viral syndrome, an ethanol "hangover," or simple physical exhaustion. To diagnose AMS, an adult must be in the setting of a recent gain in altitude, be at the new altitude for at least several hours, and report a headache *plus* at least 1 of the following symptoms: gastrointestinal upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness or lightheadedness, or difficulty sleeping. These symptoms comprise the adult Lake Louise criteria for AMS. The headache may vary from mild to severe; anorexia plus nausea, with or without vomiting, are common. Sleep disturbance caused by periodic breathing is common in all visitors to high altitudes but is exacerbated in the setting of AMS. All the symptoms of AMS can range in severity from mild to incapacitating. Symptoms develop within a few hours after ascent and generally reach maximum severity between 24 and 48 hr, followed by gradual resolution. Most adults become symptom free by the 3rd or 4th day. The vague nature of this presentation has resulted in many misdiagnoses and morbidity among adults. In the setting of recent altitude exposure, these symptoms warrant a presumptive diagnosis of AMS and limitation of further ascent. There are no diagnostic physical signs in cases of mild AMS. Any evidence of CNS dysfunction, such as mild ataxia or altered mentation, is early evidence of HACE. Similarly, while dyspnea on exertion is universal at high altitudes, dyspnea at rest is an early indicator of HAPE.

Among infants and older preverbal children (up to 3 yr of age), AMS is diagnosed using nonverbal criteria. In this age range, AMS is manifested by increased fussiness, decreased playfulness, decreased appetite, and sleep disturbance. In most cases of AMS in very young children, all of these symptoms are present. Fussiness is defined as a state of irritability that is not easily explained by a cause, such as tiredness, wet diaper, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness or muscular tension. Decreased playfulness may be profound. Alterations of appetite may progress to frank vomiting. Sleep disturbance can manifest with either increased or decreased sleep when compared to normal patterns. Most often decreased sleep and the inability to nap are noted.

The diagnosis of AMS in older children with early language skills (ages 4-11 yr) may be made with cautious use of the adult Lake Louise criteria. The language used in this adult questionnaire may be too complex and may underestimate AMS if not understood by the child. This is particularly true for questions regarding headache (the key symptom of AMS) and gastrointestinal symptoms. An age-appropriate modified Lake Louise Score for 4-11 yr old children has been proposed and used in the research setting (Fig. 73-1). Evaluating for the presence of headache can be accomplished by asking if the "head hurts" or by using a visual "faces" pain scale. Gastrointestinal symptoms are evaluated by asking children if they are "hungry" rather than trying to evaluate their appetite.

Many of the symptoms manifested by AMS in children may also result from the disruption of normal routine with travel. A change in environment, sleeping accommodation, or eating options can result in a fussy child. The threshold scores for AMS diagnostic criteria are modified to account for these baseline variations. Parents can easily learn to recognize AMS in preverbal children using the Children's Lake Louise Score to alert them to the constellation of alterations in fussiness (headache equivalent), appetite, playfulness and sleep in their young child (see Fig. 73-1). Educating parents to recognize the symptoms of AMS in themselves is also important as an ill parent can indirectly compromise a child's safety.

Other acute illnesses can mimic AMS in young children. It must be emphasized that altered mental status, neurologic abnormalities, breathing difficulty or cyanosis are not part of uncomplicated AMS. **Any of these signs warrant immediate medical attention.** If serious bacterial illness, a surgical condition, or another problem meriting specific intervention is suspected in a child, descent to lower altitude is recommended to eliminate the confounding variable of altitude illness.

Periodic Breathing

Periodic breathing at altitude is common at all ages during sleep, resulting in brief repeated episodes of oxyhemoglobin desaturation. Prepubertal children (9-12 yr old) have similar night-time oxygen

AMOUNT OF UNEXPLAINED FUSSINESS

0 1 2 3 4 5 6

No Fussiness — Intermittent Fussiness — Constant Fussiness When Awake

INTENSITY OF FUSSINESS

0 1 2 3 4 5 6

No Fussiness — Moderate Fussiness — Severe Fussiness When Awake

FUSSINESS SCORE (**FS**) = Amount + Intensity

RATE HOW WELL YOUR CHILD HAS **EATEN** TODAY (**E**)

0—Normal
1—Slightly less than normal
2—Much less than normal
3—Vomiting or not eating

RATE HOW **PLAYFUL** YOUR CHILD IS TODAY (**P**)

0—Normal
1—Playing slightly less
2—Playing much less than normal
3—Not playing

RATE ABILITY OF YOUR CHILD TO **SLEEP** TODAY (**S**)

0—Normal

2—Much less or more than normal
3—Not able to sleep

CLLS = FS + E + P + S

The CLLS must be $\geq$7 with both the FS $\geq$4 and E+P+S $\geq$3 to confirm acute mountain sickness.

Figure 73-1 Children's Lake Louise Score. Fussiness is defined as a state of irritability that is not easily explained by a cause, such as tiredness, hunger, teething or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Please rate your child's typical fussy behavior *during the last 24 hr* without the benefit of your intervention.

desaturations as their parents; they have somewhat more stable breathing patterns with less periodicity. While periodic breathing is not a sign of AMS, the exacerbation of hypoxia during sleep plays a role in AMS development. Newborn infants normally have periodicity in their respiratory pattern, and this periodicity is increased by high-altitude exposure and sleep. Oxygen saturations of awake neonates who are born in Colorado at 3,100 m range from 88-91%. During sleep with increased periodic breathing, oxygen saturation may drop to 81% during the 1st wk of life. The amount and magnitude of respiratory periodicity decreases as the child matures and saturation during sleep increases to 86% after 2 mo. A stable mature pattern is usually reached by 6 mo of age. Preterm babies may demonstrate marked periodicity with prolonged desaturation as a result of their immaturity. Acute ascent with a child born preterm is best delayed until maturity, when normal pulmonary function and respiratory drive can be demonstrated. Parents of normal young babies may become distressed as they note marked periodic breathing patterns in their child after ascent to moderate altitude. Clinicians can reassure parents that this is generally not a precursor of true apnea; however, desaturation can occur with periodic breathing in sleep, especially at higher altitudes.

Management

The management of AMS must include strict adherence to the principle that further ascent to a higher sleeping altitude is contraindicated after the symptoms of altitude illness occur. Halting ascent or activity to allow further acclimatization may reverse the symptoms; however; the ascent exacerbates the underlying pathologic processes and may lead to disastrous results. Stopping further ascent and waiting for acclimatization treats most AMS in 1-4 days. Mild cases of AMS may be treated without descent if monitoring by a reliable caregiver is available. In addition to rest, symptomatic therapy includes analgesics and antiemetics. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention mandates descent. Descent (500-1,000 m) is effective treatment for all forms of altitude illness and should be tailored to the individual response. *The presence of neurologic abnormalities (ataxia or altered mentation) or evidence of pulmonary edema (dyspnea at rest) mandates descent because these signs indicate a progression of AMS to severe altitude illness.*

Supplemental oxygen administration relieves AMS symptoms, including small amounts (1-2 L/min) given during sleep. In the wilderness, oxygen tanks are impractically heavy and are usually unavailable in adequate amounts; therefore, oxygen therapy is usually reserved for the more serious manifestations of high-altitude illness. In resort settings, oxygen may be readily available for use in the hotel or condominium, but use in children is often difficult. Hyperbaric therapy that simulates descent is also effective.

Treatment of headache and nausea can be beneficial during the course of mild AMS, and in many cases this may be all that is necessary. Ibuprofen and acetaminophen are useful for the treatment of high-altitude headache; evidence supports this conservative approach in children as well. For nausea and vomiting, ondansetron oral dissolving tablets may be used.

Acetazolamide is a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis, causing a metabolic acidosis that increases ventilation and arterial oxygenation. This respiratory stimulation improves sleep when the hypoxemia caused by periodic breathing is eradicated by acetazolamide. Acetazolamide accelerates acclimatization and, if

Table 73-1 Medications for Treatment of Altitude-Associated Illness in Children (No Studies in Children for High-Altitude Indications)

MEDICATION	CLASSIFICATION	INDICATION	DOSE AND ROUTE	ADVERSE EFFECTS
Acetazolamide	Carbonic anhydrase inhibitor	AMS prevention*	2.5 mg/kg PO every 12 hours; maximum 125 mg/dose	Collateral effects include paresthesias and taste alteration
		AMS treatment	2.5 mg/kg PO every 12 hours; maximum 250 mg/dose	
Dexamethasone	Steroid	AMS prevention†		Risk of adverse effects precludes prophylactic use
		AMS HACE treatment‡	0.15 mg/kg PO/IM/IV every 6 hr; maximum 4 mg/dose	Hypertension, gastrointestinal hemorrhage, pancreatitis, growth inhibition
Nifedipine	Calcium-channel blocker	HAPE treatment (small children)§	0.5 mg/kg PO every 4-8 hr; maximum 20 mg/dose	Hypotension
		HAPE treatment (>60 kg)§	30 mg SR PO every 12 hr or 20 mg SR PO every 8 hours	
		Reentry HAPE prevention	Same dose as HAPE treatment	
Sildenafil	Phosphodiesterase-5 inhibitor	HAPE¶	0.5 mg/kg/dose PO every 4-8 hr; maximum 50 mg/dose every 8 hr	FDA warning against chronic use in children

*AMS prophylaxis is not routinely recommended in children. It is indicated when rapid ascent profile is unavoidable or previous altitude illness in child about to undergo similar ascent profile. Doses as low as 1.25 mg/kg every 12 hr have been successful in some children.

†Use not warranted due to risk of adverse effects. Use slow graded ascent or acetazolamide.

‡Oxygen and descent are the treatment of choice for severe AMS. If acetazolamide is not tolerated dexamethasone may be used. Oxygen, descent, and dexamethasone should be used in HACE.

§In emergency settings where oxygen and descent are not an option, then nifedipine is indicated.

¶In emergency settings where oxygen and descent are not an option, if nifedipine is not well tolerated, then sildenafil may provide an alternative.

given early in the development of AMS, rapidly resolves symptoms. The dose for children is 2.5 mg/kg/dose given twice daily to a maximum of 250 mg/dose (Table 73-1). Treatment for 48 hr is usually adequate for resolution of symptoms.

The most common adverse reactions to acetazolamide in adults include paresthesias, polyuria, and taste alterations. Less common reactions include nausea, drowsiness, tinnitus, transient myopia, and, rarely, rash. Acetazolamide is a nonantibiotic sulfa compound that carries a low risk of cross-reactivity for individuals with an allergy to sulfa antibiotics. A history of anaphylaxis or severe skin reactions to any sulfa-containing medication contraindicates the use of acetazolamide. Acetazolamide should be avoided in breastfeeding mothers and pregnant women.

Dexamethasone is an effective alternative treatment for AMS in adults. Although dexamethasone can resolve the symptoms of AMS, it does not play a role in acclimatization and symptoms may recur when the treatment is withdrawn. Adverse reactions to dexamethasone of concern in the pediatric population are pancreatitis, pseudotumor cerebri, and interference with normal growth. While these reactions are generally seen with prolonged use, dexamethasone should be avoided in children for prophylaxis and used for treatment only in extreme situations where alternatives such as descent or oxygen therapy are unavailable. The dosage of dexamethasone is 0.15 mg/kg/dose orally every 6 hr to a maximum of 4 mg per dose.

Prevention

Individuals who have a known susceptibility to the development of AMS and those for whom slow ascent is impractical may consider prophylactic medication. *Acetazolamide remains the compound of choice for AMS prophylaxis.* Numerous studies have demonstrated its effectiveness in adults, and 125 mg twice daily starting 24 hr before ascent and continuing for the first 2 days at high altitude is recommended. The recommended dosage of acetazolamide for AMS prophylaxis for children is 2.5 mg/kg/dose orally up to 125 mg total given twice daily. Ibuprofen when compared to acetazolamide is equally efficacious in preventing headache in adults. Dexamethasone also prevents AMS. However the potential adverse effects in children preclude its use for prophylaxis in this age group. Recommendations for hyperhydration are frequently given in the lay literature, yet no evidence supports this advice. Drinking excessive amounts of free water may lead to hyponatremia and possibly complicate altitude illness.

HIGH ALTITUDE CEREBRAL EDEMA

Epidemiology and Risk Factors

HACE is rare in children, but it is rapidly fatal if unrecognized. Generally seen in adults with prolonged stays above 3,000 m, HACE is usually associated with concurrent AMS or HAPE, but can occur on its own.

Pathophysiology

HACE is regarded as the extreme expression of the same pathophysiology underlying AMS. In patients with HACE, MRI studies reveal white matter changes consistent with vasogenic edema that correlate with symptoms; evidence of cytotoxic edema has also been described.

Diagnosis

HACE is differentiated from severe AMS by the presence of neurologic signs. Most common are ataxia and altered mental status including confusion, progressive decrease in responsiveness, and eventually coma. Less common are focal cranial nerve palsies, motor and sensory deficits, and seizures. CT imaging is consistent with edema and increased intracranial pressure. MRI shows a high T2 signal in the white matter, specifically in the splenium of the corpus callosum, with diffusion-weighted technique.

Management

Descent remains the most effective treatment for HACE. Supplemental oxygen, if available, is useful especially if descent is not possible or delayed. Portable hyperbaric treatment is beneficial but its use should not delay descent if feasible. Dexamethasone should be administered at a dose of 0.15 mg/kg per dose given orally every 6 hr. The few mild cases of HACE reported in children have recovered with dexamethasone and descent.

HIGH ALTITUDE PULMONARY EDEMA

Epidemiology and Risk Factors

HAPE is a *noncardiogenic pulmonary edema* characterized by extravasation of intravascular fluid into the extravascular space of the lung.

HAPE generally occurs in the setting of recent ascent, most often at altitudes above 2,500 m, but in some cases at altitudes as low as 1,740 m. Among children, HAPE occurs in 2 distinct settings. **Type I HAPE** (or simply HAPE) occurs in a child who resides at low altitude who travels to high altitude. **Type II HAPE** (also termed reentry HAPE or reascent HAPE) affects children who reside at high altitude but become ill on their return home after descent to lower altitudes. HAPE may also occur in children who develop acute respiratory illnesses that exacerbate hypoxia at high altitude. Fatal outcomes of HAPE in children have been reported. Most mild and moderate cases resolve without difficulty, however if unrecognized and untreated, rapid progression to death can occur, especially when infection or cardiac conditions complicate the illness.

The incidence of HAPE is highly variable, as it depends not only on the altitude attained, but also the speed of ascent and prior history of HAPE. HAPE is significantly less common than AMS and its incidence in children resident at low altitude appears to parallel that among low-altitude-resident adults. HAPE affects male and female children more equally than adults, among whom the observed male predominance appears due to strenuous sport activities and military assignments. The occurrence and even the pathophysiology of HAPE may vary by population and genetic background. Individuals of Tibetan ancestry, resident on the Himalayan plateau and having minimal admixture with other populations, represent the extreme of adaptation to high altitude and rarely experience HAPE. Other native populations residing at high altitude, such as Andeans, do not appear to be protected from HAPE, and certain populations may have genetic polymorphisms associated with pulmonary edema. A number of conditions may predispose a child to HAPE (Table 73-2). Preexisting viral respiratory infections have been linked to HAPE, especially in children. Cardiorespiratory conditions associated with pulmonary hypertension, such as atrial and ventricular septal defects, pulmonary vein stenosis, congenital absence of a pulmonary artery, and obstructive sleep apnea also predispose to HAPE. Down syndrome is also a risk factor for HAPE development, as are previously repaired congenital heart defects and the presence of hypoplastic lungs. Undiagnosed structural cardiopulmonary abnormalities may result in severe hypoxia and/or altitude illness once ascent occurs.

Table 73-2 Conditions Associated with Increased Risk of HAPE

Condition
Environmental
Ascent above 2,500 m
Rapid rate of ascent (generally >1,000 m per day)
Cold exposure
Cardiac
Anomalies causing increased pulmonary blood flow or increased pulmonary arterial pressure
Ventricular septal defect, atrial septal defect, patent foramen ovale, patent ductus arteriosus
Anomalous pulmonary venous return or pulmonary vein stenosis
Unilateral absent pulmonary artery or isolated pulmonary artery of ductal origin
Coarctation of the aorta
Congestive heart failure
Pulmonary
Chronic lung disease
Bronchopulmonary dysplasia
Pulmonary hypoplasia
Supplemental oxygen requirement at sea level
Pulmonary hypertension
Perinatal respiratory distress
Persistent pulmonary hypertension of the newborn
Perinatal asphyxia or depression
Sleep apnea
Infectious
Upper respiratory tract infection
Bronchitis/bronchiolitis
Pneumonitis
Otitis media
Pharmacologic
Any medication causing central nervous system and respiratory depression
Alcohol
Sympathomimetics
Systemic
Down syndrome (trisomy 21)
History of premature birth or low birthweight

Physiology

Alveolar hypoxia results in vasoconstriction of pulmonary arterioles just proximal to the alveolar capillary bed. Hypoxic pulmonary vasoconstriction is a normal physiologic response to optimize ventilation/perfusion ($\dot{V}/\dot{Q}$) matching by redistributing regional pulmonary blood flow to areas of highest ventilation, thereby optimizing arterial oxygenation. Under conditions that result in widespread alveolar hypoxia, extensive pulmonary vasoconstriction will lead to significant elevations in pulmonary arterial pressure; uneven pulmonary vasoconstriction can result in localized overperfusion, increased capillary pressures, distention, and leakage in the remaining vessels. This explains the patchy and heterogeneous edema that is classically observed in HAPE. The combination of pulmonary hypertension and uneven pulmonary vasoconstriction appears to be necessary in the pathogenesis of HAPE. Children and adolescents acutely exposed to high-altitude hypoxia demonstrated pulmonary hypertension, with increases in pulmonary artery pressure inversely related to age. Once the vascular leak occurs and alveolar fluid accumulates, a defect in transepithelial sodium transport impairs the clearance of alveolar fluid and contributes to HAPE.

Diagnosis

The diagnosis of HAPE is based on clinical findings and their evolution in the context of recent ascent from lower elevation. There is no single diagnostic test or constellation of laboratory findings. Symptoms commonly develop within 24-96 hr, and onset of symptoms often occurs during the first or second night at altitude when hypoxia may be exacerbated during sleep. HAPE generally is not observed beyond 5 days after ascent to altitude (unless additional ascent occurs) because pulmonary vascular remodeling and acclimatization have taken place. The minimum criteria to diagnose HAPE include: recent exposure to altitude, dyspnea at rest, radiographic evidence of alveolar infiltrates, and near-complete resolution of both clinical and radiographic signs within 48 hr after descent or institution of oxygen therapy. Portable ultrasound has been shown useful to diagnose HAPE through the finding of "comet tails," artifacts created by microreflections of the ultrasound beam within interlobular septae thickened by interstitial and/or alveolar edema.

The symptoms of AMS and HAPE show considerable overlap, and AMS may precede the development of HAPE in approximately half of patients. Frequently patients first exhibit general malaise that may progress to more specific signs of dyspnea at rest, then cardiopulmonary distress. Young children may show agitation and general debility. Older children may complain of headache, and children of all ages frequently experience nausea and vomiting. Cough is a common pulmonary sign. Dyspnea at rest, orthopnea, cyanosis, tachycardia, and chest pain herald worsening compromise, which may advance within hours to production of pink-tinged sputum.

Findings on physical exam frequently are less severe than a patient's chest radiograph and the hypoxemia on pulse oximetry would predict. Children often appear pale, with or without visible cyanosis. Low-grade fever (<38.5°C [101.3°F]) is common and respiratory rate is generally increased. Auscultation typically reveals rales, usually greater in the right lung than the left on presentation. The radiographic pattern of pulmonary edema can be highly variable, from patchy and peripheral to more homogeneous in severe cases (Fig. 73-2). Often, the right lung shows more radiographic changes of edema than the left. Cardiomegaly is an uncommon finding, but peribronchial and perivascular cuffing are frequent, as well as enlargement of the pulmonary artery

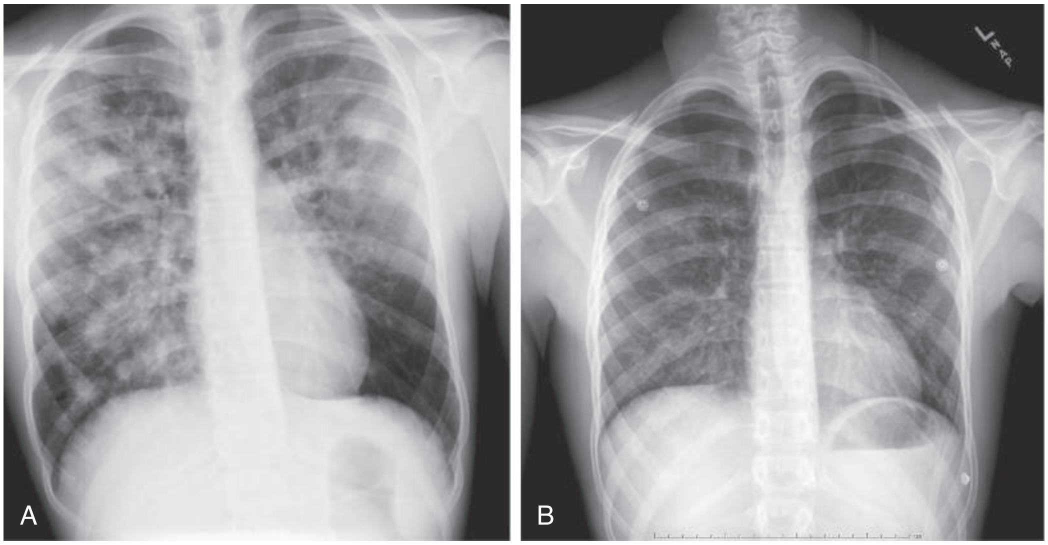

Figure 73-2 AMS and HAPE. A healthy 15 yr old male flew from Buffalo, NY, to Denver, CO, and immediately drove with his school group from the airport to a ski resort at 9,300 feet in the Rocky Mountains. The following day he felt dizzy and complained of headache. Symptoms of headache and dizziness continued along with emesis daily for 2 days. A snowboarding coach brought the patient to the local emergency facility the next day because of dyspnea, cough, headache, emesis, and fatigue. Pulse oximetry showed an arterial saturation of 51%. Chest x-ray showed diffuse pulmonary edema *(A)*. The patient was transported to Denver (5,280 feet) by ambulance with 15 L/min oxygen via a nonrebreathing mask. Saturations improved with descent and were 94% on arrival at the Children's Hospital Colorado emergency department. Breath sounds remained coarse and the patient was tachycardic and tachypneic. Oxygen flow was weaned to 1 L/min shortly after admission. Two days after presentation, lung exam was improved, without crackles. Repeat chest x-ray showed clearing of edema pattern *(B)*. The patient maintained adequate saturations without supplemental oxygen and was discharged. *(Courtesy of the Department of Radiology, Children's Hospital of Colorado.)*

silhouette and dilation of more peripheral pulmonary arteries. Significant arterial oxygen desaturation, as measured by pulse oximetry, is a consistent finding, with saturations frequently below 75%. A complete blood count often reveals a leukocytosis with a left shift of the granulocyte series.

The **differential diagnosis** of HAPE includes pneumonia, bronchitis/bronchiolitis, asthma, and other forms of cardiogenic and noncardiogenic pulmonary edema as well as pulmonary embolism. HAPE is most frequently misdiagnosed as pneumonia or a viral respiratory illness, especially when suspicion of altitude-associated pathology is not appropriately high. The presenting signs of cough, dyspnea, and orthopnea, follow by sputum production can easily be misinterpreted as pneumonia, an impression that is reinforced by the frequent accompaniment of low-grade fever. Respiratory viral infections increase the risk of developing HAPE, which may lead to further confusion in diagnosis.

Complications of HAPE in children often relate to underlying, sometimes undiagnosed, cardiopulmonary pathology or coexisting viral infections which potentiate the severity of pulmonary edema and pulmonary hypertension. Acute altitude exposure in such circumstances may lead to severe presentations that progress rapidly to extreme hypoxemia or cardiac failure and death. Children with trisomy 21, with or without structural cardiac anomalies, show increased susceptibility to HAPE and rapid symptom progression. Neonatal respiratory distress with pulmonary hypertension has been linked to exaggerated hypoxic pulmonary vasoreactivity in early adulthood and thereby a theoretical predisposition to HAPE. Other conditions related to pulmonary overcirculation (atrial and ventricular septal defects, patent foramen ovale, patent ductus arteriosus) small cross-sectional area of the pulmonary vascular bed (unilateral absent pulmonary artery, pulmonary hypoplasia), obstruction to pulmonary venous return (total anomalous pulmonary venous return, pulmonary vein stenosis), or left-sided obstruction (coarctation of the aorta) potentiate HAPE. Inflammatory processes, such as viral infection, predispose to HAPE and may worsen hypoxemia. Infection with respiratory syncytial virus, in particular, may trigger severe pulmonary hypertension.

Management

Descent with supplemental oxygen is the treatment of choice for HAPE in children. When feasible, or in the absence of medical care, rapid descent of at least 500-1,000 m usually results in rapid recovery. As with all altitude illness the magnitude of the descent is tailored to the resolution of symptoms. Oxygen and bed rest without descent can be safe and effective treatment for mild HAPE in children where careful medical observation is available. Mild HAPE in children and young adults at 3,750 m has been treated with bed rest alone, although clinical recovery may be slower compared to treatment with supplemental oxygen.

Supplemental oxygen at altitude is administered at 2-6 L/min by nasal cannula for 48-72 hr to maintain an arterial oxygen saturation of at least 90%. Increasing oxygen saturation above 90% does not result in further reduction in pulmonary artery pressure and does not accelerate edema resolution in adults. Oxygen flow can be weaned with improvement in symptoms and saturations; at flow rates below 2-4 L/min, children may be sufficiently stable and comfortable to continue treatment at home under the monitoring of family. Instructions to avoid physical exertion and exposure to cold should be given to reduce exposure to factors known to elevate pulmonary artery pressure. Most children experience complete resolution of mild HAPE within 24-72 hr of oxygen therapy when treated at altitude of symptom onset.

Pharmacotherapy for pediatric HAPE is rarely needed since oxygen and descent are so effective. In emergency situations without the options of supplemental oxygen or descent, pharmacotherapy is indicated. Nifedipine has been well studied for the treatment of adult HAPE. Extrapolated dosing for children is 0.5 mg/kg/dose given orally every 4-8 hr and titrated to response (maximum 10 mg/dose). Liquid-filled capsules of nifedipine (10 mg/0.34 mL) can be punctured to obtain doses for children less than 20 kg; sustained-release formulations cannot be broken to obtain reliable smaller doses. Patients should be monitored for hypotension during nifedipine administration. Phosphodiesterase type 5 inhibitors have been studied for HAPE prevention in adults. Although sildenafil and tadalafil have shown effectiveness in adults, there is concern around use of this class of agents in young children after the U.S. Food and Drug Administration warning against the use of sildenafil for pediatric pulmonary hypertension

between 1 and 17 yr of age because of an apparent increase in mortality during long-term therapy. Alveolar fluid clearance is upregulated by β-adrenergic agonists and inhaled β-agonists may successfully prevent and treat HAPE.

SPECIAL CONSIDERATIONS

Reentry HAPE

Children residing at high altitude may also experience HAPE of the type termed reentry or reascent HAPE. Reentry HAPE occurs upon reascent to the altitude of residence after a sojourn to low altitude. Although stays at low altitude as short as 24 hr may be sufficient to trigger reentry HAPE, most cases occur after several days at lower altitude. Children between 4 and 18 yr of age are much more likely to develop reentry HAPE than adults.

Reentry HAPE has a significant probability of recurrence and may justify pharmacologic prophylaxis to prevent the accumulated burden of morbidity. Acetazolamide has been used empirically based on its blunting of hypoxic pulmonary vasoconstriction in adults and the potential risk of hypotension and reflex tachycardia with nifedipine. The β_2-adrenergic agonist salmeterol has also been shown effective as prophylaxis in adults. Nifedipine may be a reasonable prophylactic option in older children and adolescents with histories of multiple episodes of HAPE.

Symptomatic High-Altitude Pulmonary Hypertension

Infants and young children resident at high altitude may also experience symptomatic high-altitude pulmonary hypertension, also termed **subacute infantile mountain sickness**. All infants, regardless of altitude of gestation and birth have thickened and muscularized interlobular and intralobular pulmonary arteries and pulmonary artery pressure that are initially near systemic. While muscular regression and fall in pulmonary artery pressure occur rapidly at sea level, infants permanently residing at high altitude demonstrate slowed regression of these characteristics through infancy and even childhood. Certain infants become symptomatic with exaggerated hypoxemia and signs of subacute pulmonary hypertension; these signs correlate with pathologic findings of right ventricular hypertrophy and dilation, increased muscularization of the pulmonary arterial bed and eventual right-sided congestive heart failure. Treatment may require relocation to a lower altitude.

Travel With Young Infants

Newborn infants retain some of the circulatory characteristics of recent fetal life, and these can pose a unique risk for altitude exposure. The fetal circulation has high pulmonary resistance, low pulmonary blood flow and both intra- and extra-cardiac shunts that optimize oxygenation via the placenta instead of the fetal lungs. After birth, a transition begins that closes fetal shunts and establishes normal pulmonary circulation and oxygen transport. **Exposure to marked hypoxia can result in reversion to fetal shunting patterns despite the absence of a placenta.** Normal infants at sea level complete these changes in 4-6 wk, though for infants born at moderate or high altitude, changes may last 3 mo or longer. Travel to high altitude with young infants is generally safe after 4-6 wk when circulatory changes have occurred, breastfeeding is established, and congenital abnormalities may have been detected.

Air travel with young infants frequently raises questions about the effects of exposure to hypobaric hypoxia, as the pressurization of aircraft cabins may vary up to an altitude equivalent of 8,500 feet (approximately 2,600 m). Transoceanic flights are generally not long enough to trigger AMS or HAPE; infants may experience transient desaturation with feedings during flight and likely experience discomfort because of dry air, and stress caused by noise and vibration. Former preterm infants without chronic lung disease who have attained 3 mo corrected gestational age do not appear to experience greater hypoxia during air travel than term infants; infants with more significant lung disease merit hypoxic challenge or provision for supplemental oxygen in flight.

Sickle Trait/Disease

Children with sickle cell disease or sickle trait should avoid travel to altitude, as hypoxemia may trigger sickling and painful crises, including splenic crises. Up to 20% of pediatric patients with sickle cell and sickle-thalassemia disease may experience a vasoocclusive crisis at moderate altitude or in pressurized aircraft. Oxygen is advised for air travelers with known sickle cell disease. Although the majority of children with sickle trait remain asymptomatic, children can experience splenic ischemia or infarction, with severe left upper quadrant pain. Splenic infarction may be more common in nonblack patients (often of Mediterranean origin) with sickle trait.

PREVENTION

A comprehensive approach to travel to high altitude with children should focus on 3 phases: planning the ascent and assessment of risk, recognition and management of altitude-associated illness, and follow-up of any illness relative to future travel or diagnostic testing necessary.

Planning for travel to high altitude with children should consider rate of ascent, formulation of an emergency plan for communication and evacuation, and availability of medical care at the high-altitude destination. Slow ascent with time for acclimatization is the best prevention for all forms of altitude illness. Ideally, the first night should be spent at an altitude no higher than 2,800 m and then 2-3 nights should be spent at 2,500-3,000 m, with a subsequent increase (to a new sleeping altitude) of not more than 500 m each night. One extra night of acclimatization (at the same sleeping altitude) should be taken for every 1,000 m gained. Rapid ascent by air may be avoidable through alternate routes or alternate means of transportation. Difficult descent situations (where further ascent may be necessary before descent is possible) should be avoided with children. The availability of medical care and evacuation from altitude will influence the degree of personal preparation necessary. Widespread coverage by cellular and satellite phone service may give a false sense of security in remote regions where both terrain and weather can limit the arrival of definitive help.

Medical risk assessment encompasses consideration of age, previous altitude-associated illness, and possible predisposing circumstances to altitude illness. Very young infants (younger than 4-6 wk) may not have completed the postnatal circulatory transition and may be more vulnerable to altitude-associated desaturation with periodic breathing, right-to-left shunting across the foramen ovale, and hypoxic pulmonary vasoconstriction. Infants who required supplemental oxygen during the neonatal period, especially for pulmonary hypertension, may be at risk for hypoxemia with prolonged altitude exposure. History and physical exam are useful to identify conditions predisposing to HAPE, including recent viral infections, cardiac malformations, or obstructive sleep apnea. Low-risk children should not need medications for prophylaxis and should use gradual ascent to prevent illness.

Prompt recognition of altitude-associated illness requires awareness of the context in which illness occurs and familiarity with the signs and symptoms. Parents are generally adept at recognizing deviation from baseline behavior of their children. Clinicians should emphasize to parents that breathing difficulty, cyanosis, cough productive of pink-tinged sputum, altered mental status, or neurologic abnormalities are *not* part of uncomplicated AMS, but instead are serious signs of potential HAPE or HACE that deserve immediate medical attention.

Descent is the mainstay of therapy for all forms of altitude-associated illness in children. When descent is not feasible or illness is mild, other therapeutic options may be chosen. Severe altitude illness or death can be avoided in children by adherence to 3 general principles:

1. Recognition of the early signs of altitude illness and willingness by adult caregivers to acknowledge them.
2. No further ascent, especially to sleep at a higher altitude, when experiencing even minor symptoms/signs of altitude illness.
3. Immediate descent if signs/symptoms worsen while resting/receiving treatment at the altitude of onset.

Uncomplicated AMS with full resolution of symptoms upon descent or treatment does not require diagnostic work-up, but may prompt discussion of slower ascent, specific plans for treatment, or even

prophylaxis for future travel. Signs of HAPE or severe hypoxemia in a child disproportionate to the altitude reached should prompt further diagnostic evaluation, including consideration of echocardiography. Underlying cardiac conditions may not be apparent on physical examination at low altitude; cardiac echocardiography or catheterization under conditions of controlled hypoxia or hypoxic exercise may be necessary. Families of HAPE-susceptible children should be advised to avoid travel during or shortly after viral infection.

Chapter 74

Drowning and Submersion Injury

Derya Caglar and Linda Quan

Drowning is one of the leading causes of childhood morbidity and mortality in the world. Prevention is the most important step to reducing the impact of drowning injury, followed by early initiation of cardiopulmonary resuscitation (CPR) at the scene.

ETIOLOGY

Children are at risk of drowning when they are exposed to a water hazard in their environment. The World Congress of Drowning definition of drowning is: "Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid." The term *drowning* does not imply the final outcome—death or survival; the outcome should be denoted as fatal or nonfatal drowning. Use of this terminology should improve consistency in reporting and research; the use of confusing descriptive terms such as "near," "wet," "dry," "secondary," "silent," "passive," and "active" should be abandoned. The injury following a drowning event is hypoxia.

EPIDEMIOLOGY

From 2005-2009, an average of 3,880 people per year were victims of fatal drowning and an estimated 5,789 persons were treated in U.S. hospital emergency departments (EDs) for nonfatal drowning. Compared with other types of injuries, drowning has one of the highest case fatality rates. Highest drowning death rates were seen in children ages 1-4 yr and 15-19 yr (2.55 and 1.29/100,000, respectively). In children, drowning is second only to motor vehicle injury as a leading cause of death from unintentional injury in the United States. Pediatric hospitalization rates associated with drowning ranged from 4.7 to 2.4 per 100,000 between 1993 and 2008. Rates of fatal drowning hospitalization declined from 0.5 to 0.3 deaths per 100,000 during the same period. Morbidity following nonfatal drowning is poorly studied.

The risk of drowning and the circumstances leading to it vary by age (Fig. 74-1). Drowning risk also relates to other host factors including male gender, alcohol use, a history of seizures, swimming lessons. Environmental risk factors include exposure to water and varying supervision. These factors are embedded in the context of geography, climate, socioeconomic status, and culture.

Children Younger Than 1 Year of Age

Most (71%) drowning deaths in children younger than 1 yr occur in the bathtub, when an infant is left alone or with an older sibling. Infant tub seats or rings may exacerbate the risk by giving caregivers a false sense of security that the child is safe in the tub. The next major risk to this age group is the large (5-gallon) household bucket, implicated in 16% of infant drowning deaths. These buckets are approximately 30 cm tall and designed to not tip over when half full. The average 9-mo-old child tends to be top-heavy, so can easily fall head first into a half-full bucket, become stuck, and drown within minutes.

Children 1-4 Years of Age

Drowning rates are consistently highest in 1-4 yr old children, likely because of their curious, but unaware, nature, coupled with the rapid progression of their physical capabilities. U.S. rates are highest in the southern regions, in some areas as high as 7.62/100,000, which approaches rates seen in developing countries. A common factor in many of these deaths is a lapse in adult supervision, often <5 min. Most U.S. drownings occur in residential swimming pools. Usually, the child is in the child's own home and the caregiver does not expect the child to be anywhere near the pool.

In rural areas, children in this age group often drown in irrigation ditches or nearby ponds and rivers. The circumstances are similar to those noted previously, in a body of water that is near the house. Drowning is one of the leading causes of farm injury–related deaths in children.

School-age Children

School-age children are at increased risk of drowning in natural bodies of water such as lakes, ponds, rivers, and canals. Although swimming pools account for the majority of nonfatal drownings, open water accounts for a higher death rate from this age group on through adolescence. Unlike for preschool children, swimming or boating activities are important factors in drowning injuries in school-aged children.

Adolescents

The second major peak in drowning death rates occurs in older adolescents, age 15-19 yr. Almost 70% drown in natural freshwater. In this age group particularly, striking disparities in drowning deaths exist in gender and race. Males account for 80% of fatal drownings. The drowning rates for adolescent males are nearly 10 times higher than those for adolescent females. The gender disparity may likely be related to males' greater risk-taking behavior, greater alcohol use, less perception about risks associated with drowning, as well as greater belief in their swimming ability than females. In 2009, as in previous years, drowning rates for black males age 15-19 yr were nearly double those for white males of the same age. Racial differences are only partially explained by socioeconomic status; other cultural factors contribute. Black children are more likely to drown in unguarded public or apartment pools, whereas white children are more likely to drown in private residential pools. Hispanic and foreign-born children have lower rates of drowning than their white counterparts. Differences in exposure to swimming lessons, cultural attitudes, and fears about swimming, as well as experience around water, may contribute to drowning risk.

Underlying Conditions

Several underlying medical conditions are associated with drowning at all ages. A number of studies have found an increased risk, up to 19-fold, in individuals with epilepsy. Drowning risk for children with seizures is greatest in bathtubs and swimming pools. Cardiac etiologies, including arrhythmias, myocarditis, and prolonged QT syndromes have been found in some children who die suddenly in the water (see Chapters 435.5), particularly in those with a family history of syncope, cardiac arrest, prior drowning, or QT prolongation. Some children with long QT syndrome are misdiagnosed as having seizures.

Drowning may also be an intentional injury. A history of the event that changes or is inconsistent with the child's developmental stage is the key to recognition of intentional drowning. Physical examination and other physical injuries rarely provide clues. Child abuse is more often recognized in bathtub-related drownings. Suicide usually occurs in lone swimmers in open water.

Alcohol Use

The use of alcohol and drugs greatly increases the risk of drowning. Of teenagers and adults who die, 30-40% have positive blood alcohol

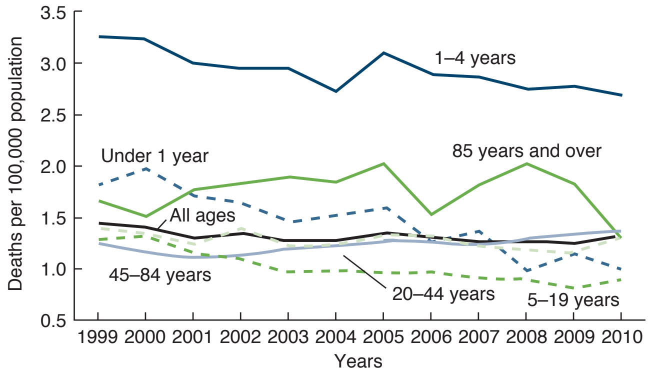

Figure 74-1 Death rates from unintentional drowning, by age group: United States, 1999-2010. A total of 46,419 deaths from unintentional drowning occurred in the United States from 1999 through 2010, an average of 3,868 deaths per year. Source: CDC/NCHS, National Vital Statistics System, Mortality. *(From Xu JQ: Unintentional drowning deaths in the United States, 1999-2010. NCHS Data Brief 149. Hyattsville, MD: National Center for Health Statistics, 2014.)*

levels. Alcohol can impair judgment, leading to riskier behavior, decreased balance and coordination, and blunted ability to self-rescue. Furthermore, an intoxicated adult may provide less-effective supervision of children around water.

Sports and Recreation

Most drowning deaths in the United States occur during recreational activities. Drowning is the leading cause of noncardiac sports-related deaths. Surveys confirm that alcohol use is common during water recreation, as is not using a personal flotation device (PFD) during boating activities. In 2012, the United States Coast Guard reported that almost 90% of those who drowned in boating accidents in the United States were not wearing a PFD.

Global Impact of Drowning

Drowning injury is a significant problem for children worldwide, with the vast majority (96%) of fatalities occurring in low and middle income countries in Asia. Given the relative size of the pediatric population in many of these countries, drowning is one of the leading causes of death globally. A recent UNICEF study estimated that approximately 77,000 children in this region alone died from drowning between 2004 and 2008. This number vastly underestimates the global drowning rate, as many drowning deaths in this region go unreported, with 64-100% of immediate fatalities going unrecognized. In addition, these data exclude any cases of drowning as the result of intentional harm or assault, accidents of watercraft or water transport, and drowning related to forces of nature/cataclysmic storms, which usually claim large numbers of lives per incident; thus true numbers of fatal drownings are likely much higher.

Some patterns of pediatric drowning are similar in all countries. By most accounts, the highest rates are seen in males and in children 1-4 yr old.

Whereas bathtubs and places of recreation (i.e., pools, spas) are significant locations for drowning in U.S. children, these are virtually unreported locations for drownings in developing countries. Instead, the predominant locations are near or around the home, involving bodies of water used for activities of daily living. These include water-collecting systems, ponds, ditches, creeks, and watering holes. In tropical areas, death rates increase during monsoon season, when ditches and holes rapidly fill with rain, and are highest during daylight hours, when caregivers are busy with daily chores.

Drowning during natural disasters such as storms and floods is important in all areas of the world. The largest numbers of reported flood-related deaths occur in developing nations; most are drownings that occur during the storm surge. In the United States and much of Europe, advances in weather monitoring and warning systems have reduced such deaths. U.S. flooding incidents, including hurricanes Katrina and Sandy, showed that drowning caused the most deaths, particularly when people became trapped in their vehicles, were unable or refused to evacuate homes, or attempted to rescue others.

PATHOPHYSIOLOGY

Drowning victims drown silently and do not signal distress or call for help. Vocalization is precluded by efforts to achieve maximal lung volume to keep the head above the water or by aspiration leading to laryngospasm. Young children can struggle for only 10-20 sec and adolescents for 30-60 sec before final submersion. A swimmer in distress is vertical in the water, pumping the arms up and down. This splashing or efforts to breathe are often misconstrued by nearby persons as merely “playing” in the water until the victim sinks.

Anoxic–Ischemic Injury

After experimental submersion, a conscious animal initially panics, trying to surface. During this stage, small amounts of water enter the hypopharynx, triggering laryngospasm. There is a progressive decrease in arterial blood oxygen saturation (Sao_2), and the animal soon loses consciousness from hypoxia. Profound hypoxia and medullary depression lead to terminal apnea. At the same time, the cardiovascular response leads to progressively decreasing cardiac output and oxygen delivery to other organs. By 3-4 min, myocardial hypoxia leads to abrupt circulatory failure. Ineffective cardiac contractions with electrical activity may occur briefly, without effective perfusion (pulseless electrical activity). With early initiation of CPR, spontaneous circulation may initially be successfully restored. The extent of the global hypoxic–ischemic injury determines the final outcome and becomes more evident over subsequent hours.

With modern intensive care, the cardiorespiratory effects of resuscitated drowning victims are usually manageable and are less often the cause of death than irreversible hypoxic–ischemic central nervous system (CNS) injury (see Chapter 68). CNS injury is the most common cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury begins is uncertain, it is probably on the order of 3-5 min. Ninety percent of victims with reported submersions of less than 5 min survive and appear normal at hospital discharge.

Several hours after cardiopulmonary arrest, cerebral edema may occur, although the mechanism is not entirely clear. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; intracranial hypertension is an ominous sign of profound CNS damage.

All other organs and tissues may exhibit signs of hypoxic–ischemic injury. In the lung, damage to the pulmonary vascular endothelium can lead to acute respiratory distress syndrome (see Chapter 71). Aspiration may also compound pulmonary injury. Myocardial dysfunction (so-called stunning), arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute kidney injury, cortical necrosis, and renal failure are common complications of major hypoxic–ischemic events (see Chapter 535.1). Vascular endothelial injury may initiate disseminated intravascular coagulation, hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage; bloody diarrhea with mucosal sloughing may be seen and often portends a fatal injury. Serum levels of hepatic transaminases and pancreatic enzymes are often acutely increased. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

Pulmonary Injury

Pulmonary aspiration (see Chapter 397) occurs in a majority of drowning victims, but the amount of aspirated fluid is usually small. Aspirated water does not obstruct airways and is readily moved into the

pulmonary circulation with positive pressure ventilation. It can wash out surfactant and cause alveolar instability, ventilation-perfusion mismatch, and intrapulmonary shunting. In humans, aspiration of small amounts (1-3 mL/kg) can lead to marked hypoxemia and a 10-40% reduction in lung compliance. The composition of aspirated material can affect the patient's clinical course: Gastric contents, pathogenic organisms, toxic chemicals, and other foreign matter can injure the lung or cause airway obstruction. Clinical management is not significantly different in saltwater and freshwater aspirations, because most victims do not aspirate enough fluid volume to make a clinical difference. A few children may have massive aspiration, increasing the likelihood of severe pulmonary dysfunction.

Cold Water Injury

Drowning should be differentiated from **cold water immersion** injuries, in which the victim remains afloat, keeping the head above water without respiratory impairment in cold waters. The definition of cold water varies from less than 15-20°C (59-68°F).

Heat loss through conduction and convection is more efficient in water than in air. Children are at increased risk for hypothermia because of their relatively high ratio of body surface area to mass, decreased subcutaneous fat, and limited thermogenic capacity. Hypothermia can develop as a result of prolonged surface contact with cold water during immersion, while the airway is above water, or with submersion. Body temperature may also continue to fall as a result of cold air, wet clothes, hypoxia, and hospital transport. Hypothermia in pediatric drowning victims may be observed even after drowning in relatively warm water and in warm climates.

Immersion in cold water has immediate respiratory and cardiovascular effects. Victims experience **cold water shock**, a dynamic series of cardiorespiratory physiologic responses that can cause drowning. In adults, immersion in icy water results in intense involuntary reflex hyperventilation and to a decrease in breath-holding ability to <10 sec, which leads to fluid aspiration. Severe bradycardia, the diving reflex, occurs in adults but is transient and rapidly followed by supraventricular and ectopic tachycardia and hypertension. There is no evidence that the diving reflex has any protective effect.

Even after surviving the chaotic minutes of cold water shock, after an additional 5-10 min of cold water immersion, the victim can become incapacitated. Cooling of large and small muscles disables the victim's ability to grab hold, swim or perform other self-rescue maneuvers. Depending on water and air temperature, insulation, body surface area, thermogenic capacity, physical condition, swimming efforts, or high water flow rates, heat loss with continued immersion can significantly decrease core temperature to hypothermic levels within 30-60 min.

The symptoms and severity of hypothermia are categorized based on body temperature. The victim with mild hypothermia has a temperature of 34-36°C (93.2-96.8°F) with intact thermogenic mechanisms (shivering and nonshivering thermogenesis, vasoconstriction) and active movements. Compensatory mechanisms usually attempt to restore normothermia at body temperatures >32°C (89.6°F). Lower core temperatures lead to impaired cognition, coordination, and muscle strength and with it, less ability to self-rescue. Thermoregulation may fail and spontaneous rewarming will not occur. With moderate hypothermia (30 to <34°C [86 to <93.2°F]), loss of consciousness leads to water aspiration. Progressive bradycardia, impaired myocardial contractility, and loss of vasomotor tone contribute to inadequate perfusion, hypotension, and possible shock. At body temperatures <28°C (82.4°F), extreme bradycardia is usually present with decreases in cardiac output, and the propensity for spontaneous ventricular fibrillation or asystole is high. Central respiratory center depression with moderate to severe hypothermia results in hypoventilation and eventual apnea. A deep coma, with fixed and dilated pupils and absence of reflexes at very low body temperatures (<25-29°C [77-84.2°F]), may give the false appearance of death.

The brain can cool to a neuroprotective level if the cooling process is quick and cardiac output lasts long enough for sufficient heat loss to occur prior to the onset of severe hypoxia. However, if submersion leading to drowning occurs prior to development of a neuroprotective level of hypothermia, severe anoxia devastates tissue organs. The theoretical benefits, implications, and consequences of hypothermia in drowning victims are areas of controversy. Known adverse effects are associated with hypothermia, and these must be balanced against the potential benefits observed in experimental data. One should clearly differentiate among (a) controlled hypothermia, such as that used in the operating room before the onset of hypoxia or ischemia, (b) accidental hypothermia, such as occurs in drowning, which is uncontrolled and variable, with onset during or shortly after hypoxia–ischemia, and (c) therapeutic hypothermia, involving the purposeful and controlled lowering and maintenance of body (or brain) temperature at some time after a hypoxic–ischemic event.

In drowning victims with uncontrolled accidental hypothermia associated with icy water submersion, there are a few case reports of good neurologic recovery after prolonged (10-150 min) cardiopulmonary arrest. Almost all of these rare survivors have been in freezing water (<5°C [41°F]) and had core body temperatures <30°C (86°F), often much lower. Presumably, very rapid and sufficiently deep hypothermia developed in these fortunate survivors before irreversible hypoxic–ischemic injury occurred.

Most often hypothermia is a poor prognostic sign, and a neuroprotective effect has not been demonstrated. In King County, Washington, where the water is cold but rarely icy, 92% of drowning survivors with good neurologic outcomes had initial body temperatures ≥34°C (93.2°F), whereas 61% of those who died or had severe neurologic injury had temperatures <34°C (93.2°F). In another study of comatose drowning patients admitted to pediatric intensive care units (PICUs), 65% of hypothermic patients (body temperature <35°C [95°F]) died, compared with a 27% observed mortality rate in nonhypothermic victims. Similarly, in Finland (where the median water temperature was 16°C [60.9°F]) and in the United States, a beneficial effect of drowning-associated hypothermia was not seen in pediatric submersion victims; submersion duration <10 min was most strongly related to good outcome, not water temperature.

MANAGEMENT

The clinical course and outcome for a submersion victim are primarily determined by the duration of submersion, the speed of the rescue, and the effectiveness of resuscitative efforts. Two groups may be identified on the basis of responsiveness at the scene. The first group consists of children who require minimal resuscitation at the scene and quickly regain spontaneous respiration and consciousness. They have good outcomes and minimal complications. These victims should be transported from the scene to the ED for further evaluation and observation.

The second group comprises children in cardiac arrest who require aggressive or prolonged resuscitation and have a high risk of multiorgan system complications, major neurologic morbidity, or death. Compared with cardiac arrest from other causes, cardiac arrest from drowning has a higher survival rate.

Initial management of drowning victims requires coordinated and experienced prehospital care following the ABCs (airway, breathing, circulation) of emergency resuscitation (see Chapter 67). Cardiopulmonary resuscitation of drowning victims must include providing ventilation. Children with severe hypoxic injury and symptoms often remain comatose and lack brainstem reflexes despite the restoration of oxygenation and circulation. Subsequent ED and PICU care often involve advanced life support strategies and management of multiorgan dysfunction.

Initial Evaluation and Resuscitation

See Chapter 67.

Once a submersion has occurred, immediate institution of CPR efforts at the scene is imperative. The goal is to reverse the anoxia from submersion and limit secondary hypoxic injury after submersion. Every minute that passes without the reestablishment of adequate

breathing and circulation dramatically decreases the possibility of a good outcome. When safe for the victim and the rescuer, institution of in-water resuscitation for nonbreathing victims by trained personnel may improve the likelihood of survival. Victims usually need to be extricated from the water as quickly as possible so that effective CPR can be provided. Common themes in children who have good recovery are a short duration of event and initiation of CPR as soon as possible, prior to arrival of emergency medical services.

Initial resuscitation must focus on rapidly restoring oxygenation, ventilation, and adequate circulation. The airway should be clear of vomitus and foreign material, which may cause obstruction or aspiration. **Abdominal thrusts should not be used** for fluid removal, because many victims have a distended abdomen from swallowed water; abdominal thrusts may increase the risk of regurgitation and aspiration. In cases of suspected airway foreign body, chest compressions or back blows are preferable maneuvers.

The cervical spine should be protected in anyone with potential traumatic neck injury (see Chapters 68 and 72). Cervical spine injury is a rare concomitant injury in drowning; only approximately 0.5% of submersion victims have cervical spine injuries. History of the event and victim age guide suspicion of cervical spine injury. Drowning victims with cervical spine injury are usually preteens or teenagers whose drowning event involved diving, a motorized vehicle crash, a fall from a height, a water sport accident, child abuse, or other clinical signs of serious traumatic injury. In such cases, the neck should be maintained in a neutral position and protected with a well-fitting cervical collar. Patients rescued from unknown circumstances may also warrant cervical spine precautions. In low-impact submersions, spinal injuries are exceedingly rare, and routine spinal immobilization is not warranted.

If the victim has ineffective respiration or apnea, ventilatory support must be initiated immediately (see Chapter 67). Mouth-to-mouth or mouth-to-nose breathing by trained bystanders often restores spontaneous ventilation. As soon as it is available, supplemental oxygen should be administered to all victims. Positive-pressure bag-mask ventilation with 100% inspired oxygen should be instituted in patients with respiratory insufficiency. If apnea, cyanosis, hypoventilation, or labored respiration persists, trained personnel should perform endotracheal tube intubation as soon as possible. Intubation is also indicated to protect the airway in patients with depressed mental status or hemodynamic instability. Hypoxia must be corrected rapidly to optimize the chance of recovery.

Concurrent with securing of airway control, oxygenation, and ventilation, the child's cardiovascular status must be evaluated and treated according to the usual resuscitation guidelines and protocols. Heart rate and rhythm, blood pressure, temperature, and end-organ perfusion require urgent assessment. CPR should be instituted immediately in pulseless, bradycardic, or severely hypotensive victims. Continuous monitoring of the electrocardiogram (ECG) allows appropriate diagnosis and treatment of arrhythmias. Slow capillary refill, cool extremities, and altered mental status are potential indicators of shock (see Chapter 70).

Recognition and treatment of hypothermia are the unique aspects of cardiac resuscitation in the drowning victim (Table 74-1). Core temperature must be evaluated, especially in children, because moderate to severe hypothermia can depress myocardial function and cause arrhythmias. Wet clothing should be removed to prevent ongoing heat losses, however, in the hemodynamically stable patient, rewarming should be initiated in the controlled environment of the receiving ED or PICU. Unstable patients (i.e. arrhythmias) should be warmed to 34°C (93.2°F), taking care not to overheat. Trials are investigating if therapeutic hypothermia might be helpful or if avoiding hyperthermia is actually the key element to long-term neurologic survival.

Often, IV fluids and cardioactive medications are required to improve circulation and perfusion. Vascular access should be established as quickly as possible for the administration of fluids or pressors. Intraosseous catheter placement is a potentially lifesaving vascular access technique that avoids the delay usually associated with multiple attempts to establish IV access in critically ill children. Epinephrine is usually the initial drug of choice in victims with bradyasystolic cardiopulmonary arrest (the IV dose is 0.01 mg/kg of 1 : 10,000 solution given q3-5min as needed). Epinephrine can be given intratracheally (endotracheal tube dose is 0.1-0.2 mg/kg of 1 : 1,000 solution) if no IV access is available. An intravascular bolus of lactated Ringer solution or 0.9% normal saline (10-20 mL/kg) is often used to augment preload; repeated doses may be necessary. Hypotonic or glucose-containing solutions should not be used for intravascular volume administration of drowning victims.

Hospital-Based Evaluation and Treatment

Most pediatric drowning victims should be observed for at least 6-8 hr, even if they are asymptomatic on presentation to the ED. At a minimum, serial monitoring of vital signs (respiratory rate, heart rate, blood pressure, and temperature) and of oxygenation by pulse oximetry, repeated pulmonary examination, and neurologic assessment should be performed in all drowning victims. Other studies may also be warranted, depending on the specific circumstances (possible abuse or neglect, traumatic injuries, or suspected intoxication). Almost half of asymptomatic or minimally symptomatic alert children (those who do not require advanced life support in the prehospital setting or who have an initial ED Glasgow Coma Scale [GCS] score of ≥13) experience some level of respiratory distress or hypoxemia progressing to pulmonary edema, usually during the 1st 4-8 hr after submersion. Most alert children with early respiratory symptoms respond to oxygen and, despite abnormal initial radiographs, become asymptomatic with a return of normal room air Sa_{O_2} and pulmonary examination by 4-6 hr. Subsequent delayed respiratory deterioration is extremely unlikely in such children. Selected low-risk patients who are alert and asymptomatic with normal physical findings and oxygenation levels may be considered for discharge after 6-8 hr of observation, as long as appropriate follow-up can be ensured.

Cardiorespiratory Management

For children who are not in cardiac arrest, the level of respiratory support should be appropriate to the patient's condition and is a continuation of prehospital management. Frequent assessments are required to ensure that adequate oxygenation, ventilation, and airway control are maintained (see Chapter 71). *Hypercapnia should generally be avoided in potentially brain-injured children.* Patients with actual or potential hypoventilation or markedly elevated work of breathing should receive mechanical ventilation to avoid hypercapnia and decrease the energy expenditures of labored respiration.

Measures to stabilize cardiovascular status should also continue. Conditions contributing to myocardial insufficiency include hypoxic–ischemic injury, ongoing hypoxia, hypothermia, acidosis, high airway pressures during mechanical ventilation, alterations of intravascular volume, and electrolyte disorders. Heart failure, shock, arrhythmias, or cardiac arrest may occur. Continuous ECG monitoring is mandatory for recognition and treatment of arrhythmias (see Chapter 435).

The provision of adequate oxygenation and ventilation is a prerequisite to improving myocardial function. Fluid resuscitation and inotropic agents are often necessary to improve heart function and restore tissue perfusion (see Chapter 67). Increasing preload with IV fluids may be beneficial through improvements in stroke volume and cardiac output. Overzealous fluid administration, especially in the presence of poor myocardial function, can worsen pulmonary edema.

For patients with persistent cardiopulmonary arrest on arrival in the ED after *non–icy water* drowning, the decision to withhold or stop resuscitative efforts can be addressed by review of the history and the response to treatment. Because there are reports of good outcome following ongoing CPR in the ED, most drowning victims should be treated aggressively upon presentation. However, for children who do not show ready response to aggressive resuscitative efforts, the need for prolonged ongoing CPR after non–icy water submersion almost invariably predicts death or persistent vegetative state. Consequently, in most cases, discontinuation of CPR in the ED is probably warranted

Table 74-1 Approach to Drowning-Prevention Strategies

	HOME	RECREATION	NEIGHBORHOOD
Water hazards	Swimming pools Ponds Bathtubs Large buckets	Playing in water- swimming, wading Playing near water Being on water—boating	Irrigation ditches Watering holes Water drainage
Common risks	Lapse in supervision Unexpected toddler exposure Delayed discovery of child Reliance on water wings or pool toys Reliance on sibling or bath seat for bathing supervision	Lapse in supervision Change in weather Unfamiliarity with or change(s) in water conditions: • Steep drop-off • Current/tide • Low temperature Alcohol use Peer pressure	Lapse in supervision, particularly when caregiver is socializing Risky behavior when with peers
Prevention strategies	Recognize hazards and risks Provide constant adult supervision around water Install 4-sided, isolation fencing of pools Install rescue equipment and phone at poolside Learn swimming and water survival skills Avoid bath, instead shower, if a child/teen with seizure disorder Learn first aid and CPR	Provide constant adult supervision Swim in lifeguarded areas Know when and how to wear U.S. Coast Guard–approved PFDs Avoid alcohol and other drugs Learn swimming and water survival skills Teach children about water safety Be aware of current weather and water conditions Learn first aid and CPR	Identify hazardous bodies of water Prevent access to water with barriers Provide fenced-in "safe area" for water recreation Provide lifeguarded swim sites Provide access to low cost swim/water survival lessons

for victims of non–icy water submersion who do not respond to resuscitation within 25-30 min. Final decisions regarding whether and when to discontinue resuscitative efforts must be individualized, with the understanding that the possibility of good outcome is generally very low with protracted resuscitation efforts.

Neurologic Management

Drowning victims who present to the hospital awake and alert usually have normal neurologic outcomes. In comatose victims, irreversible CNS injury is highly likely. The most critical and effective neurologic intensive care measures after drowning are rapid restoration and maintenance of adequate oxygenation, ventilation, and perfusion. Core body temperature and glucose management may also be important modulators of neurologic injury after hypoxia–ischemia.

Comatose drowning patients are at risk for intracranial hypertension. There is little evidence that ICP monitoring and therapy to reduce intracranial hypertension improve outcomes for drowning victims. Patients with elevated ICP usually have poor outcomes—either death or persistent vegetative state. Children with normal ICP can also have poor outcomes, although less frequently. Conventional neurologic intensive care therapies, such as fluid restriction, hyperventilation, and administration of muscle relaxants, osmotic agents, diuretics, barbiturates, and steroids, have not been shown to benefit the drowning victim, either individually or in combination. There is some evidence that these therapies may reduce overall mortality but increase the number of survivors with severe neurologic morbidity.

Electroencephalographic monitoring has only limited value in the management of drowning victims and is generally not recommended, except to detect seizures or as an adjunct in the clinical evaluation of brain death (see Chapter 68.1). Seizures should be treated if possible, although they tend to be very refractory. There is no evidence that treatment of seizures after drowning improves outcome. Fosphenytoin or phenytoin (loading dose of 10-20 mg of phenytoin equivalents/kg, followed by maintenance dosing with 5-8 mg of phenytoin equivalents/kg/day in 2-3 divided doses; levels should be monitored) may be considered as an anticonvulsant; it may have some neuroprotective effects and may mitigate neurogenic pulmonary edema. Benzodiazepines, barbiturates, and other anticonvulsants may also have some role in seizure therapy.

With optimal management, many initially comatose children can have impressive neurologic improvement, but usually do so within the 1st 24-72 hr. Unfortunately, almost half of deeply comatose drowning victims admitted to the PICU die of their hypoxic brain injury or survive with severe neurologic damage. Many children become brain dead. Deeply comatose drowning victims who do not show substantial improvement on neurologic examination after 24-72 hr and whose coma cannot be otherwise explained should be seriously considered for limitation or withdrawal of support.

Other Management Issues

A few drowning victims may have traumatic injury (see Chapter 72), especially if their drowning event involved participation in high energy water sports such as personal watercraft, boating, diving, or surfing. A high index of suspicion for such injury is required. Spinal precautions should be maintained in victims with altered mental status and suspected traumatic injury. Significant anemia suggests trauma and internal hemorrhage.

Hypoxic–ischemic injury can have multiple systemic effects, although protracted organ dysfunction is uncommon in the absence of severe CNS injury. Hyperglycemia is associated with a poor outcome in pediatric drowning victims. Its etiology is unclear but it is possibly a stress response.

Manifestations of acute kidney injury may be seen after hypoxic–ischemic injury (see Chapter 535). Diuretics, fluid restriction, and dialysis are occasionally needed to treat fluid overload or electrolyte disturbances; renal function usually normalizes in survivors. Rhabdomyolysis after drowning has been reported.

Profuse bloody diarrhea and mucosal sloughing usually portend a grim prognosis; conservative management includes bowel rest, nasogastric suction, and gastric pH neutralization. Nutritional support for most drowning victims is usually not difficult, because the majority of children either die or recover quickly and resume a normal diet within a few days; enteral tube feeding or parenteral nutrition is occasionally indicated in children who do not recover quickly.

Hyperthermia after drowning or other types of brain injury may increase the risk of mortality and exacerbate hypoxic–ischemic CNS damage. Almost half of drowning victims have a fever during the 1st 48 hr after submersion. Hyperthermia is usually not caused by

infection and resolves without antibiotics in approximately 80% of patients. Generally, prophylactic antibiotics are not recommended. However, there is general consensus that fever or hyperthermia (core body temperature >37.5°C [99.5°F]) in comatose drowning victims resuscitated from cardiac arrest should be prevented at all times in the acute recovery period (at least the 1st 24-48 hr).

Psychiatric and psychosocial sequelae in the family of a pediatric drowning victim are common. Grief, guilt, and anger are common among family members, including siblings. Divorce rates of up to 80% within a few years of the injury have been reported, and parents often report difficulties with employment or substance abuse. Friends and family may blame the parents for the event. Professional counseling, pastoral care, or social work referral should be initiated for drowning victims and their families.

Hypothermia Management

Attention to core body temperature starts in the field and continues during transport and in the hospital. The goal is to prevent or treat moderate or severe hypothermia. Damp clothing should be removed from all drowning victims. Rewarming measures are generally categorized as passive, active external, or active internal (see Chapter 76). Passive rewarming measures can be applied in the prehospital or hospital setting; they include the provision of dry blankets, a warm environment, and protection from further heat loss. They should be instituted as soon as possible for hypothermic drowning victims who have not had a cardiac arrest.

Full CPR with chest compressions is indicated for hypothermic victims if no pulse can be found or if narrow complex QRS activity is absent on ECG (see Chapters 67 and 76). When core body temperature is <30°C (86°F), resuscitative efforts should proceed according to the current American Heart Association guidelines for CPR, but IV medications may be given at a lower frequency in moderate hypothermia because of decreased drug clearance. When ventricular fibrillation is present in severely hypothermic victims (core temperature <30°C [86°F]), defibrillation should be initiated but may not be effective until the core temperature is ≥30°C (86°F), at which time successful defibrillation may be more likely.

Significant controversy surrounds the discontinuation of prolonged resuscitative efforts in hypothermic drowning victims. Body temperature should be taken into account before resuscitative efforts are terminated. Other considerations include whether the victim may have been immersed prior to submerged, whether water was icy or the cooling was very rapid with fast-flowing cold water. Victims with profound hypothermia may appear clinically dead, but full neurologic recovery is possible, although rare. Attempts at lifesaving resuscitation should not be withheld on the basis of initial clinical presentation unless the victim is obviously dead (dependent lividity or rigor mortis). Rewarming efforts should usually be continued until the temperature is 32-34°C (89.6-93.2°F); if the victim continues to have no effective cardiac rhythm and remains unresponsive to aggressive CPR, then resuscitative efforts may be discontinued.

Complete rewarming is not indicated for all arrest victims before resuscitative efforts are abandoned. Discontinuing resuscitation in victims of non–icy water submersion who remain asystolic despite 30 min of CPR is probably warranted. Physicians must use their individual clinical judgment about deciding to stop resuscitative efforts, taking into account the unique circumstances of each incident.

Once a drowning victim has undergone successful CPR after a cardiac arrest, temperature management should be carefully considered, and body temperature should be continuously monitored. In victims in whom resuscitation duration was brief and who are awake soon after resuscitation, attempts to restore and maintain normothermia are warranted. Careful monitoring is necessary to prevent unrecognized worsening hypothermia, which can have untoward consequences.

For drowning victims who remain comatose after successful CPR, more contentious issues include rewarming of hypothermic victims and controlled application of therapeutic hypothermia. Although there is no evidence basis or consensus of opinion, many investigators cautiously recommend that hypothermic drowning victims who remain unresponsive because of hypoxic–ischemic encephalopathy after restoration of adequate spontaneous circulation should not be actively rewarmed to normal body temperatures. Active rewarming should be limited to victims with core body temperatures <32°C (89.6°F), but temperatures 32-37.5°C (89.6-99.5°F) should be allowed without further rewarming efforts.

More controversial is the induction of therapeutic hypothermia in drowning victims who remain comatose because of hypoxic-ischemic encephalopathy after CPR for cardiac arrest. The 2002 World Congress on Drowning recommended that hypothermia (32-34°C [89.6-93.2°F]) be instituted as soon as possible after resuscitation and sustained for 12-24 hr. They recommended that patients be intubated, mechanically ventilated, and treated with sedatives and/or analgesics (with or without neuromuscular blocking agents) as necessary to prevent shivering and maintain hypothermia then gradually rewarmed.

However, a specific recommendation for therapeutic hypothermia, especially in children, is not yet generally accepted. The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation (2002) did not recommend therapeutic hypothermia in drowned children resuscitated after cardiopulmonary arrest, citing insufficient evidence and older studies demonstrating a potential deleterious effect in pediatric drowning victims. Several subsequent studies evaluating extracorporeal membrane circulation, rewarming, and therapeutic hypothermia in pediatric and adult drowned patients have shown no significant improvement in neurologic outcome or mortality rates.

PROGNOSIS

The outcomes for drowning victims are remarkably bimodal: The great majority of victims either have a good outcome (intact or mild neurologic sequelae) or a bad outcome (severe neurologic sequelae, persistent vegetative state or death), with very few exhibiting intermediate neurologic injury at hospital discharge. Subsequent evaluation of good outcome survivors may identify significant persistent cognitive deficits. Of hospitalized pediatric drowning victims, 15% die and as many as 20% survive with severe permanent neurologic damage.

Strong predictors of outcome are based on the incident and response to treatment at the scene. Intact survival or mild neurologic impairment has been seen in 91% of children with submersion duration <5 min and in 87% with resuscitation duration <10 min. Children with normal sinus rhythm, reactive pupils, or neurologic responsiveness at the scene virtually always had good outcomes (99%). Poor outcome is highly likely in patients with deep coma, apnea, absence of papillary responses, and hyperglycemia in the ED, with submersion durations >10 min, and with failure of response to CPR given for 25 min. In one comprehensive case series, all children with *resuscitation durations* >25 min either died or had severe neurologic morbidity, and all victims with *submersion durations* >25 min died. Long-term health-related quality of life and school performance in subjects who had received either bystander or emergency medical service personnel initiated CPR was high if their submersion duration was <10 mins. Higher morbidity, mortality, and lower quality of life was reported in those patients with >10 mins submersion durations. In several studies of pediatric drowning, submersion duration was the best predictor of outcome and water temperature was not. However, there are rare case reports of intact recovery following non–icy water drowning with longer submersion or resuscitation duration.

The GCS score has some limited utility in predicting recovery. Children with a score ≥6 on hospital admission generally have a good outcome, whereas those with a score ≤5 have a much higher probability of poor neurologic outcome. Occasionally, children with a GCS score of 3 or 4 in the ED have complete recovery. Improvement in the GCS score during the first several hours of hospitalization may indicate a better prognosis. Overall, early GCS assessments fail to adequately

distinguish children who will survive intact from those with major neurologic injury.

Neurologic examination and progression during the 1st 24-72 hr are the best prognosticators of long-term CNS outcome. Children who regain consciousness within 48-72 hr, even after prolonged resuscitation, are unlikely to have serious neurologic sequelae. In a small series of comatose victims of non–icy water submersion, all survivors with a good outcome had spontaneous purposeful movements and normal brainstem function within 24 hr; good recovery did not occur in any child with abnormal brainstem function or absence of purposeful movements at 24 hr. In another small series of drowning victims who remained unconscious >24 hr and survived for at least 1 yr, 73% remained in a persistent vegetative state and the rest had severe neurologic impairment, had many complications and a high mortality rate: 45% died during the study's 1-yr follow-up period.

In a large retrospective series of 274 pediatric drowning victims, of those with an initial GCS score of 3 in the ED, only 14% survived intact. Almost all, 95%, of victims who demonstrated purposeful neurologic function within 48 hr survived intact and 100% of those whose first purposeful neurologic response occurred within 6 hr survived intact. Laboratory and technologic methods to improve prognostication have not yet proved superior to neurologic examination. Serial neurologic evaluations after CPR should be performed over the ensuing 48-72 hr, with consideration given to limitation or withdrawal of support in patients who do not have significant neurologic recovery, even though this may occur before absolute prognostic certainty is achieved.

PREVENTION

The most effective way to decrease the injury burden of drowning is prevention. Drowning is a multifaceted problem, but several evidence based preventive strategies are effective. The pediatrician has a prime opportunity to identify and inform families at risk of these strategies through anticipatory guidance. In 2010, the American Academy of Pediatrics Committee on Injury, Violence, and Poison Prevention revised its policy statement on the prevention of drowning to advocate for more anticipatory guidance regarding the appropriate supervision of children, access to swim lessons, the presence of lifeguards, barriers to swimming pools, and use of PFDs. A family-centered approach to anticipatory guidance for water safety helps explore and identify the water hazards that each family is exposed to in their environment. The practitioner can then discuss the best tools and strategies for prevention that are relevant for the particular family. It is important to identify the risks both in and around the home and in other locations they may frequent, often when vacationing, such as vacation or relatives' homes. For some families the focus may be on bathtubs and bucket safety; for others, home pools or hot tubs may be the major hazards. If the family recreates near or on open water, they also need to learn about safety around boats and open water. In a rural environment, water collection systems and natural bodies of water may pose great risk.

Parents must build layers of water protection around their children. Table 74-1 provides an approach to the hazards and preventive strategies relevant to the most common sources of water involved in childhood drowning. A common preventive strategy for exposure to all water types and all ages is ensuring appropriate supervision. Pediatricians should define for parents what constitutes appropriate supervision at the various developmental levels of childhood. Many parents either underestimate the importance of adequate supervision or are simply unaware of the risks associated with water. Even parents who say that constant supervision is necessary will often admit to brief lapses while their child is alone near water. Parents also overestimate the abilities of older siblings; many bathtub drownings occur when an infant or toddler is left with a child younger than 5 yr.

Supervision of infants and young children means that a responsible adult should be with the child every moment. The caregiver must be alert, must not be consuming alcohol or other drugs or socializing, and must be attentive and focused entirely on watching the child. Even a brief moment of inattention, such as to answer a phone, get a drink, or hold a conversation, can have tragic consequences. If the child does not swim, "touch supervision" is required, meaning that the caregiver should be within arm's reach at all times. Adolescents require active adult supervision and avoidance of alcohol or drug use during water activities. Learning to swim offers another layer of protection. Children may start swim lessons at an early age that are developmentally appropriate and aimed at the individual child's readiness and skill level. Swim lessons are beneficial and to provide some level of protection to young children. A study from Bangladesh, where drowning accounts for 20% of all deaths in children ages 1-4 yr, showed that swim lessons and water safety curricula are cost-effective and led to a decrease in mortality from drowning. As with any other water safety intervention, parents need to know that swimming lessons and acquisition of swim skills cannot be solely relied on to prevent drowning. No child can be "drown-proof." A supervising caretaker should be aware of where and how to get help and know how to safely rescue a child in trouble. Because only those trained in water rescue can safely attempt it, families should be encouraged to swim in designated areas only when and where a lifeguard is on duty.

Children and adolescents should never swim alone regardless of their swimming abilities. Even as they become more independent and participate in recreational activities without their parents, they should be encouraged to seek areas that are watched by lifeguards. Lifeguards rescue more than 100,000 Americans each year from drowning, and probably prevent millions more drownings through verbal warnings and prompt interventions when needed. It is important to emphasize that even if the child is considered a strong swimmer, the ability to swim in a pool does not translate to being safe in open water, where water temperature, currents, and underwater obstacles can present additional and unfamiliar challenges. For swimmers, supervision by lifeguards reduces drowning risk, because lifeguards monitor risk behaviors and are trained in the difficult and potentially dangerous task of rescuing drowning victims.

Two of the preventive strategies listed in Table 74-1 deserve special mention. The most vigorously evaluated and effective drowning intervention applies to swimming pools. Isolation fencing that completely surrounds a pool, with a secure, self-locking gate, reduces the risk of drowning. Guidelines for appropriate fencing, provided by the U.S. Consumer Product Safety Commission, are very specific; they were developed through testing of active toddlers in a gymnastics program on their ability to climb barriers of different materials and heights and recent studies show them to be effective in preventing drowning in young children. In families who have a pool on their property, caregivers often erroneously believe that if a child falls into the water there will be a loud noise or splash to alert them. Sadly, these events are usually silent, delaying timely rescue. This finding highlights the need for a fence that actually separates the pool from the house, not just surrounds the entire property. The use of U.S. Coast Guard–approved lifejackets or PFDs should be advised with all families spending time around open water, not just those who consider themselves boaters. This issue is also particularly important for families who will participate in aquatic activities on a vacation. A PFD should be chosen with respect to the weight of the child and the proposed activity. Young children should wear PFDs that will float their head up. Parents should be urged to wear PFDs, too, as their use is associated with greater use by their children. Toys such as water wings and "floaties" should not be relied upon as drowning prevention measures.

Effective preventive efforts must also consider cultural practices. Different ethnic groups may have certain attitudes, beliefs, dress, or other customs that may affect their water safety. The higher drowning risk of minority children needs to be addressed by community-based prevention programs.

In addition to anticipatory guidance, pediatricians can play an active role in drowning prevention by participating in advocacy efforts to

improve legislation for pool fencing, PFD use, and alcohol consumption in various water activities. Several counties in the United States, Australia, and New Zealand have laws requiring isolation fencing for pools. Their effectiveness has been limited by a lack of enforcement. Similarly, all states have boating-under-the-influence laws but, similarly, rarely enforce them. Furthermore, efforts at the community level may be needed to ensure the availability of swimming lessons for underserved populations and lifeguarded swim areas.

Chapter 75

Burn Injuries

Alia Y. Antoon and Mary K. Donovan

Burns are a leading cause of unintentional injury in children, second only to motor vehicle crashes. There has been a decline in the incidence of burn injury requiring medical care that has coincided with a stronger focus on burn treatment and prevention, increased fire and burn prevention education, greater availability of regional treatment centers, widespread use of smoke detectors, greater regulation of consumer products and occupational safety, and societal changes such as reductions in smoking and alcohol abuse.

EPIDEMIOLOGY

Approximately 2 million people in the United States require medical care for burn injuries each year. Approximately 50% of these patients are younger than age 5 yr, with an average age of 32 mo. The principal cause of the burn is scald; one of the causes of scald burn is heating liquids in the microwave. The leading cause of burn in children 5-14 yr of age is flame injury. In children ages 5-10 yr, this is usually a result of match play, whereas, for older children, it is usually a result of gasoline ignition. Fires are a major cause of mortality in children, accounting for up to 34% of fatal injuries in those younger than age 16 yr. Scald burns account for 85% of total injuries and are most prevalent in children younger than 4 yr. Although the incidence of hot water scalding has been reduced by legislation requiring new water heaters to be preset at 48.9°C (120°F), scald injury remains the leading cause of hospitalization for burns. Steam inhalation used as a home remedy to treat respiratory infections is another potential cause of burns. Flame burns account for 13%; the remaining are electrical and chemical burns. Clothing ignition events have declined since passage of the Federal Flammable Fabric Act requiring sleepwear to be flame-retardant; however, the U.S. Consumer Product Safety Commission has voted to relax the existing children's sleepwear flammability standard. Polyester is the fabric most resistant to ignition by small flame source. Polyester does burn deeply as it melts, but it self-extinguishes when the flame source is removed. Cotton, on the other hand, continues to burn after the flame source has been removed resulting in large deep burns. Polyester melts downward, sparing the face and respiratory tract; cotton burns upward toward the face. Pellet stove, glass front stoves, and flat top stoves are becoming frequent sources of hand burns in children. Approximately 18% of burns are the result of child abuse (usually scalds), making it important to assess the pattern and site of injury and their consistency with the patient history (see Chapter 40). Friction burns from treadmills are also a problem. Hands are the most commonly injured sites, with deep 2nd-degree friction injury sometimes associated with fractures of the fingers. Anoxia, not the actual burn, is a major cause of morbidity and mortality in house fires.

Review of the history usually shows a common pattern: scald burns to the side of the face, neck, and arm if liquid is pulled from a table or stove; burns in the pant leg area if clothing ignites; burns in a splash pattern from cooking; and burns on the palm of the hand from contact with a hot stove. However, "glove or stocking" burns of the hands and feet, single-area deep burns on the trunk, buttocks, or back, and small, full-thickness burns (cigarette burns) in young children should raise the suspicion of child abuse (see Chapter 40).

Burn care involves a range of activities: prevention, acute care and resuscitation, wound management, pain relief, reconstruction, rehabilitation, and psychosocial adjustment. Children with massive burns require early and appropriate psychological and social support as well as resuscitation. Surgical debridement, wound closure, and rehabilitative efforts should be instituted concurrently to promote optimal rehabilitation. Aggressive surgical removal of devitalized tissue, infection control, and judicious use of antibiotics, as well as early nutrition and cautious use of intubation and mechanical ventilation, are necessary to maximize survival. Children who have sustained burn injuries differ in appearance from their peers, necessitating supportive efforts for reentry to school and social and sporting activities.

PREVENTION

The aim of burn prevention is a continuing reduction in the number of serious burn injuries (Table 75-1). Effective first aid and triage can decrease both the extent (area) and the severity (depth) of injuries. The use of flame-retardant clothing and smoke detectors, control of hot water temperature (thermostat settings) to 48.9°C (120°F) within buildings, and prohibition of cigarette smoking have been partially successful in reducing the incidence of burn injuries. Treatment of children with significant burn injuries in dedicated burn centers facilitates medically effective care, improves survival, and leads to greater cost efficiency. Survival of at least 80% of patients with burns of 90% of the body surface area (BSA) is possible; the overall survival rate of children with burns of all sizes is 99%. Death is more likely in children with irreversible anoxic brain injury sustained at the time of the burn. It is well-known that burns occur in predictable patterns. Seasonal pattern sources include:

Winter

- Glass front fireplaces/pellet stoves and radiators increase hand burns
- Treadmill injuries as more people exercise inside—child imitates adults or young child touches belt

Summer

- Fireworks, sparkler—temperatures reach 537.8°C (1000°F)
- Burn contact with hot grill; hand/feet burn from hot embers
- Lawnmowers

Spring/Fall

- Burning leaves
- Gasoline burns
- Tap water scalds are essentially preventable through a combination of behavioral and environmental changes

Pediatricians can play a major role in preventing the most common burns by educating parents and healthcare providers. Simple, effective, efficient, and cost-effective preventive measures include the use of appropriate clothing and smoke detectors, and the planning of routes for emergency exit from the home. The National Fire Protection Association (NFPA) recommends replacing smoke detector batteries annually and the smoke detector alarm every 10 yr (or earlier, if indicated on the device). Child neglect and abuse must be seriously considered when the history of the injury and the distribution of the burn do not match.

ACUTE CARE, RESUSCITATION, AND ASSESSMENT

Indications for Admission

Burns covering >10% of total BSA, burns associated with smoke inhalation, burns resulting from high-tension (voltage) electrical injuries,

Table 75-1 Burn Prophylaxis

PREVENT FIRES Install and use smoke detectors Control the hot water thermostat—in public buildings, the maximum water temperature should be 48.9°C (120°F) Keep fire, matches, and lighters out of the reach of children Avoid cigarette smoking, especially in bed Do not leave lit candles unattended Use flame retardant–treated clothing Use caution when cooking, especially with oil Keep cloth items off heaters
PREVENT INJURY Roll, but do not run, if clothing catches fire; wrap in a blanket Practice escape procedures Crawl beneath smoke if a fire occurs indoors Use educational materials*

*National Fire Protection Association pamphlets and videos.

Table 75-2 Indications for Hospitalization for Burns

Burns affecting >10% of BSA Burns >10-20% of BSA in adolescent/adult 3rd-Degree burns Electrical burns caused by high-tension wires or lightening Chemical burns Inhalation injury, regardless of the amount of BSA burned Inadequate home or social environment Suspected child abuse or neglect Burns to the face, hands, feet, perineum, genitals, or major joints Burns in patients with preexisting medical conditions that may complicate the acute recovery phase Associated injuries (fractures) Pregnancy

and burns associated with suspected child abuse or neglect should be treated as emergencies, and the child hospitalized (Table 75-2). Small 1st- and 2nd-degree burns of the hands, feet, face, perineum, and joint surfaces also require admission if close follow-up care is difficult to provide. Children who have been in enclosed-space fires and those who have face and neck burns should be hospitalized for at least 24 hr for observation for signs of central nervous system (CNS) effects of anoxia from carbon monoxide poisoning and pulmonary effects from smoke inhalation.

First Aid Measures

Acute care should include the following measures:

1. Extinguish flames by rolling the child on the ground; cover the child with a blanket, coat, or carpet.
2. After determining that the airway is patent, remove smoldering clothing or clothing saturated with hot liquid. Jewelry, particularly rings and bracelets, should be removed or cut away to prevent constriction and vascular compromise during the edema phase in the 1st 24-72 hr after burn injury.
3. In cases of chemical injury, brush off any remaining chemical, if powdered or solid; then use copious irrigation or wash the affected area with water. Call the local poison control center for the neutralizing agent to treat a chemical ingestion.
4. Cover the burned area with clean, dry sheeting and apply cold (not iced) wet compresses to small injuries. Significant large-burn injury (>15% of BSA) decreases body temperature control and contraindicates the use of cold compresses.
5. If the burn is caused by hot tar, use mineral oil to remove the tar.
6. Administer analgesic medications.

Table 75-3 Acute Treatment of Burns

First aid, including washing of wounds and removal of devitalized tissue Fluid resuscitation Provision of energy requirements Control of pain Prevention of infection—early excision and grafting Prevention of excessive metabolic expenditures Control of bacterial wound flora Use of biologic and synthetic dressings to close the wound

Emergency Care

Life-support measures are as follows (Table 75-3):

1. Rapidly review the cardiovascular and pulmonary status and document pre-existing or physiologic lesions (asthma, congenital heart disease, renal or hepatic disease).
2. Ensure and maintain an adequate airway and provide humidified oxygen by mask or endotracheal intubation (Fig. 75-1). The latter may be needed in children who have facial burns or a burn sustained in an enclosed space, before facial or laryngeal edema becomes evident. If hypoxia or carbon monoxide poisoning is suspected, 100% oxygen should be used (see Chapters 67 and 71).
3. Children with burns >15% of BSA require intravenous (IV) fluid resuscitation to maintain adequate perfusion. In an emergency situation if IV access is unattainable, an intraosseous line should be placed. When inserting central lines to provide high-volume fluid, special attention should be paid to use a very-small-caliber catheter in small children to avoid injury to the vascular lining, which may predispose to formation of clots. All inhalation injuries, regardless of the extent of BSA burn, require venous access to control fluid intake. All high-tension and electrical injuries require venous access to ensure forced alkaline diuresis in case of muscle injury to avoid myoglobinuric renal damage. Lactated Ringer solution, 10-20 mL/kg/hr (normal saline may be used if lactated Ringer solution is not available), is initially infused until proper fluid replacement can be calculated. Consultation with a specialized burn unit should be made to coordinate fluid therapy, the type of fluid, the preferred formula for calculation, and preferences for the use of colloid agents, particularly if transfer to a burn center is anticipated.
4. Evaluate the child for associated injuries, which are common in patients with a history of high-tension electrical burn, especially if there has also been a fall from a height. Injuries to the spine, bones, and thoracic or intraabdominal organs may occur (see Chapter 72). Cervical spine precautions should be observed until this injury is ruled out. There is a very high risk of cardiac abnormalities, including ventricular tachycardia and ventricular fibrillation, resulting from conductivity of the high electric voltage. Cardiopulmonary resuscitation should be instituted promptly at the scene, and cardiac monitoring should be started upon the patient's arrival at the emergency department (see Chapter 67).
5. Children with burns of >15% of BSA should not receive oral fluids (initially), because gastric distention may develop. These children require insertion of a nasogastric tube in the emergency department to prevent aspiration.
6. A Foley catheter should be inserted to monitor urine output in all children who require IV fluid resuscitation.
7. All wounds should be wrapped with sterile dressings until a decision is made about whether to treat the patient on an outpatient basis or refer the patient to an appropriate facility for treatment.
8. A carbon monoxide measurement (carboxyhemoglobin [HbCO]) should be obtained for fire victims, and 100% oxygen administered until the result is known.

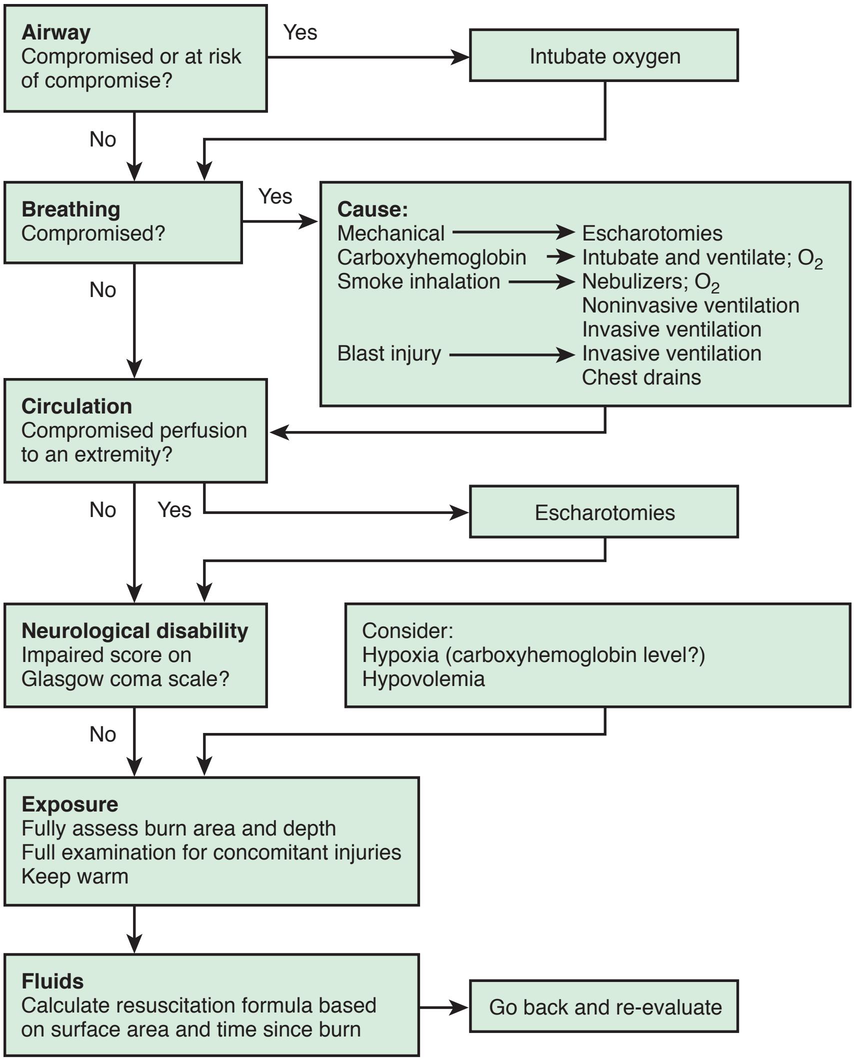

Figure 75-1 Algorithm for the primary survey of a major burn injury. O_2, oxygen. *(From Hettiaratchy S, Papini R: Initial management of a major burn I: overview.* BMJ *328:1555-1557, 2004.)*

9. Review child immunization, burns under 10% BSA do not require tetanus prevention, burns over 10% need tetanus immunization; use diphtheria, tetanus toxoids and acellular pertussis (DTaP) for tetanus prophylaxis for ages <11 yr, and tetanus, diphtheria and pertussis (TdaP) for ages >11 yr (see Chapter 211).

Classification of Burns

Proper triage and treatment of burn injury require assessment of the extent and depth of the injury (Table 75-4 and Fig. 75-2). **First-degree burns** involve only the epidermis and are characterized by swelling, erythema, and pain (similar to mild sunburn). Tissue damage is usually minimal, and there is no blistering. Pain resolves in 48-72 hr; in a small percentage of patients, the damaged epithelium peels off, leaving no residual scars.

A **2nd-degree burn** involves injury to the entire epidermis and a variable portion of the dermal layer (vesicle and blister formation are characteristic). A **superficial** 2nd-degree burn is extremely painful because a large number of remaining viable nerve endings are exposed. Superficial 2nd-degree burns heal in 7-14 days as the epithelium regenerates in the absence of infection. Midlevel to deep 2nd-degree burns also heal spontaneously if wounds are kept clean and infection-free. Pain is less than in more superficial burns because fewer nerve endings remain viable. Fluid losses and metabolic effects of deep dermal (2nd-degree) burns are essentially the same as those of 3rd-degree burns.

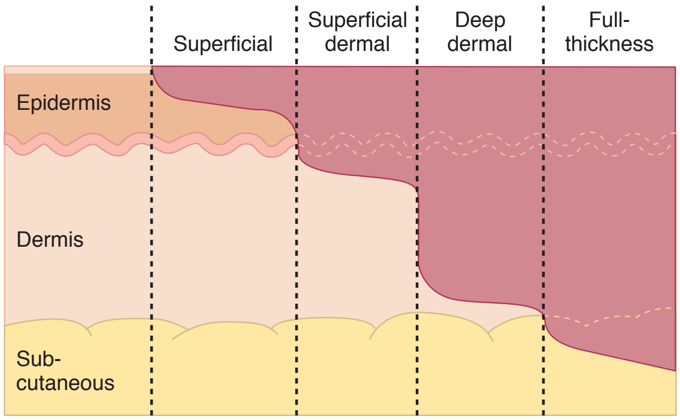

Figure 75-2 Diagram of the different burn depths. *(From Hettiaratchy S, Papini R: Initial management of a major burn II: assessment and resuscitation,* BMJ *329:101-103, 2004.)*

Full-thickness, or 3rd-degree, burns involve destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the damaged area. The wound cannot epithelialize and can heal only by wound contraction or skin grafting. The absence of painful sensation and capillary filling demonstrates the loss of nerve

Table 75-4 Categories of Burn Depth

	1ST-DEGREE BURN	2ND-DEGREE, OR PARTIAL-THICKNESS, BURN	3RD-DEGREE, OR FULL-THICKNESS, BURN
Surface appearance	Dry, no blisters Minimal or no edema Erythematous Blanches, bleeds	Moist blebs, blisters Underlying tissue is mottled pink and white, with fair capillary refill Bleeds	Dry, leathery eschar Mixed white, waxy, khaki, mahogany, soot-stained No blanching or bleeding
Pain	Very painful	Very painful	Insensate
Histologic depth	Epidermal layers only	Epidermis, papillary, and reticular layers of dermis May include domes of subcutaneous layers	Down to and may include fat, subcutaneous tissue, fascia, muscle, and bone
Healing time	2-5 days with no scarring	Superficial: 5-21 days with no grafting Deep partial: 21-35 days with no infection; if infected, converts to full-thickness burn	Large areas require grafting, but small areas may heal from the edges after wks

and capillary elements. The use of Doppler scanner has become a valuable adjunct tool in burn depth assessment and burn healing potential.

Estimation of Body Surface Area for a Burn

Appropriate burn charts for different childhood age groups should be used to accurately estimate the extent of BSA burned. The volume of fluid needed in resuscitation is calculated from the estimation of the extent and depth of burn surface. Mortality and morbidity also depend on the extent and depth of the burn. The variable growth rate of the head and extremities throughout childhood makes it necessary to use BSA charts, such as that modified by Lund and Brower or the chart used at the Shriners Hospital for Children in Boston (Fig. 75-3). The **rule of nines** used in adults may be used only in children older than 14 yr or as a very rough estimate to institute therapy before transfer to a burn center. In small burns, <10% of BSA, the **rule of palm** may be used, especially in outpatient settings: The area from the wrist crease to the finger crease (the palm) in the child equals 1% of the child's BSA.

TREATMENT

Outpatient Management of Minor Burns

A patient with 1st- and 2nd-degree burns of <10% of BSA may be treated on an outpatient basis unless family support is judged inadequate or there are issues of child neglect or abuse. These outpatients do not require a tetanus booster (unless not fully immunized) or prophylactic penicillin therapy. Blisters should be left intact and dressed with bacitracin or silver sulfadiazine cream (Silvadene). Dressings should be changed once daily, after the wound is washed with lukewarm water to remove any cream left from the previous application. Very small wounds, especially those on the face, may be treated with bacitracin ointment and left open. Debridement of the devitalized skin is indicated when the blisters rupture. A variety of wound dressings/wound membranes are available (e.g., AQUACEL Ag dressing [ConvaTec USA, Skillman, NJ] in a soft felt-like material impregnated with silver ion) may be applied to 2nd-degree burns and wrapped with a dry sterile dressing; similar wound membranes provide pain control, prevention of wound desiccation, and reduction in wound colonization (Table 75-5). These dressings are usually kept on for 7-10 days but are checked twice a week.

Burns to the palm with large blisters usually heal beneath the blisters; they should receive close follow-up on an outpatient basis. The great majority of superficial burns heal in 10-20 days. Deep 2nd-degree burns take longer to heal and may benefit from enzymatic debridement ointment application (collagenase ointment) applied daily on the wound, which aids in the removal of the dead tissue. These ointments should not be applied to the face to avoid the risk of getting them into the eyes.

The depth of scald injuries is difficult to assess early; conservative treatment is appropriate initially, with the depth of the area involved

Table 75-5 Partial Listing of Some Commonly Used Wound Membranes—Selected Characteristics

MEMBRANE	CHARACTERISTIC(S)
Porcine xenograft	Adheres to coagulum Excellent pain control
Biobrane	Bilaminate Fibrovascular in growth into inner layer
Acticoat	Nonadherent dressing that delivers silver
AQUACEL-Ag	Absorptive hydrofiber that delivers silver
Various semipermeable membranes	Provide vapor and bacterial barrier
Various hydrocolloid dressings	Provide vapor and bacterial barrier Absorb exudates
Various impregnated gauzes	Provide barrier while allowing drainage

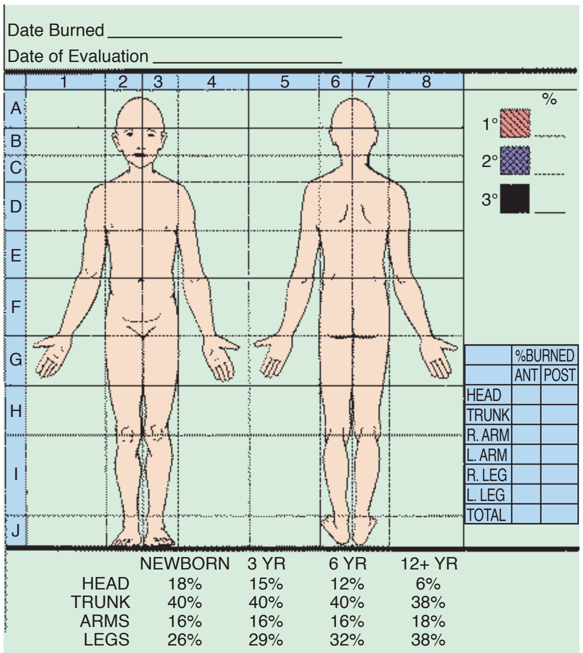

Figure 75-3 **Chart to determine the developmentally related percentage of BSA affected by a burn injury.** ANT, anterior; POST, posterior; R., right; L., left. *(Courtesy of Shriners Hospital for Crippled Children, Burn Institute, Boston Unit.)*

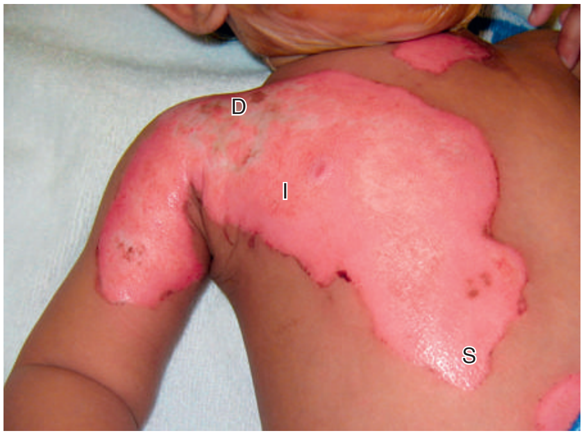

Figure 75-4 Tea scald over the chest and shoulder of a child showing heterogeneity of burn depth. D, deep; I, intermediate; S, superficial. *(From Enoch S, Roshan A, Shah M: Emergency and early management of burns and scalds,* BMJ *338:937-941, 2009.)*

determined before grafting is attempted (Fig. 75-4). This approach obviates the risk of anesthesia and unnecessary grafting.

Fluid Resuscitation

Fluid resuscitation should begin soon after the injury has occurred, in the emergency department before transferring to a burn center. For most children, the Parkland formula is an appropriate starting guideline for fluid resuscitation (4 mL lactated Ringer solution/kg/% BSA burned). Half of the fluid is given over the 1st 8 hr, calculated from the time of onset of injury; the remaining fluid is given at an even rate over the next 16 hr. The rate of infusion is adjusted according to the patient's response to therapy. Pulse and blood pressure should return to normal, and an adequate urine output (>1 mL/kg/hr in children; 0.5-1.0 mL/kg/hr in adolescents) should be accomplished by varying the IV infusion rate. Vital signs, acid–base balance, and mental status reflect the adequacy of resuscitation. Because of interstitial edema and sequestration of fluid in muscle cells, patients may gain up to 20% over baseline (preburn) body weight. Patients with burns of 30% of BSA require a large venous access (central venous line) to deliver the fluid required over the critical 1st 24 hr. Patients with burns of >60% of BSA may require a multilumen central venous catheter; these patients are best cared for in a specialized burn unit. In addition to fluid resuscitation, children should receive standard maintenance fluids (see Chapter 56).

During the 2nd 24 hr after the burn, patients begin to reabsorb edema fluid and to experience diuresis. Half of the 1st day's fluid requirement is infused as lactated Ringer solution in 5% dextrose. Children younger than 5 yr may require the addition of 5% dextrose in the 1st 24 hr of resuscitation. Controversy exists as to whether colloid should be provided in the early period of burn resuscitation. One preference is to use colloid replacement concurrently if the burn is >85% of total BSA. Colloid is usually instituted 8-24 hr after the burn injury. In children younger than 12 mo, sodium tolerance is limited; the volume and sodium concentration of the resuscitation solution should be decreased if the urinary sodium level is rising. The adequacy of resuscitation should be constantly assessed by means of vital signs as well as urine output, blood gas, hematocrit, and serum protein measurements. Some patients require arterial and central venous lines, particularly those undergoing multiple excision and grafting procedures, as needed, for monitoring and replacement purposes. Central venous pressure monitoring may be indicated to assess circulation in patients with hemodynamic or cardiopulmonary instability. Femoral vein cannulation is a safe access for fluid resuscitation, especially in infants and children. Burn patients who require frequent blood gas monitoring benefit from radial or femoral arterial catheterization.

Oral supplementation may start as early as 48 hr after burn. Milk formula, artificial feedings, homogenized milk, or soy-based products can be given by bolus or constant infusion through a nasogastric or small bowel feeding tube. As oral fluids are tolerated, IV fluids are decreased proportionately in an effort to keep the total fluid intake constant, particularly if pulmonary dysfunction is present.

A 5% albumin infusion may be used to maintain the serum albumin levels at a desired 2 g/dL. The following rates are effective: for burns of 30-50% of total BSA, 0.3 mL of 5% albumin/kg/% BSA burn is infused over 24 hr; for burns of 50-70% of total BSA, 0.4 mL/kg/% BSA burn is infused over 24 hr; and for burns of 70-100% of total BSA, 0.5 mL/kg/% BSA burn is infused over 24 hr. Infusion of packed red blood cells is recommended if the hematocrit falls to <24% (hemoglobin = 8 g/dL). Some authorities recommend treatment for hematocrit <30% or hemoglobin <10 g/dL in patients with systemic infection, hemoglobinopathy, cardiopulmonary disease, anticipated (or ongoing) blood loss, and if repeated excision and grafting of full-thickness burns are needed. Fresh-frozen plasma is indicated if clinical and laboratory assessment shows a deficiency of clotting factors, a prothrombin level >1.5 times control, or a partial thromboplastin time >1.2 times control in children who are bleeding or are scheduled for an invasive procedure or a grafting procedure that could result in an estimated blood loss of more than half of blood volume. Fresh-frozen plasma may be used for volume resuscitation within 72 hr of injury in patients younger than 2 yr with burns over 20% of BSA and associated inhalation injury.

Sodium supplementation may be required for children with burns of >20% of BSA if 0.5% silver nitrate solution is used as the topical antibacterial burn dressing. Sodium losses with silver nitrate therapy are regularly as high as 350 mmol/m^2 burn surface area. Oral sodium chloride supplement of 4 g/m^2 burn area/24 hr is usually well tolerated, divided into 4-6 equal doses to avoid osmotic diarrhea. The aim is to maintain serum sodium levels >130 mEq/L and urinary sodium concentration >30 mEq/L. Young children under 5 yr of age are especially susceptible to hyponatremic and cerebral edema. IV potassium supplementation is supplied to maintain a serum potassium level >3 mEq/dL. Potassium losses may be significantly increased when 0.5% silver nitrate solution is used as the topical antibacterial agent or when aminoglycoside, diuretic, or amphotericin therapy is required.

Prevention of Infection and Surgical Management of the Burn Wound

Controversy exists over the prophylactic use of penicillin for all patients hospitalized with acute burn injury and the periodic replacement of central venous catheters to prevent infection. In some units, a 5-day course of penicillin therapy is used for all patients with acute burns; standard-dose crystalline penicillin is given orally or intravenously in 4 divided doses. Erythromycin may be used as an alternative in penicillin-allergic children. Other units have discontinued prophylactic use of penicillin therapy without an increase in the infection rate. Similarly, there is conflicting evidence as to whether relocation of the IV catheter every 48-72 hr decreases or increases the incidence of catheter-related sepsis. Some recommend that the central venous catheter be replaced and relocated every 5-7 days, even if the site is not inflamed and there is no suspicion of catheter-related sepsis.

Mortality related to burn injury is associated not with the toxic effect of thermally injured skin, but with the metabolic and bacterial consequences of a large open wound, reduction of the patient's host resistance, and malnutrition. These abnormalities set the stage for life-threatening bacterial infection originating from the burn wound. Wound treatment and prevention of wound infection also promote early healing and improve aesthetic and functional outcomes. Topical treatment of the burn wound with 0.5% silver nitrate solution, silver sulfadiazine cream, or mafenide acetate (Sulfamylon) cream or topical solution at a concentration of 2.5-5% to be used for wounds with multidrug–resistant bacteria aims at prevention of infection (Table 75-6). These 3 agents have tissue-penetrating capacity. Regardless of the choice of topical antimicrobial agent, it is essential that all 3rd-degree burn tissue be fully excised before bacterial colonization occurs and that the area is grafted as early as possible to prevent deep wound sepsis. Children with a burn of >30% of BSA should be housed in a bacteria-controlled nursing unit to prevent cross-contamination

Table 75-6 Topical Agents Used for Burns

AGENT	EFFECTIVENESS	EASE OF USE
Silvadene cream (silver sulfadiazine)	Good penetration	Changed once daily Residue *must* be washed off with each dressing change
Mafenide acetate cream* (Sulfamylon cream)	Broad spectrum, including *Pseudomonas* Rapid and deep wound penetration	Closed dressings Changed twice daily Residue *must* be washed off with each dressing changed
0.5% Silver nitrate solution	Bacteriostatic Broad spectrum, including some fungi Superficial penetration	Closed bulky dressing soaked every 2 hr and changed once daily
AQUACEL Ag	Dressing impregnated with silver	Applied directly to 2nd-degree burn; occlusive dressing kept for 10 days

*Mafenide acetate solution at concentrations of 2.5% or 5% for use on heavily colonized multidrug–resistant organisms to be used for 5 days only.

and to provide a temperature- and humidity-controlled environment to minimize hypermetabolism.

Deep 2nd-degree burns of >10% of BSA benefit from early excision and grafting. To improve outcome, sequential excision and grafting of 3rd-degree and deep 2nd-degree burns is required in children with large burns. Prompt excision with immediate wound closure is achieved with autografts, which are often meshed to increase the efficiency of coverings. Alternatives for wound closure, such as allografts, xenografts, and Integra (Integra LifeSciences, York, PA) and other synthetic skin coverings (bilaminate membrane composed of a porous lattice of crosslinked chondroitin-6-sulfate engineered to induce neovascularization as it is biodegraded), may be important for wound coverage in patients with extensive injury to limit fluid, electrolyte, and protein losses and to reduce pain and minimize temperature loss. Epidermal cultured cells (autologous keratinocytes) are a costly alternative and are not always successful. An experienced burn team can safely perform early-stage or total excision while burn fluid resuscitation continues. Important keys to success are: (1) accurate preoperative and intraoperative determination of burn depth, (2) the choice of excision area and appropriate timing, (3) control of intraoperative blood loss, (4) specific instrumentation,(5) the choice and use of perioperative antibiotics, and (6) the type of wound coverage chosen. This process can accomplish early wound coverage without the use of recombinant human growth hormone.

Nutritional Support

Supporting the increased energy requirements of a patient with a burn is a high priority. The burn injury produces a hypermetabolic response characterized by both protein and fat catabolism. Depending on the time lapse since the burn, children with a burn of 40% of total BSA require basal energy expenditure (oxygen consumption) approximately 50-100% higher than predicted for their age. Early excision and grafting can decrease the energy requirement. Pain, anxiety, and immobilization increase the physiologic demands. Additional energy expenditure is caused by cold stress if environmental humidity and temperature are not controlled; this is especially true in young infants, in whom the large surface area : mass ratio allows proportionately greater heat loss than in adolescents and adults. Providing environmental temperatures of 28-33°C (82.4-91.4°F), adequate covering during transport and liberal use of analgesics and anxiolytics can decrease caloric demands. Special units to control ambient temperature and humidity may be necessary for children with large surface area burns. Appropriate sleep intervals are necessary and should be part of the regimen. Sepsis increases metabolic rates, and early enteral nutrition, initially with high-carbohydrate, high-protein caloric support (1,800 cal/m^2/24 hr maintenance plus 2,200 cal/m^2 of burn/24 hr) reduces metabolic stress.

The objective of caloric supplementation programs is to maintain body weight and minimize weight loss by meeting metabolic demands. This reduces the loss of lean body mass. Calories are provided at approximately 1.5 times the basal metabolic rate, with 3-4 g/kg of protein/day. The focus of nutritional therapy is to support and compensate for the metabolic needs. Multivitamins, particularly the B vitamin group, vitamin C, vitamin A, and zinc, are also necessary.

Alimentation should be started as soon as is practical, both enterally and parenterally, to meet all of the caloric needs and keep the gastrointestinal tract active and intact after the resuscitative phase. Patients with burns of >40% of total BSA need a flexible nasogastric or small bowel feeding tube to facilitate continuous delivery of calories without the risk of aspiration. To decrease the risk of infectious complications, parenteral nutrition is discontinued as soon as is practical, after delivery of sufficient enteral calories are established. Continuous gastrointestinal feeding is essential, even if feeding is interrupted, causing frequent visits to the operating room, until full grafting takes place. The use of anabolic agents (growth hormone, oxandrolone, low-dose insulin) or anticatabolic agents (propranolol) remains controversial, although β-blocking agents may reduce metabolic stress. Burn centers caring for large burns (>50% BSA, 3rd-degree) in patients who might be malnourished have used the anabolic steroid oxandrolone, at a dose of 0.1-0.2 mg/kg/day given orally, to promote better protein synthesis while the nutritional support by nasogastric feeding and IV hyperalimentation continues.

Topical Therapy

Topical therapy is widely used and is effective against most burn wound pathogens (see Table 75-6). A number of topical agents are used: 0.5% silver nitrate solution, sulfacetamide acetate cream or solution, silver sulfadiazine cream, and Accuzyme ointment or AQUACEL Ag+. Accuzyme is an enzymatic debridement agent and may cause a stinging feeling for 15 min after application. Preferences vary among burn units. Each topical agent has advantages and disadvantages in application, comfort, and bacteriostatic spectrum. Mafenide acetate is a very effective broad-spectrum agent with the ability to diffuse through the burn eschar; it is the treatment of choice for injury to cartilaginous surface, such as the ear; mafenide acetate solution at a concentration of 5% is useful for the treatment of burn wounds that are heavily colonized with multidrug–resistant bacteria (use should be limited to 5 days). The carbonic anhydrase inhibition activity of mafenide acetate may cause acid–base imbalance if large surface areas are treated, and adverse reactions to the sulfur-containing agents may produce transient leukopenia. This latter reaction is mostly noted with the use of silver sulfadiazine cream when applied over large surface areas in children younger than 5 yr of age. This phenomenon is transient, self-limiting, and reversible. No sulfa-containing agent should be used if the child has a history of sulfa allergies.

Inhalational Injury

Inhalational injury is serious in the infant and child, particularly if preexisting pulmonary conditions are present (see Chapter 71). Inhalation injury should be suspected in a patient confined to a closed space (building), with a history of an explosion or a decreased level of consciousness, or with evidence of carbon deposits in the oropharynx or nose, singed facial hair and carbonaceous sputum. Mortality estimates vary, depending on the criteria for diagnosis, but are 45-60% in adults; exact figures are not available in children. Evaluation aims at early identification of inhalation airway injuries. These may occur from (1) direct heat (greater problems with steam burns), (2) acute asphyxia, (3) carbon monoxide poisoning, and (4) toxic fumes, including cyanides from combustible plastics. Sulfur and nitrogen oxides and alkalis

formed during the combustion of synthetic fabrics produce corrosive chemicals that may erode mucosa and cause significant tissue sloughing. Exposure to smoke may cause degradation of surfactant and decrease its production, resulting in atelectasis. Inhalation injury and burn injury are synergistic, and the combined effect can increase morbidity and mortality.

The pulmonary complications of burns and inhalation can be divided into 3 syndromes that have distinct clinical manifestations and temporal patterns:

1. Early complications include carbon monoxide poisoning, airway obstruction, and pulmonary edema.
2. The acute respiratory distress syndrome usually becomes clinically evident later, at 24-48 hr, although it can occur even later (see Chapter 71).
3. Late complications (days to weeks) include pneumonia and pulmonary emboli.

Inhalation injury should be assessed from the evidence of obvious injury (swelling or carbonaceous material in the nasal passages), wheezing, crackles or poor air entry, and laboratory determinations of (HbCO) and arterial blood gases.

Treatment is initially focused on establishing and maintaining a patent airway through prompt and early nasotracheal or orotracheal intubation and adequate ventilation and oxygenation. Wheezing is common, and β-agonist aerosols or inhaled corticosteroids are useful. Aggressive pulmonary toilet and chest physiotherapy are necessary in patients with prolonged nasotracheal intubation or in the rare patient with a tracheotomy. An endotracheal tube can be maintained for months without the need for tracheostomy. If tracheotomy must be performed, it should be delayed until burns at and near the site have healed, and then it should be performed electively, with the child under anesthesia and the use of optimal tracheal positioning and hemostasis. In children with inhalation injury or burns of the face and neck, upper airway obstruction can develop rapidly; endotracheal intubation becomes a lifesaving intervention. Extubation should be delayed until the patient meets the accepted criteria for maintaining the airway.

Signs of CNS injury from hypoxemia caused by asphyxia or carbon monoxide poisoning vary from irritability to depression. Carbon monoxide poisoning may be mild (<20% HbCO), with slight dyspnea, headache, nausea, and decreased visual acuity and higher cerebral functions; moderate (20-40% HbCO), with irritability, agitation, nausea, dimness of vision, impaired judgment, and rapid fatigue; or severe (40-60% HbCO), producing confusion, hallucination, ataxia, collapse, acidosis, and coma. Measurement of HbCO is important for diagnosis and treatment. The PaO_2 value may be normal and the HbCO saturation values misleading because HbCO is not detected by the usual tests of oxygen saturation. Carbon monoxide poisoning is assumed until the tests are performed, and it is treated with 100% oxygen. Significant carbon monoxide poisoning requires hyperbaric oxygen therapy (see Chapter 63).

Patients with severe inhalation injury or with other causes of respiratory deterioration that lead to acute respiratory distress syndrome who do not improve with conventional pressure-controlled ventilation (progressive oxygenation failure, as manifested by oxygen saturation <90% while receiving FIO_2 of 0.9-1.0 and positive end-expiratory pressure of at least 12.5 cm H_2O) may benefit from high-frequency ventilation or nitric oxide inhalation treatment. Nitric oxide usually is administered through the ventilator at 5 parts per million (ppm) and increased to 30 ppm. This method of therapy reduces the need for extracorporeal membrane oxygenation.

Pain Relief and Psychologic Adjustment

See Chapter 62.

It is important to provide adequate analgesia, anxiolytics, and psychologic support to reduce early metabolic stress, decrease the potential for posttraumatic stress syndrome, and allow future stabilization as well as physical and psychologic rehabilitation. Patients and family members require team support to work through the grieving process and accept long-term changes in appearance.

Children with burn injury show frequent and wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn; the stage of healing; the patient's age and stage of emotional development and cognition; the experience and efficiency of the treating team; the use of analgesics and other drugs; the patient's pain threshold; and interpersonal and cultural factors. From the onset of treatment, **preemptive pain control** during dressing changes is of paramount importance. The use of a variety of nonpharmacologic interventions as well as pharmacologic agents must be reviewed throughout the treatment period. Opiate analgesia, prescribed in an adequate dose and timed to cover dressing changes, is essential to comfort management. A supportive person who is consistently present and "knows" the patient profile can integrate and encourage patient participation in burn care. The problem of undermedication is most prevalent in adolescents, in whom fear of drug dependence may inappropriately influence treatment. A related problem is that the child's specific pain experience may be misinterpreted; for anxious patients, those who are confused and alone, or those with preexisting emotional disorders, even small wounds may illicit intense pain. Anxiolytic medication added to the analgesic is usually helpful and has more than a synergistic effect. Equal attention is necessary to decrease stress in the intubated patient. Other modalities of pain and anxiety relief (relaxation techniques) can decrease the physiologic stress response. Oral morphine sulfate (immediate release) is recommended at a consistent schedule at a dose of 0.3-0.6 mg/kg every 4-6 hr initially and until wound cover is accomplished. Morphine sulfate IV bolus at a dose of 0.05-0.1 mg/kg maximum of 2-5 mg every 2 hr is administered. Morphine sulfate rectal suppositories may be useful at a dose of 0.3-0.6 mg/kg every 4 hr when oral administration is not possible. The use of codeine preparation should be limited to children older than age 6 yr because of the "ultrarapid metabolizers" of codeine into morphine. For anxiety, lorazepam is given on a consistent schedule, 0.05-0.1 mg/kg/dose every 6-8 hr. To control pain during a procedure (dressing change or debridement), oral morphine at a dose of 0.3-0.6 mg/kg is given 1-2 hr before the procedure and this is supplemented by a morphine IV bolus at a dose of 0.05-0.1 mg/kg given immediately before the procedure. Lorazepam at a dose of 0.04 mg/kg is given orally or intravenously, if necessary, for anxiety before the procedure. Midazolam (Versed) is also very useful for conscious sedation given at a dose of 0.01-0.02 mg/kg for nonintubated patients and 0.05-0.1 mg/kg for intubated patients, as an intravenous infusion or bolus, and may be repeated in 10 min. During the process of weaning from analgesics, the dose of oral opiates is reduced by 25% over 1-3 days, sometimes with the addition of acetaminophen as opiates are tapered. Antianxiety medications are tapered by reducing the dose of benzodiazepines at 25-50% per dose daily over 1-3 days.

For ventilated patients, pain control is accomplished by using morphine sulfate intermittently as an IV bolus at a dose of 0.05-0.1 mg/kg every 2 hr. Doses may need to be increased gradually, and some children may need continuous infusion; a starting dose of 0.05 mg/kg/hr given as an infusion is increased gradually as the need of the child changes. Naloxone is rarely needed but should be immediately available to reverse the effect of morphine, if necessary; if needed for an airway crisis, it should be given in a dose of 0.1 mg/kg up to a total of 2 mg, either intramuscularly or intravenously. For patients undergoing assisted respiration who require treatment of anxiety, midazolam is used as an intermittent IV bolus (0.04 mg/kg given by slow push every 4-6 hr) or as a continuous infusion. For intubated patients, opiates do not need to be discontinued during the process of weaning from the ventilator. Benzodiazepine should be reduced to approximately half the dose over 24-72 hr before extubation; too-rapid weaning from a benzodiazepine can lead to seizures.

There is a growing use of psychotropic medication in the care of children with burns, including prescription of selective serotonin reuptake inhibitors as antidepressants, the use of haloperidol as a neuroleptic in the critical care setting, and the treatment of posttraumatic stress disorder with benzodiazepines. Conscious sedation utilizing ketamine or propofol may be used for major dressing changes.

Reconstruction and Rehabilitation

To ensure maximum cosmetic and functional outcome, occupational and physical therapy must begin on the day of admission, continue throughout hospitalization, and, for some patients, continue after discharge. Physical rehabilitation involves body and limb positioning, splinting, exercises (active and passive movement), assistance with activities of daily living, and gradual ambulation. These measures maintain adequate joint and muscle activity with as normal a range of movement as possible after healing or reconstruction. Pressure therapy is necessary to reduce hypertrophic scar formation; a variety of prefabricated and custom-made garments are available for use in different body areas for prevention of hypertrophic scarring. These custom-made garments deliver consistent pressure on scarred areas; they shorten the time of scar maturation and decrease the thickness of the scar, the redness, and the associated itching. Continued adjustments to scarred areas (scar release, grafting, rearrangement) and multiple minor cosmetic surgical procedures are necessary to optimize long-term function and improve appearance. Replacement of areas of alopecia and scarring has been achieved with the use of tissue expander techniques. The use of ultrapulse laser for reduction of scarring is an adjunct in scar management.

School Reentry and Long-Term Outcome

It is best for the child to return to school immediately after discharge. Occasionally, a child may need to attend a few half-days (because of rehabilitation needs). It is important for the child to return to the child's normal routine of attending school and being with peers. Planning for a return to home and school often requires a *school reentry program* that is individualized to each child's needs. For a school-age child, planning for the return to school occurs simultaneously with planning for discharge. The hospital schoolteacher contacts the local school and plans the program with the school faculty, nurses, social workers, recreational/child-life therapists, and rehabilitation therapists. This team should work with students and staff to ease anxiety, answer questions, and provide information. Burns and scars evoke fears in those who are not familiar with this type of injury and can result in a tendency to withdraw from or reject the burned child. A school reentry program should be appropriate to a child's development and changing educational needs.

Major advances have made it possible to save the lives of children with massive burns; whereas some children have had lingering physical difficulties, most have a satisfactory quality of life. The comprehensive burn care that includes experienced multidisciplinary aftercare plays an important role in recovery. Table 75-7 lists the long-term complications of burns.

Table 75-7 Common Long-Term Disabilities in Patients with Burn Injuries

DISABILITIES AFFECTING THE SKIN AND SOFT TISSUE
Hypertrophic scars
Susceptibility to minor trauma
Dry skin
Contractures
Itching and neuropathic pain
Alopecia
Chronic open wounds
Skin cancers
ORTHOPEDIC DISABILITIES
Amputations
Contractures
Heterotopic ossification
Temporary reduction in bone density
METABOLIC DISABILITIES
Heat sensitivity
Obesity
PSYCHIATRIC AND NEUROLOGIC DISABILITIES
Sleep disorders
Adjustment disorders
Posttraumatic stress syndrome
Depression
Body image issues
Neuropathy and neuropathic pain
Long-term neurologic effects of carbon monoxide poisoning
Anoxic brain injury
LONG-TERM COMPLICATIONS OF CRITICAL CARE
Deep-vein thrombosis, venous insufficiency, or varicose veins
Tracheal stenosis, vocal cord disorders, or swallowing disorders
Renal or adrenal dysfunction
Hepatobiliary or pancreatic disease
Cardiovascular disease
Reactive airway disease or bronchial polyposis
PREEXISTING DISABILITIES THAT CONTRIBUTED TO THE INJURIES
Risk-taking behavior
Untreated or poorly treated psychiatric disorder

Modified from Sheridan RL, Schultz JT, Ryan CM, et al: Case records of the Massachusetts General Hospital: weekly clinicopathological exercises: case 6-2004: a 35-year-old woman with extensive, deep burns from a nightclub fire, N Engl J Med *350:810-821, 2004.*

SPECIAL SITUATIONS

Electrical Burns

There are 3 types of electrical burns. **Minor electrical burns** usually occur as a result of biting on an extension cord. These injuries produce localized burns to the mouth, which usually involve the portions of the upper and lower lips that come in contact with the extension cord. The injury may involve or spare the corners of the mouth. Because these are nonconductive injuries (do not extend beyond the site of injury), hospital admission is not necessary and care is focused on the area of the injury visible in the mouth, it is low voltage, does not cause entry or exit wounds, or cardiac issues. Treatment with topical antibiotic creams is sufficient until the patient is seen in a burn unit outpatient department or by a plastic surgeon.

A more serious category of electrical burn is the **high-tension electrical wire burn**, for which children must be admitted for observation, regardless of the extent of the surface area burn. Deep muscle injury is typical and cannot be readily assessed initially. These injuries result from high voltage (>1,000 V) and occur particularly at high-voltage installations, such as electric power stations or railroads; children climb an electric pole and touch an electric box out of curiosity or accidentally touch a high-tension electric wire. Such injuries have a mortality rate of 3-15% for children who arrive at the hospital for treatment. Survivors have a high rate of morbidity, including major limb amputations. Points of entry of current through the skin and the exit site show characteristic features consistent with current density and heat. The majority of entrance wounds involve the upper extremity, with small exit wounds in the lower extremity. The electrical path, from entrance to exit, takes the shortest distance between the 2 points and may produce injury in any organ or tissue in the path of the current. Multiple exit wounds in some patients attest to the possibility of several electrical pathways in the body, placing virtually any structure in the body at risk (Table 75-8). Damage to the abdominal viscera, thoracic structures, and the nervous system (confusion, coma, paralysis) in areas remote from obvious extremity injury occurs and must be sought, particularly in injuries with multiple current pathways or those in which the victim falls from a high pole. Sometimes an **ignition** occurs and results in concurrent flame burn and clothing fire. Cardiac abnormalities, manifested as ventricular fibrillation or cardiac arrest, are common; patients with high-tension electrical injury need an initial electrocardiogram and cardiac monitoring until they are stable and have been fully assessed. Higher-risk patients have abnormal electrocardiographic findings and a history of loss of consciousness. Renal damage from deep muscle necrosis and subsequent myoglobinuria is another complication; such patients need forced alkaline diuresis to minimize renal damage. Soft-tissue (muscle) injury of an extremity may produce a compartment syndrome. Aggressive removal of all dead

Table 75-8 Electrical Injury: Clinical Considerations

	CLINICAL MANIFESTATIONS	MANAGEMENT
General	—	Extricate the patient; perform ABCs of resuscitation; immobilize the spine History: voltage, type of current Complete blood count with platelets, electrolytes, blood urea nitrogen (BUN), creatinine, glucose
Cardiac	Dysrhythmias: asystole, ventricular fibrillation, sinus tachycardia, sinus bradycardia, premature atrial contractions, premature ventricular contractions, conduction defects, atrial fibrillation, ST-T wave changes	Treat dysrhythmias Cardiac monitor, electrocardiogram, and radiographs with suspected thoracic injury Creatinine phosphokinase with isoenzyme measurements if indicated
Pulmonary	Respiratory arrest, acute respiratory distress, aspiration syndrome	Protect and maintain the airway Mechanical ventilation if indicated, chest radiograph, arterial blood gas levels
Renal	Acute renal failure, myoglobinuria	Provide aggressive fluid management unless a central nervous system injury is present Maintain adequate urine output, >1 mL/kg/hr Consider central venous or pulmonary artery pressure monitoring Measure urine myoglobin; perform urinalysis; measure BUN, creatinine
Neurologic	Immediate: loss of consciousness, motor paralysis, visual disturbances, amnesia, agitation; intracranial hematoma Secondary: pain, paraplegia, brachial plexus injury, syndrome of inappropriate antidiuretic hormone secretion, autonomic disturbances, cerebral edema Delayed: paralysis, seizures, headache, peripheral neuropathy	Treat seizures Provide fluid restriction if indicated Consider spine radiographs, especially cervical CT scan of the brain if indicated
Cutaneous/oral	Oral commissure burns, tongue and dental injuries; skin burns resulting from ignition of clothes, entrance and exit burns, and arc burns Electrical burns to the mouth could include oral commissures and lips, low voltage electrical burns secondary to high conductivity of saliva	Search for the entrance/exit wound Treat cutaneous burns; determine the tetanus status Obtain a plastic surgery of ear, nose, and throat consultation if needed No entry or exit wounds, no cardiac involvement. All injuries are localized management is observation till eschar slough off and granulation tissue fills in. Obtain plastic surgeon evaluation after first healing had occurred usually with scar formation.
Abdominal	Viscus perforation and solid organ damage; ileus; abdominal injury rare without visible abdominal burns	Place a nasogastric tube if the patient has airway compromise or ileus Obtain serum glutamate oxaloacetate transaminase or aspartate aminotransferase, serum glutamate-pyruvic transaminase, alanine aminotransferase, amylase, BUN, and creatinine measurements and, CT scans as indicated
Musculoskeletal	Compartment syndrome from subcutaneous necrosis limb edema and deep burns Long bone fractures, spine injuries	Monitor the patient for possible compartment syndrome Obtain radiographs and orthopedic/general surgery consultations as indicated
Ocular	Visual changes, optic neuritis, cataracts, extraocular muscle paresis	Obtain an ophthalmology consultation as indicated

Modified from Hall ML, Sills RM: Electrical and lightning injuries. In Barkin RM, editor: Pediatric emergency medicine, *St. Louis, 1997, Mosby, p. 484.*

and devitalized tissue, even with the risk of functional loss, remains the key to effective management of the electrically damaged extremity. Early debridement facilitates early closure of the wound. Damaged major vessels must be isolated and buried in a viable muscle to prevent exposure. Survival depends on immediate intensive care, whereas a functional result depends on long-term care and delayed reconstructive surgery.

Lightning burns occur when a high-voltage current directly strikes a person (most dangerous) or when the current strikes the ground or an adjacent (in-contact) object. A step voltage burn is observed when lightning strikes the ground and travels up one leg and down the other (the path of least resistance). Lightning burns depend on the current path, the type of clothing worn, the presence of metal, and cutaneous moisture. Entry, exit, and path lesions are possible; the prognosis is poorest for lesions of the head or legs. Internal organ injury along the path is common and does not relate to the severity of the cutaneous burn. Linear burns, usually 1st- or 2nd-degree, are in the locations where sweat is present. Feathering or an arborescent pattern is characteristic of lightning injury. Lightning may ignite clothing or produce serious cutaneous burns from heated metal in the clothing. Internal complications of lightning burns include cardiac arrest caused by asystole, transient hypertension, premature ventricular contractions, ventricular fibrillation, and myocardial ischemia. Most severe cardiac complications resolve if the patient is supported with cardiopulmonary resuscitation (see Chapter 67). CNS complications include cerebral edema, hemorrhage, seizures, mood changes, depression, and paralysis of the lower extremities. Rhabdomyolysis and myoglobinuria (with possible renal failure) also occur. Ocular manifestations include vitreous hemorrhage, iridocyclitis, retinal tearing or retinal detachment.

Chapter 76

Cold Injuries

Alia Y. Antoon and Mary K. Donovan

The involvement of children and youth in snowmobiling, mountain climbing, winter hiking, and skiing places them at risk for cold injury. Cold injury may produce either local tissue damage, with the injury pattern depending on exposure to damp cold (frostnip, immersion foot, or trench foot), dry cold (which leads to local frostbite), or generalized systemic effects (hypothermia).

PATHOPHYSIOLOGY

Ice crystals may form between or within cells, interfering with the sodium pump, and may lead to rupture of cell membranes. Further damage may result from clumping of red blood cells or platelets, causing microembolism or thrombosis. Blood may be shunted away from an affected area by secondary neurovascular responses to the cold injury; this shunting often further damages an injured part while improving perfusion of other tissues. The spectrum of injury ranges from mild to severe and reflects the result of structural and functional disturbance in small blood vessels, nerves, and skin.

ETIOLOGY

Body heat may be lost by conduction (wet clothing, contact with metal or other solid conducting objects), convection (wind chill), evaporation, or radiation. Susceptibility to cold injury may be increased by dehydration, alcohol or drug use, impaired consciousness, exhaustion, hunger, anemia, impaired circulation as a consequence of cardiovascular disease, and sepsis; it is also greater in very young or older persons. Certain medications may contribute to hypothermia, while others may display reduced metabolism or clearance during hypothermia (Table 76-1).

Hypothermia occurs when the body can no longer sustain normal core temperature by physiologic mechanisms, such as vasoconstriction, shivering, muscle contraction, and nonshivering thermogenesis. When shivering ceases, the body is unable to maintain its core temperature; when the body core temperature falls to <35°C (95°F), the syndrome of hypothermia occurs. Wind chill, wet or inadequate clothing, and other factors increase local injury and may cause dangerous hypothermia, even in the presence of an ambient temperature that is not <17-20°C (50-60°F).

CLINICAL MANIFESTATIONS

Frostnip

Frostnip results in the presence of firm, cold, white areas on the face, ears, or extremities. Blistering and peeling may occur over the next 24-72 hr, occasionally leaving mildly increased hypersensitivity to cold for some days or weeks. Treatment consists of warming the area with an unaffected hand or a warm object before the lesion reaches a stage of stinging or aching and before numbness supervenes. Rewarming in a water bath (40-42.2°C [104-108°F]) is effective.

Table 76-1 Drugs Displaying Reduced Metabolism or Clearance in Hypothermia

Atropine	Procaine
Digoxin	Propranolol
Fentanyl	Sulfanilamide (AVC cream)
Gentamicin	Succinylcholine
Lidocaine	D-Tubocurarine
Phenobarbital	

Modified from Bope ET, Kellerman RD, editors, Conn's current therapy 2014, Philadelphia, 2014, Elsevier/Saunders, Box 3, p. 1135.

Immersion Foot (Trench Foot)

Immersion foot occurs in cold weather when the feet remain in damp or wet, poorly ventilated boots. The feet become cold, numb, pale, edematous, and clammy. Tissue maceration and infection are likely, and prolonged autonomic disturbance is common. This autonomic disturbance leads to increased sweating, pain, and hypersensitivity to temperature changes, which may persist for years. Treatment includes drying the foot, gentle rewarming and nonsteroidal antiinflammatory drugs for pain. Prevention consists of using well-fitting, insulated, waterproof, nonconstricting footwear. Once damage has occurred, patients must choose clothing and footwear that are more appropriate, dry, and well-fitting. The disturbance in skin integrity is managed by keeping the affected area dry and well-ventilated and by preventing or treating infection. Only supportive measures are possible for control of autonomic symptoms.

Frostbite

With frostbite, initial stinging or aching of the skin progresses to cold, hard, white anesthetic and numb areas. Clear or hemorrhagic vesicles may develop over the exposed areas. On rewarming, the area becomes blotchy, itchy, and often red, swollen, and painful. The injury spectrum ranges from complete normality to extensive tissue damage, even gangrene, if early relief is not obtained.

Treatment consists of warming the damaged area. It is important not to cause further damage by attempting to rub the area with ice or snow. The area may be warmed against an unaffected hand, the abdomen, or an axilla during transfer of the patient to a facility where more rapid warming with a warm (not hot) water bath is possible. If the skin becomes painful and swelling occurs, antiinflammatory agents are helpful and an analgesic agent is necessary. Freeze and rethaw cycles are most likely to cause permanent tissue injury, and it may be necessary to delay definitive warming and apply only mild measures if the patient is required to walk on the damaged feet en route to definitive treatment. In the hospital, the affected area should be immersed in warm water (approximately 42°C [107.6°F]), with care taken not to burn the anesthetized skin. Broken vesicles may be debrided, but intact vesicles should be left alone. Vasodilating agents, such as prazosin and phenoxybenzamine, may be helpful. Use of anticoagulants (heparin, dextran) has had equivocal results; results of chemical and surgical sympathectomy have also been equivocal. Oxygen is of help only at high altitudes. Meticulous local care, prevention of infection, and keeping the rewarmed area dry, open, and sterile provide optimal results. Recovery can be complete, and prolonged observation with conservative therapy is justified before any excision or amputation of tissue is considered. Analgesia and maintenance of good nutrition are necessary throughout the prolonged waiting period.

Hypothermia

Hypothermia may occur in winter sports when injury, equipment failure, or exhaustion decreases the level of exertion, particularly if sufficient attention is not paid to wind chill. Immersion in frozen bodies of water and wet wind chill rapidly produce hypothermia. As the core temperature of the body falls, insidious onset of extreme lethargy, fatigue, incoordination, and apathy occurs, followed by mental confusion, clumsiness, irritability, hallucinations, and finally, bradycardia. A number of medical conditions, such as cardiac disease, diabetes mellitus, hypoglycemia, sepsis, β-blocking agent overdose, and substance abuse, may need to be considered in a differential diagnosis. The decrease in rectal temperature to <34°C (93°F) is the most helpful diagnostic feature. Hypothermia associated with drowning is discussed in Chapter 74.

Prevention is a high priority. Of extreme importance for those who participate in winter sports is wearing layers of warm clothing, gloves, socks within insulated boots that do not impede circulation, and a warm head covering, as well as application of adequate waterproofing and protection against the wind. Thirty percent of heat loss for infants occurs from the head. Ample food and fluid must be provided during exercise. Those who participate in sports should be alert to the presence of cold or numbing of body parts, particularly the nose, ears, and

extremities, and they should review methods to produce local warming and know to seek shelter if they detect symptoms of local cold injury. Application of petrolatum (Vaseline) to the nose and ears gives certain protection against frostbite.

Treatment at the scene aims at prevention of further heat loss and early transport to adequate shelter (Table 76-2). Dry clothing should be provided as soon as practical, and transport should be undertaken if the victim has a pulse. If no pulse is detected at the initial review, cardiopulmonary resuscitation is indicated (see Chapter 67; Fig. 76-1). During transfer, jarring and sudden motion should be avoided because these occurrences may cause ventricular arrhythmia. It is often difficult to attain a normal sinus rhythm during hypothermia.

If the patient is conscious, mild muscle activity should be encouraged, and a warm drink offered. If the patient is unconscious, external warming should be undertaken initially with use of blankets and a sleeping bag; wrapping the patient in blankets or sleeping bag with a warm companion may increase the efficiency of warming. On arrival at a treatment center while a warming bath of 45-48°C (113-118°F) water is prepared, the patient should be warmed through inhalation of warm, moist air or oxygen or with heating pads or thermal blankets. Monitoring of serum chemistry values and an electrocardiogram are

ECG, electrocardiogram; CPR, cardiopulmonary resuscitation; HPMK, Hypothermia Prevention Management Kit; IV, intravenous; IO, intraosseous; ETCO2, end-tidal carbon dioxide; VT, ventricular tachycardia; VF, ventricular fibrillation; AED, automatic external defibrillator; US, ultrasound; ICU, intensive care unit; ECC, extracorporeal circulation. *(From Zafren K, Giesbrecht GG, Danzl DF, et al: Wilderness Medical Society Practice Guidelines for the Out-of-Hospital Evaluation and Treatment of Accidental Hypothermia: 2014 Update,* Wilderness Environ Med *25:S66–S85, 2014. Fig 2.)*

Table 76-2 Management of Hypothermia

HISTORY AND PHYSICAL
Gentle handling of the patient to prevent arrhythmias
ABCDE: cardiopulmonary resuscitation for ventricular fibrillation and asystole
Underlying disease diagnosis and treatment
Vital signs, pulse oximetry, electrocardiogram
Wet or cold clothing removed and patient placed in warm environment
LABORATORY TESTS
Arterial blood gas analysis corrected for temperature
Electrolytes, BUN creatinine, Ca, Mg, P
CBC with differential, PT/PTT, fibrinogen
Glucose, amylase/lipase
LFT
Additional labs, if appropriate, such as toxicology screen
PASSIVE REWARMING
≥32°C (89.6°F) in patients who are capable of spontaneous thermogenesis
ACTIVE REWARMING
<32°C (89.6°F), cardiovascular instability, patients at risk for developing hypothermia
Close monitoring for core-temperature afterdrop
Acute: external and/or core rewarming
Chronic (<32°C [89.6°F] for longer than 24 hr): core rewarming
Extracorporeal membrane oxygenation
Availability of rapid deployment

ABCDE, *a*irway and possibly *a*ntibiotics, *b*reathing, *c*irculation, *d*isability or neurologic and possible *d*extrose, *e*xtracorporeal support if all else fails; BUN, blood urea nitrogen; Ca, calcium; CDC, complete blood count; LFT liver function test; Mg, magnesium; P, phosphorus; PT, prothrombin time; PTT, partial thromboplastin time.

necessary until the core temperature rises to >35°C (95°F) and can be stabilized. Control of fluid balance, pH, blood pressure, and oxygen concentration is necessary in the early phases of the warming period and resuscitation. In severe hypothermia, there may be a combined respiratory and metabolic acidosis. Hypothermia may falsely elevate pH; nonetheless, most authorities recommend warming the arterial blood gas specimen to 37°C (98.6°F) before analysis and regarding the result as one from a normothermic patient. In patients with marked abnormalities, warming measures, such as gastric or colonic irrigation with warm saline or peritoneal dialysis, may be considered, but the effectiveness of these measures in treating hypothermia is unknown. In accidental deep hypothermia (core temperature 28°C [82.4°F]) with circulatory arrest, rewarming with cardiopulmonary bypass may be lifesaving for previously healthy young individuals. If rewarming is not successful despite appropriate measures, one should suspect infection, drug overdose, endocrine disorders, or a futile resuscitation.

Chilblain (Pernio)

Chilblain (pernio) is a form of cold injury in which erythematous, vesicular, or ulcerative lesions occur. The lesions are presumed to be of vascular or vasoconstrictive origin. They are often itchy, may be painful, and result in swelling and scabbing. The lesions are most often found on the ears, the tips of the fingers and toes, and exposed areas of the legs. The lesions last for 1-2 wk but may persist for longer. Treatment consists of prophylaxis: avoiding prolonged chilling and protecting potentially susceptible areas with a cap, gloves, and stockings. Prazosin and phenoxybenzamine may be helpful in improving circulation if this is a recurrent problem. For significant itching, local corticosteroid preparations may be helpful.

COLD-INDUCED FAT NECROSIS (PANNICULITIS)

A common, usually benign injury, cold-induced fat necrosis occurs upon exposure to cold air, snow, or ice and manifests in exposed (or, less often, covered) surfaces as red (or, less often, purple to blue) macular, papular, or nodular lesions. Treatment is with nonsteroidal antiinflammatory agents. The lesions may last 10 days to 3 wk (see Chapter 660) but may persist for longer. There is a possibility of severe coagulopathy associated with poor outcome in some of the severe cold injuries, thus meriting anticoagulation therapy.

Human Genetics

PART X

Chapter 77

Integration of Genetics Into Pediatric Practice

Brendan Lee

Genetic testing involves analyzing genetic material to obtain information related to a person's health status using chromosomal (cytogenetic) analysis (see Chapter 81) or DNA-based testing.

DIAGNOSTIC TESTING

Diagnostic genetic testing helps explain a set of signs and/or symptoms of a disease. The list of disorders for which specific genetic tests is available is extensive. The website http://www.ncbi.nlm.nih.gov/gtr/ provides a database of available tests that is provider driven and so claims are not validated by the site's host, the National Institutes of Health.

Single-gene disorders can be tested by at least 3 different approaches: linkage analysis, array comparative genomic hybridization (aCGH), and direct mutation (DNA sequence-based) analysis, usually by DNA sequencing (Table 77-1). Linkage analysis is used if the responsible gene is mapped but not yet identified, or if it is impractical to find specific mutations, usually because of the large size and larger number of different mutations in some genes. aCGH can be used to detect large multigene deletions or duplications (**copy number variations**). In addition, with increasing resolution, single gene or smaller intragenic deletions or duplications can be detected by aCGH. *Direct DNA mutation analysis is preferred and is possible with the availability of the complete human genome sequence.* An emerging feature is the increasing recognition of oligogenic disease where more than 1 disease gene contributes to a complex phenotype. The ability to sequence hundreds to thousands of genes at once has provided insight into this added layer of complexity in disease pathogenesis.

Linkage testing involves tracking a genetic trait through a family using closely linked polymorphic markers as a surrogate for the trait (Fig. 77-1). It requires testing an extended family and is vulnerable to several pitfalls, such as genetic recombination, genetic heterogeneity, and incorrect diagnosis in the proband. **Genetic recombination** occurs between any pair of loci, the frequency being proportional to the distance between them. This problem can be ameliorated by using very closely linked markers and, if possible, using markers that flank the specific gene. **Genetic heterogeneity** can be problematic for a linkage-based test if there are multiple distinct genomic loci that can cause the same phenotype, resulting in the risk that the locus tested for is not the one responsible for disease in the family. **Incorrect diagnosis** in the proband also leads to tracking the wrong gene. Linkage testing remains useful for several genetic conditions, though it is increasingly being superseded by the availability of direct DNA sequencing. It is critically important that genetic counseling be provided to the family to explain the complexities of interpretation of test results.

aCGH (see Chapter 81) can detect copy number variation in a patient's DNA by comparing it to a standard control DNA. In so doing, it provides a level of genetic resolution between what is available with DNA sequencing and what is available with chromosome analysis. Whereas earlier technologies could only identify large deletions or duplications that might encompass multiple genes, aCGH can resolve deletions or duplications of several kilobases within 1 gene. In theory, this approach can detect deletion and duplication mutations that would be missed by either chromosome analysis or direct mutation testing by DNA sequencing. However, because the specific resolution and coverage of different aCGH platforms can vary tremendously for different gene regions, the sensitivity for detecting deletions and duplications can vary for different diseases and laboratories.

Direct DNA-based mutation testing avoids the pitfalls of linkage testing by detecting the specific gene mutation (i.e., sequence change). The specific approach used is customized to the biology of the gene being tested. In some disorders, 1 or a few distinct mutations occur in all affected individuals. This is the case in sickle cell anemia, in which the same single base substitution occurs in everyone with the disorder. In other conditions, there may be many possible mutations that account for the disorder in different individuals. Cystic fibrosis is an example: more than 1,000 distinct mutations have been found in the *CFTR* gene. Mutation analysis is challenging because no single technique can detect all possible mutations. However, with the completion of the human genome sequence and high-throughput DNA sequencing technology, the approach of choice is to directly sequence DNA that is generated by **polymerase chain reaction** amplification of DNA isolated from peripheral blood white blood cells. The limitation of this approach is that only DNA that is amplified is sequenced, and usually this is restricted to the *coding* or *exonic* regions of a gene. Because mutations sometimes occur in the *noncoding intronic* regions, failure to detect a mutation does not exclude the diagnosis. In addition, genes in a deleted region will not be deleted. Although DNA sequencing can be highly specific, it is not completely sensitive because of practical limitations of what is commercially available. This is, however, rapidly changing because of technologic advances.

The most useful development in clinical DNA diagnosis is application of **next-generation sequencing** technology to testing panels of genes that target disease symptoms (e.g., low bone mass, ataxia) or the **whole exome (whole exome sequencing [WES])**. Here, advances in sequencing methodology have allowed for massively parallel sequencing of hundreds of genes of all of the gene coding sequences (approximately 20,000 genes) from single sample. The challenge is not so much the generation of DNA sequence, but the interpretation of enormous genetic variation within a single sample. Direct sequencing of tens to hundreds of genes in next generation sequencing panels offer a potentially higher sensitivity as the "depth" of read is higher without complicating high discovery rate of **variants of unknown sequences (VUS)**. WES also offers the potential for identifying new disease-gene associations as well as phenotypes caused by more than one disease gene (i.e., oligogenic phenotypes). An important ethical consideration is the reporting of incidental findings, whether medically or nonmedically actionable in a patient; WES may identify mutations that cause aminoglycoside sensitive hearing loss. This would be medically actionable. At the same time, the discovery of apolipoprotein E variants in a child that increase Alzheimer disease risk susceptibility may not. Hence, counseling for patients undergoing WES is important so that only wanted results are reported back to the patient. Guidelines are currently evolving for reporting of incidental findings for WES by the American College of Medical Genetics (www.acmg.net). Practice varies among institutions and recommendations vary among international genetic organizations about the approach for revealing incidental findings to patients. Many leave the choice up to the patient/family about revealing incidental findings from WES/whole genome sequencing. Most require revealing to the patient/family significant diseases

Table 77-1 Approaches for Genetic Testing

TYPE OF MUTATION TESTING	RESOLUTION	ADVANTAGES	DISADVANTAGES	SAMPLE REQUIREMENTS
Linkage	Depends on location of polymorphic markers near putative disease gene	Possible when specific disease-causing genetic mutation is not identifiable or found	Can give only diagnostic probability based on likelihood of genetic recombination between presumed DNA mutation and polymorphic markers	Requires multiple family members with documented mendelian pattern of inheritance within family
aCGH	Several kilobases to several hundreds of kilobases	Able to detect small deletion or duplications within 1 or more genes	Can miss small deletions or insertions depending on resolution of the array used	Single patient sample sufficient, though having sample from biological parents can help with interpretation
Direct DNA-based testing (e.g., DNA sequencing)	Single base-pair changes	High specificity if previously described deleterious mutation is found	Can miss deletion or duplication of a segment of gene	Single patient sample sufficient, though having sample from biological parents can help with interpretation

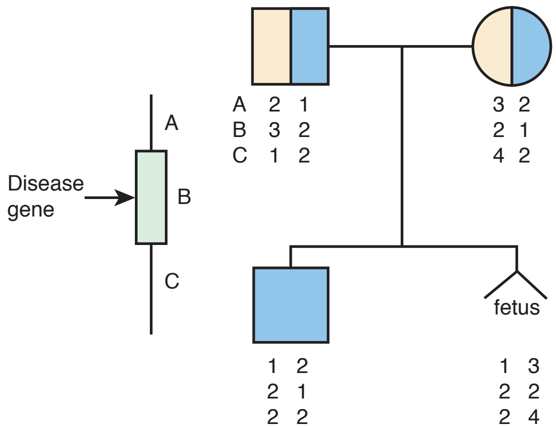

Figure 77-1 **Use of linkage analysis in prenatal diagnosis of an autosomal recessive disorder.** Both parents are carriers, and they have 1 affected son. The numbers below the symbols indicate alleles at 3 polymorphic loci: A, B, and C. Locus B resides within the disease gene. The affected son inherited the 1-2-2 chromosome from his father and the 2-1-2 chromosome from his mother. The fetus has inherited the same chromosome from the father, but the 3-2-4 chromosome from the mother and therefore is most likely to be a carrier.

(actionable) with a specific and successful treatment/prevention strategy (Table 77-2).

Genetic testing is interpreted in light of 3 factors: analytical validity, clinical validity, and clinical utility. **Analytical validity** is test accuracy: Does the test correctly detect the presence or absence of mutation? Most genetic tests have a very high analytical validity, assuming that human error, such as sample mix-up, has not occurred. Such errors are possible, and unlike most medical tests, a genetic test is unlikely to be repeated, because it is assumed that the result will not change over time. Therefore, human errors can go undetected for long periods of time.

Clinical validity is the degree to which the test correctly predicts presence or absence of disease. False-positive and false-negative test results can occur. **False-positive results** are more likely for predictive tests than for diagnostic tests. An important contributing factor is **nonpenetrance:** An individual with an at-risk genotype might not clinically express the condition. Another factor is the finding of a genetic variant of unknown significance. Detection of a base sequence variation in an affected patient does not prove that it is the cause of the patient's disorder. In exomic sequencing, there may be more than 30,000 VUS; in whole genome sequencing there may be more than 3,000,000 VUS. Various lines of evidence are used to establish

Table 77-2 Variants That Are Incidental Findings Are Assigned to 1 of 4 Categories

Childhood onset	Medically actionable*
Childhood onset	Not medically actionable†
Adult onset	Medically actionable*
Adult onset	Not medically actionable†

*"Medically actionable" refers to a variant in a gene in which knowledge of the particular variant will affect medical decision making such as initiation of a treatment, family planning, etc.

†"Not medically actionable" refers to variants that increase the individual's risk for a disease in which no treatment is proven to significantly change medical decision making.

From Bick D, Dimmock D: Whole exome and whole genome sequencing. Curr Opin Pediatr 23:594–600, 2011, Table 2, p. 597.

pathogenicity. These include finding the variant only in affected individuals, inferring that the variant alters the function of the gene product, determining whether the amino acid altered by the mutation is conserved in evolution, and determining whether the mutation segregates with disease in the family. In some cases, it is possible to be sure whether the variant is pathogenic or incidental. In spite of all of these approaches, it might still be impossible to definitively assign causality with 100% confidence.

False-negative results reflect an inability to detect a mutation in an affected patient. This occurs principally in disorders where genetic heterogeneity—**allelic** (different mutations occur in one causative gene) heterogeneity or **locus** (more than one gene can cause a disease) heterogeneity—is the rule. It is difficult to detect all possible mutations within a gene, because mutations can be varied in location within the gene and in the type of mutation. Direct sequencing may miss gene deletions or rearrangements, and mutations may be found within noncoding sequences such as introns or the promoter; a negative DNA test does not necessarily exclude a diagnosis.

Clinical utility is the degree to which the results of a test guide clinical management. For genetic testing, clinical utility includes establishing a diagnosis that obviates the need for additional workup or guiding surveillance or treatment. Test results may also be used as a basis for genetic counseling. For some disorders, genetic testing is possible but the test results do not add to the clinical assessment. If the diagnosis and genetic implications are already clear, it might not be necessary to pursue genetic testing.

PREDICTIVE TESTING

Predictive genetic testing involves performing a test in a person who is at risk for developing a genetic disorder **(presymptomatic),** usually on the basis of family history, yet who does not manifest signs or

symptoms. This is usually done for disorders that display age-dependent penetrance; the likelihood of manifesting signs and symptoms increases with age, as in cancer or Huntington disease.

A major caution with predictive testing is that the presence of a gene mutation does not necessarily mean that the disease will develop. Many of the disorders with age-dependent penetrance display *incomplete penetrance*. A person who inherits a mutation might never develop signs of the disorder. There is concern that a positive DNA test could result in stigmatization of the person and might not provide information that will guide medical management. Stigmatization might include psychological stress, but it could also include discrimination, including denial of health, life, or disability insurance, or employment (see Chapter 78).

It is generally agreed that predictive genetic tests should be performed for children if the results of the test will benefit the medical management of the child. Otherwise, the test should be deferred until the child has an understanding of the risks and benefits of testing and can provide informed consent. Individual states offer varying degrees of protection from discrimination on the basis of genetic testing. A major milestone in the prevention of genetic discrimination was the passage of the Genetic Information Nondiscrimination Act (GINA) in 2008, which is a federal law that prohibits discrimination in health coverage or employment based on genetic information; it does not protect against refusal of life insurance.

PREDISPOSITIONAL TESTING

It is expected that genetic tests will become available that will predict risk of disease. Common disorders are multifactorial in etiology; there may be many different genes that contribute to risk of any specific condition (see Chapter 82). Most of the genetic variants that have been found to correlate with risk of a common disease add small increments of relative risk, probably in most cases too little to guide management. It is possible that further discovery of genes that contribute to common disorders will reveal examples of variants that convey more significant levels of risk. It is also possible that testing several genes together will provide more information about risk than any individual gene variant would confer. The rationale for predispositional testing is that the results would lead to strategies aimed at risk reduction as part of a *personalized approach* to healthcare maintenance. This might include avoidance of environmental exposures that would increase risk of disease (cigarette smoking and α_1-antitrypsin deficiency), medical surveillance (familial breast cancer and mammography), or, in some cases, pharmacologic (statins and hypercholesteremia) treatment. The value of predispositional testing will need to be critically appraised through outcomes studies as these tests are developed.

PHARMACOGENETIC TESTING

Polymorphisms in drug metabolism genes can result in distinctive patterns of drug absorption, metabolism, excretion, or effectiveness (see Chapters 59 and 82). Knowledge of individual genotypes will guide pharmacologic therapy, allowing customization of choice of drug and dosage to avoid toxicity and provide a therapeutic response. An example of this is testing for polymorphisms within the methylenetetrahydrofolate reductase (*MTHFR*) gene for susceptibility of potentially increased toxicity to methotrexate antimetabolite therapy for treatment of acute lymphoblastic leukemia.

77.1 Genetic Counseling

Brendan Lee

Genetic counseling is a communication process in which the genetic contribution to health is explained, along with specific risks of transmission of a trait and options to manage the condition and its inheritance (Table 77-3). The counselor is expected to present information in a neutral, nondirective manner and to provide support to the individual and family to cope with decisions that are made.

Table 77-3 Indications for Genetic Counseling
Advanced parental age
• Maternal age ≥35 yr
• Paternal age ≥50 yr
Previous child with or family history of
• Congenital abnormality
• Dysmorphology
• Intellectual disability
• Isolated birth defect
• Metabolic disorder
• Chromosome abnormality
• Single-gene disorder
Adult-onset genetic disease (presymptomatic testing)
• Cancer
• Huntington disease
Consanguinity
Teratogen exposure (occupational, abuse)
Repeated pregnancy loss or infertility
Pregnancy screening abnormality
• Maternal serum α-fetoprotein
• Maternal triple or quad screen or variant of this test
• Fetal ultrasonography
• Fetal karyotype
Heterozygote screening based on ethnic risk
• Sickle cell anemia
• Tay-Sachs, Canavan, and Gaucher diseases
• Thalassemias
Follow-up to abnormal neonatal genetic testing
Prior to whole genome or exome sequencing
Prior to preimplantation genetic testing

Genetic counseling has evolved from a model of care that was developed in the context of prenatal diagnosis and pediatrics (see Table 77-3). For prenatal diagnosis, the task is to assess risk of a couple having a child with a genetic condition and to advise the couple about options to manage that risk, including reproductive options such as artificial insemination and prenatal or preimplantation genetic diagnosis. In pediatrics, the task is to establish a diagnosis in a child, provide longitudinal care for the child, and advise the parents about risk of recurrence as well as options to deal with that risk.

The genetic counseling role has expanded, particularly with advances in understanding the genetics of adult-onset or common disorders. Genetic counseling has a major role in risk assessment for cancer, especially breast and ovarian cancer or colon cancer, for which well-defined genetic tests are available to assess risk to an individual.

TALKING TO FAMILIES

The type of information provided to a family depends on the urgency of the situation, the need to make decisions, and the need to collect additional information. There are 4 situations in which genetic counseling is particularly important.

The first is the **prenatal diagnosis** of a congenital anomaly or genetic disease. The need for information is urgent because a family must often decide whether to continue or to terminate a pregnancy. Risks to the mother must also be considered. The second type of situation occurs when a child is born with a life-threatening congenital anomaly or genetic disease. Decisions must be made immediately with regard to how much support should be provided for the child and whether certain types of therapy should be attempted. The third situation arises later in life when a diagnosis with a genetic implication is made; a couple is planning a family and there is a family history of a genetic problem, including whether one member of a couple carries a translocation or is a carrier of an abnormal gene for an autosomal recessive or X-linked disorder; an adolescent or young adult has a family history of an adult-onset genetic disorder (Huntington disease, breast cancer); unusual features are present and a diagnosis is wanting or not possible; and there is suspected exposure to a toxic substance or teratogen. It is often necessary to have several meetings with a family in this third situation. Urgency is not as much of an issue as being sure that they have

as much information and as many options as are available. The fourth situation is counselling prior to genome sequencing where the family is given options of what they want reported back to them (actionable, nonactionable incidental findings vs. a specific diagnosis).

GENETIC COUNSELING

Providing accurate information to families requires:

- Taking a careful family history and constructing a pedigree that lists the patient's relatives (including abortions, stillbirths, deceased persons) with their sex, age, and state of health, up to and including 3rd-degree relatives.
- Gathering information from hospital records about the affected individual and, in some cases, about other family members.
- Documenting prenatal, pregnancy, and delivery histories.
- Reviewing the latest available medical, laboratory, and genetic information concerning the disorder.
- Performing a careful physical examination of the affected individual (photographs, measurements) and of apparently unaffected individuals in the family.
- Establishing or confirming the diagnosis by the diagnostic tests available.
- Giving the family information about support groups.
- Providing new information to the family as it becomes available (a mechanism for updating needs to be established).

Counseling sessions must include the specific condition, knowledge of the diagnosis of the particular condition, the natural history of the condition, the genetic aspects of the condition and the risk of recurrence, prenatal diagnosis and prevention, therapies and referral, support groups, and nondirective counseling.

Specific Condition or Conditions

If a specific diagnosis is made and confirmed, that should be discussed with the family and information should be provided in writing. However, often the disorder fits into a spectrum (e.g., one of many types of arthrogryposis) or the diagnosis is clinical rather than laboratory based. In those situations, the family needs to understand the limits of present knowledge and that additional research will probably lead to better information in the future.

Knowledge of the Diagnosis of the Particular Condition

Although it is not always possible to make an exact diagnosis, having a diagnosis as accurate as possible is important. Estimates of recurrence risk for various family members depend on an accurate diagnosis. When a specific diagnosis cannot be made (as in many cases of multiple congenital anomalies), the various possibilities in the differential diagnosis should be discussed with the family and empirical information should be provided. If specific diagnostic tests are available, they should be discussed. Often, empirical recurrence risks can be given even without a specific laboratory-based diagnosis. At the same time, even negative laboratory testing can further modify this risk.

Natural History of the Condition

It is very important to discuss the natural history of the specific genetic disorder in the family. Affected persons and their families have questions regarding the prognosis and potential therapy that can be answered only with knowledge of the natural history. If there are other possible diagnoses, their natural history may also be discussed. If the disorder is associated with a spectrum of clinical outcomes or complications, the worst and best scenarios, as well as treatment and referral to the appropriate specialist, should be addressed.

Genetic Aspects of the Condition and Recurrence Risk

The genetic aspects and risk of recurrence are important because all family members need to be aware of their reproductive choices. The genetics of the disorder can be explained with visual aids (e.g., diagrams of chromosomes). It is important to provide accurate occurrence and recurrence risks for various members of the family, including unaffected individuals. If a definite diagnosis cannot be made, it is necessary to use empirical recurrence risks. Counseling should give patients the necessary information to understand the various options and let the patients make their own informed decisions regarding pregnancy, adoption, artificial insemination, prenatal diagnosis, screening, carrier detection, and termination of pregnancy. It may be necessary to have more than 1 counseling session.

Prenatal Diagnosis and Prevention

Many different methods of prenatal diagnosis are available, depending on the specific genetic disorder (see Chapter 96). The use of ultrasonography allows prenatal diagnosis of anatomic abnormalities such as congenital heart defects. Amniocentesis and chorionic villus sampling are used to obtain fetal tissue for analysis of chromosomal abnormalities, biochemical disorders, and DNA studies. Maternal blood or serum sampling is used for some types of screening. Fetal cells can be retrieved from the umbilical cord or from maternal blood (free fetal DNA) for testing, although mothers might harbor cells from all previous pregnancies.

Therapies and Referral

A number of genetic disorders require the care of a specialist. Girls with Turner syndrome usually need to be evaluated by an endocrinologist. Prevention of known complications is a priority. The psychological adjustment of the family might require specific intervention. When to discuss the diagnosis of a chronic disease with the patient is always a difficult decision. The decision to do so should always involve the parents and an assessment of the maturity and capacity of the child or adolescent.

Alternative medicines or nontraditional therapies are often brought to attention by parents after exhaustive Internet searches. Such treatments should not necessarily be dismissed out of hand because the physician and counselor should serve as an important resource for helping parents navigate the maze of nonstandard treatments. Instead, the relative merits of treatments should be framed in the context of cost and benefit, scientific rationale, evidence from controlled and/or observational studies, the placebo effect, safety of the treatment, and the gaps in our own scientific knowledge base.

Support Groups

A large number of community lay support groups have been formed to provide information and to fund research on specific genetic and nongenetic conditions. An important part of genetic counseling is to give information about these groups to patients and to suggest a contact person for the families. Many groups have established websites with very helpful information; it is important to stress to families that their individual disease course will be unique.

Follow-up

Families should be encouraged to continue to ask questions and keep up with new information about the specific disorder. New developments often influence the diagnosis and therapy of specific genetic disorders. Lay support groups are a good source of new information.

Nondirective Counseling

Genetic counseling is usually nondirective; choices about reproduction are left to the family to decide what is right for them. The role of the counselor (physician, genetic counselor, nurse, medical geneticist) is to provide information in understandable terms and outline the range of options available.

77.2 Management and Treatment of Genetic Disorders

Brendan Lee

Genetic conditions are often chronic disorders; few are amenable to curative therapies. Nevertheless, many management options are

available. All patients and families should be provided information about the disorder, genetic counseling, anticipatory guidance, and appropriate medical surveillance. Surgical management is available for many conditions that are associated with congenital anomalies or predisposition to tumors.

Resources for patients include the National Organization of Rare Disorders (www.rarediseases.org), the Genetic Alliance (www.geneticalliance.org), the National Library of Medicine (www.nlm.nih.gov/medlineplus/geneticdisorders.html), and a large number of disease-specific websites. A current listing of federally and privately funded clinical trials, including many for genetic diseases, is available at www.*ClinicalTrials.gov*.

Specific medical therapies for genetic disorders can be classified into physiologic and replacement therapies. Much effort is currently focused in developing gene and cell therapies.

PHYSIOLOGIC THERAPIES

Physiologic therapies attempt to ameliorate the phenotype of a genetic disorder by modifying the physiology of the affected individual. The underlying defect itself is not altered by treatment. Physiologic therapies are used in the treatment of **inborn errors of metabolism** (see Chapter 84). These include dietary manipulation, such as avoiding phenylalanine by persons with phenylketonuria; coenzyme supplementation for some patients with methylmalonic acidemia and mitochondrial diseases; stimulation of alternative pathways to excrete ammonia for those with urea cycle disorders; bisphosphonate treatment for those with osteogenesis imperfecta to reduce bone fractures; and avoiding cigarette smoking by persons with α_1-antitrypsin deficiency. Physiologic treatments can be highly effective, but they usually need to be maintained for a lifetime because they do not affect the underlying genetic disorder. Many of these treatments are most effective when begun early in life before irreversible damage has occurred. This is the rationale for comprehensive newborn screening for inborn errors of metabolism.

Many physiologic therapies use small-molecule pharmaceuticals (e.g., to remove ammonia in those with urea cycle disorders). Pharmacologic treatments directly target a defective cellular pathway that is altered by an abnormal or a missing gene product. However, there are relatively few such therapies. One example is the development of imatinib, a small molecule tyrosine kinase inhibitor developed specifically to target the biologic pathway altered in chronic myelogenous leukemia (CML). CML is usually associated with a chromosome 9;22 translocation (the Philadelphia chromosome) that creates a fusion of the BCR protein and the *Abl* oncogene. Imatinib is a small molecule that blocks the adenosine triphosphate binding in the fusion protein; it is highly effective in treatment of CML and several other malignancies. Other examples include large-molecule biologics such as “humanized” monoclonal antibodies.

REPLACEMENT THERAPIES

Replacement therapies include replacement of a missing metabolite, an enzyme, an organ, or even a specific gene.

Enzyme Replacement

Enzyme replacement therapy is a component of the treatment of cystic fibrosis to manage intestinal malabsorption. Pancreatic enzymes are easily administered orally, because they must be delivered to the gastrointestinal tract.

Enzyme replacement strategies are effective for some lysosomal storage disorders. Enzymes are targeted for the lysosome by modification with mannose-6-phosphate, which binds to a specific receptor. This receptor is also present on the cell surface, so lysosomal enzymes with exposed mannose-6-phosphate residues can be infused into the blood and are taken into cells and transported to lysosomes. Enzyme replacement therapies are available for Gaucher disease and Fabry disease, some mucopolysaccharidoses (I, II, VI), Niemann-Pick disease type C, and Pompe disease.

One complication of enzyme replacement therapy is antibody response to the enzyme. The magnitude of this response is not always predictable and varies depending on the enzyme preparation and the disease. In most cases, the patient’s antibody response does not affect the treatment’s efficacy (e.g., in Gaucher disease), but in other situations it may be a significant hurdle (e.g., in Pompe disease).

Transplantation

Cell and organ transplantation are potentially effective approaches to replacement of a defective gene. Aside from transplantation to replace damaged tissues, transplantation of stem cells, liver, or bone marrow is also used for several diseases, mainly inborn errors of metabolism, and hematologic or immunologic disorders. A successful transplant is essentially curative, though there may be significant risks and side effects (see Chapters 135-139). Cell and tissue transplantation are effective in many clinical scenarios, but there is always short-term morbidity, often associated with either surgical (liver) or preparative (bone marrow) regimens, and long-term morbidity related to chronic immunosuppression and graft failure. Bone marrow transplantation is the best example of stem cell therapy, but much effort is focused on identifying, characterizing, expanding, and using other tissue stem cells for regenerative therapies.

Alternatively, research has focused on replacing a defective gene (gene therapy). In theory, if we can target the specific tissue that has a deficiency in the gene or gene product, this can offer a less invasive means of achieving a cure of a genetic disorder. Ultimately, gene therapy depends on the unique interaction of the disease pathophysiology, which is specific to the patient, and the gene delivery vehicle.

Gene-transfer vehicles include viral and nonviral approaches. Most human clinical trials have used viral vectors because of their efficiency of tissue transduction. In some diseases, such as X-linked and adenosine deaminase-deficient severe combined immunodeficiency, clinical gene therapy is a viable and effective option (see Chapter 126.1). Preliminary results suggest that gene therapy (intraocular delivery) may be effective for Leber congenital amaurosis.

Chapter 78

The Genetic Approach in Pediatric Medicine

Daryl A. Scott and Brendan Lee

Since the completion of the Human Genome Project, we have seen an unprecedented expansion in our understanding of how human health is impacted by variations in genomic sequence and epigenetic, non-sequence-based, changes that affect gene expression. This period has also seen the development and implementation of new clinical tests that have made it easier for physicians to detect such changes. In addition, this period has seen a dramatic increase in the availability of information about the genetic aspects of pediatric diseases, particularly on the Internet (Table 78-1).

THE BURDEN OF GENETIC DISORDERS IN CHILDHOOD

Medical problems associated with genetic disorders can appear at any age with the most obvious and serious problems typically manifesting in childhood. It has been estimated that 53/1,000 children and young adults can be expected to have diseases with an important genetic component. If congenital anomalies are included, the rate increases to 79/1,000. In 1978, it was estimated that just over half of admissions to

pediatric hospitals were for a genetically determined condition. By 1996, owing to changes in healthcare delivery and a greater understanding of the genetic basis of many disorders, that percentage rose to 71% in 1 large pediatric hospital in the United States, and 96% of chronic disorders leading to admission had an obvious genetic component or were influenced by genetic susceptibility. Major categories of genetic disorders include single-gene, genomic, chromosomal, and multifactorial conditions.

Individually, **single-gene disorders** are rare, but collectively they represent an important contribution to childhood disease. The hallmark of a single-gene disorder is that the phenotype is overwhelmingly determined by changes that affect an individual gene. The phenotypes associated with single-gene disorders can vary from one patient to another based on the severity of the change affecting the gene and additional modifications caused by genetic, environmental, and/or stochastic factors. This feature of genetic disease is termed **variable expressivity**. Common single-gene disorders include sickle cell anemia and cystic fibrosis.

Single-gene disorders tend to occur when changes in a gene have a profound effect on the quantity of the gene product produced—either too much or too little—or the function of the gene product—either a loss of function or a harmful gain of function. Single-gene disorders can be caused by de novo changes that are not found in the unaffected parents of the affected individual or they may be caused by inherited changes. When a single-gene disorder is known to be caused by changes in only 1 gene or a small number of individual genes, searching for deleterious changes is most often performed by directly sequencing that gene and, in some cases, looking for small deletions and/or duplications. When multiple genes can potentially cause a particular disorder, it is sometimes more efficient and cost effective to screen large numbers of disease causing genes using a disease-specific panel that takes advantage of next generation sequencing technology than to screen genes individually. When such panels are not available, or when the diagnosis is in question, physicians may consider screening the protein coding regions of all genes by **whole exome sequencing** on a clinical basis. Indeed in many circumstances, whole exome sequencing is less expensive than sequencing multiple individual genes. In the future, whole genome sequencing—in which an individual's entire genome is sequenced—may become a valid clinical option as the cost of such tests fall and our ability to interpret the clinical consequences of thousands of changes that are identified in such tests improves.

The risk of having a child with a particular single gene disorder can vary from one population to another. In some cases this is the result of a **founder effect,** in which a specific change affecting a disease-causing gene becomes relatively common in a population derived from a small number of founders. This high frequency is maintained when there is relatively little interbreeding with persons outside of that population because of social, religious, or physical barriers. This is the case for Tay-Sachs disease in Ashkenazi Jews and French Canadians. Other changes may be subject to positive selection when found in the heterozygous carrier state. In this case, carriers of a genetic change (heterozygotes) have a survival advantage over noncarriers. This can occur even when individuals who inherit 2 copies of the change (homozygotes) have severe medical problems. This type of positive selection is evident among individuals in sub-Saharan Africa who carry a hemoglobin mutation that confers relative resistance to malaria but causes sickle cell anemia in homozygotes.

Genomic disorders are a group of diseases caused by alterations in the genome, including deletions (copy number loss), duplications (copy number gain), inversions (altered orientation of a genomic region) and chromosomal rearrangements (altered location of a genomic region). **Contiguous gene disorders** are caused by changes that affect two or more genes that contribute to the clinical phenotype and are located near each other on a chromosome. DiGeorge syndrome, which is caused by deletions of genes located on chromosome 22q11, is a common example. Some genomic disorders are associated with distinctive phenotypes whose pattern can be recognized clinically. Other genomic disorders do not have a distinctive pattern of anomalies, but can cause developmental delay, cognitive impairment, structural birth defects, abnormal growth patterns and changes in physical appearance. Fluorescent in situ hybridization (FISH) can provide information about the copy number and location of a specific genomic region. Array-based copy number detection assays can be used to screen for chromosomal deletions (large and small) and duplication across the genome but do not provide information about the orientation or location of genomic regions. A chromosome analyses (karyotyping) can detect relatively large chromosomal deletions and duplications and can also be useful in identifying inversions and chromosomal rearrangements even when they are copy-number neutral

changes that do not result in a deletion or duplication of genomic material.

Deletions, duplications, and chromosomal rearrangements that affect whole chromosomes, or large portions of a chromosome, are commonly referred to as **chromosomal disorders.** One of the most common chromosomal disorders is Down syndrome, which is most commonly associated with the presence of an extra copy, or **trisomy,** of an entire chromosome 21. When all or a part of a chromosome is missing, the disorder is referred to as **monosomy**. Translocations are a type of chromosomal rearrangement in which a genomic region from 1 chromosome is transferred to a different location on the same chromosome or on a nonhomologous chromosome. Translocations can be balanced, meaning that no genetic material has been lost or gained, or they can be unbalanced, in which case some genetic material has been deleted or duplicated. Chromosomal disorders can often be identified on a chromosome analysis (karyotype) or by FISH. Evidence of a chromosomal disorder may also be revealed by an array-based copy number detection assays if genetic material has been gained or lost.

In some cases, only a portion of cells that make up a person's body are affected by the single gene defect, the genomic disorder or the chromosomal defect. This is referred to as **mosaicism** and indicates that the individual's body is made up of 2 or more distinct cell populations.

Polygenic disorders are caused by the cumulative effects of changes or variations in more than 1 gene. Multifactorial disorders are caused by the cumulative effects of changes or variations in multiple genes and/or the combined effects of both genetic and environmental factors. Spina bifida and isolated cleft lip or palate are common birth defects that display multifactorial inheritance patterns. Multifactorial inheritance is seen in many common pediatric disorders, such as asthma and diabetes mellitus. These traits can cluster in families but do not have a mendelian pattern of inheritance (see Chapter 80). In most cases, the genetic changes or variations that are contributing to a particular case are unknown and genetic counseling is based on empirical data.

THE CHANGING PARADIGM OF GENETICS IN MEDICINE

Genetic testing is increasingly available for a wide variety of both rare and relatively common genetic disorders. Genetic testing is commonly used in pediatric medicine to resolve uncertainty regarding the underlying etiology of a child's medical problems and provides a basis for improved genetic counseling and possibly specific therapy. Even in cases where a specific treatment is not available, identifying a genetic cause can aid physicians in providing individuals and family with accurate prognostic and recurrence risk information and usually helps to relieve unfounded feelings of guilt and/or stem the tide of misdirected blame.

Genetic tests will ultimately come to underlie a high proportion of medical decisions and will be seamlessly incorporated into routine medical care. Although most genetic testing is presently aimed at identifying or confirming a diagnosis, in the future, genetic testing may find wider application as a means of determining if an individual is predisposed to develop a particular disease. Another area in which genetic testing could make a significant impact is on individualized drug treatment. It has long been known that genetic variation in the enzymes involved in drug metabolism underlies differences in the therapeutic effect and toxicity of some drugs. As the genetic changes that underlie these variations are identified, new genetic tests may be developed that will allow physicians to tailor treatments based on individual variations in drug metabolism, responsiveness, and susceptibility to toxicity (see Chapter 59). It is likely that the expansion of such testing will depend, at least in part, on the extent to which such testing can be linked to strategies to prevent disease or improve outcome (see Chapter 77). If such links can be made, it could usher in a new era of personalized medical treatment.

Long-standing and highly successful carrier screening programs have existed for disorders such as Tay-Sachs disease and many other rare single-gene disorders that are prevalent in specific populations. Couples are commonly offered screening for a variety of conditions, in part based on ancestry (Tay-Sachs disease, hemoglobinopathies, cystic fibrosis). Couples found to be at increased risk for such disorders can be offered prepregnancy or prenatal testing aimed at detecting specific disease causing mutations.

Prenatal screening is routinely offered for chromosomal disorders such as trisomy 13, trisomy 18, and Down syndrome. An increasing number of pregnancies affected by these and other genetic disorders are being recognized by noninvasive screening tests of maternal serum in the first and second trimesters and by fetal ultrasound. When genetic disorders are suspected, chorionic villus sampling at 10-12 wk of gestation or by amniocentesis at 16-18 wk of gestation can provide material for genetic testing. Approaches to noninvasive prenatal diagnosis by sampling of cell-free fetal DNA or fetal cells in maternal blood are also becoming available. When a couple is at risk for a specific genetic defect, **preimplantation genetic diagnosis** can sometimes be used to select unaffected early embryos, which are then implanted as part of an in vitro fertilization procedure.

Although prenatally obtained genetic material can be used to identify single-gene disorders, genomic disorders, and chromosomal anomalies, the information obtained on any pregnancy depends on the tests that are ordered. It is important that physicians select the most appropriate prenatal tests and that couples understand both the limitations of these tests and that no amount of genetic testing can guarantee the birth of a healthy child.

Specific treatments are not available for the majority of genetic disorders. However, there are some important exceptions. Inborn errors of metabolism were the first genetic disorders to be recognized, and many are amenable to treatment by dietary manipulation (see Chapter 84). These conditions result from genetically determined deficiency of specific enzymes, leading to the buildup of toxic substrates and/or deficiency of critical end products.

Individual metabolic disorders tend to be very rare, but their combined impact on the pediatric population is significant. Tandem mass spectrometry has made it relatively inexpensive to screen for a large number of these disorders in the newborn period. Use of this technology not only dramatically increases the number of metabolic disorders identified within a population but also allows treatment to be initiated at a much earlier stage in development (see Chapters 77 and 84).

Another area where progress has been made regarding genetic therapies has been in the treatment of lysosomal storage disorders. These are a group of metabolic diseases caused by defects in lysosomal function. Lysosomes are cellular organelles that contain specific digestive enzymes. Some of these disorders that were lethal or associated with intractable chronic illness can now be treated using specially modified enzymes that are administered by intravenous infusion. These enzymes are then taken up by cells and incorporated into lysosomes. Conditions such as Gaucher disease and Fabry disease are routinely treated using **enzyme replacement,** and similar therapies are being developed for other lysosomal disorders.

Therapeutic advances are also being made in the treatment of nonmetabolic genetic disorders. Improvements in surgical techniques and intensive care medicine are extending the survival of children with life-threatening birth defects like congenital diaphragmatic hernia and severe cardiac defects. In many cases, the life expectancy of children with debilitating genetic disorders is also increasing. A good example is the increasing life expectancy of individuals with cystic fibrosis, largely owing to improvements in antibiotic therapy as well as the management of chronic pulmonary disease and malabsorption. A major consequence of these advances is that an increasing percentage of affected patients is surviving into adulthood, creating a need to transition care from pediatric to adult providers.

Gene-replacement therapies have long been anticipated. However, it has proved difficult to develop safe and effective approaches for inserting genes into diseased tissues in a way that allows physiologically meaningful levels of gene expression to be maintained over long periods. Stem cell-based therapies have also been touted as a potential treatment for a number of intractable disorders, but clear evidence that such therapies are effective has yet to materialize.

ETHICS ISSUES

Like all medical care, genetic testing, diagnosis, and treatment should be performed confidentially. Nothing is as personal as one's genetic information, and all efforts should be made to avoid any stigma for the patient. Many people fear that results of genetic testing will put them, or their child, at risk for genetic discrimination. Genetic discrimination occurs when people are treated unfairly because of a difference in their DNA that suggests that they have a genetic disorder or are at an increased risk of developing a certain disease. In the United States, the Genetic Information Nondiscrimination Act of 2008 protects individuals from genetic discrimination at the hands of health insurers and employers, but does not extend protection against discrimination from providers of life, disability, or long-term care insurance.

Like all medical decision-making, the decisions about genetic testing should be based on a careful evaluation of the potential benefits and risks. In the pediatric setting, these decisions may be more difficult because physicians and parents are often called on to make decisions for a child who cannot directly participate in discussions about the testing. Molecular diagnostic tests are often used to diagnose malformation syndromes, cognitive delay, or other disabilities wherein there is a clear benefit to the child. In other cases, such as genetic testing for susceptibility to adult-onset diseases, it is appropriate to wait until the child or adolescent is mature enough to weigh the pros and cons and make his or her own decisions about genetic testing.

Policies regarding genetic testing of children have been developed collaboratively by the American Academy of Pediatrics (AAP) and the American College of Medical Genetics and Genomics (ACMG; *Pediatrics* 131[3]:620-622, 2013). These recommendations are outlined here:

1. Decisions about whether to offer genetic testing and screening should be driven by the best interest of the child.
2. Genetic testing is best offered in the context of genetic counseling. Genetic counseling can be performed by clinical geneticists, genetic counselors, or any other health care provider with appropriate training and expertise. The AAP and ACMG support the expansion of educational opportunities in human genomics and genetics for medical students, residents, and practicing pediatric primary care providers.

Diagnostic Testing

3. In a child with symptoms of a genetic condition, the rationale for genetic testing is similar to that of other medical diagnostic evaluations. Parents or guardians should be informed about the risks and benefits of testing, and their permission should be obtained. Ideally, and when appropriate, the assent of the child should be obtained.
4. When performed for therapeutic purposes, pharmacogenetic testing of children is acceptable, with permission of parents or guardians and, when appropriate, the child's assent. If a pharmacogenetic test result carries implications beyond drug targeting or dose-responsiveness, the broader implications should be discussed before testing.

Newborn Screening

5. The AAP and ACMG support the mandatory offering of newborn screening for all children. After education and counseling about the substantial benefits of newborn screening, its remote risks, and the next steps in the event of a positive screening result, parents should have the option of refusing the procedure, and an informed refusal should be respected.

Carrier Testing

6. The AAP and ACMG do not support routine carrier testing in minors when such testing does not provide health benefits in childhood. The AAP and ACMG advise against school-based testing or screening programs, because the school environment is unlikely to be conducive to voluntary participation, thoughtful consent, privacy, confidentiality, or appropriate counseling about test results.
7. For pregnant adolescents or for adolescents considering reproduction, genetic testing and screening should be offered as clinically indicated, and the risks and benefits should be explained clearly.

Predictive Genetic Testing

8. Parents or guardians may authorize predictive genetic testing for asymptomatic children at risk of childhood-onset conditions. Ideally, the assent of the child should be obtained.
9. Predictive genetic testing for adult-onset conditions generally should be deferred unless an intervention initiated in childhood may reduce morbidity or mortality. An exception might be made for families for whom diagnostic uncertainty poses a significant psychosocial burden, particularly when an adolescent and his or her parents concur in their interest in predictive testing.
10. For ethical and legal reasons, healthcare providers should be cautious about providing predictive genetic testing to minors without the involvement of their parents or guardians, even if a minor is mature. Results of such tests may have significant medical, psychological, and social implications, not only for the minor but also for other family members.

Histocompatibility Testing

11. Tissue compatibility testing of minors of all ages is permissible to benefit immediate family members but should be conducted only after thorough exploration of the psychosocial, emotional, and physical implications of the minor serving as a potential stem cell donor. A donor advocate or similar mechanism should be in place from the outset to avert coercion and safeguard the interests of the child.

Adoption

12. The rationale for genetic testing of children in biological families should apply for adopted children and children awaiting placement for adoption. If a child has a known genetic risk, prospective adoptive parents must be made aware of this possibility. In rare cases, it may be in a child's best interest to undergo predictive genetic testing for a known risk before adoption to ensure the child's placement with a family capable of and willing to accept the child's potential medical and developmental challenges. In the absence of such indications, genetic testing should not be performed as a condition of adoption.

Disclosure

13. At the time of genetic testing, parents or guardians should be encouraged to inform their child of the test results at an appropriate age. Parents or guardians should be advised that, under most circumstances, a request by a mature adolescent for test results should be honored.
14. Results from genetic testing of a child may have implications for the parents and other family members. Healthcare providers have an obligation to inform parents and the child, when appropriate, about these potential implications. healthcare providers should encourage patients and families to share this information and offer to help explain the results to the extended family or refer them for genetic counseling.
15. Misattributed paternity, use of donor gametes, adoption, or other questions about family relationships may be uncovered "incidentally" whenever genetic testing is performed, particularly when testing multiple family members. This risk should be discussed, and a plan about disclosure or nondisclosure should be in place before testing.

Direct-to-Consumer Testing

16. The AAP and ACMG strongly discourage the use of direct-to-consumer and home-kit genetic testing of children because of the lack of oversight on test content, accuracy, and interpretation.

Chapter 79

The Human Genome

Daryl A. Scott and Brendan Lee

The Human Genome Project, culminated in the sequencing of the human genome and greatly expanded our ability to study human genes and to explore the roles of genes in both rare and common disorders. Over time, it has also become apparent that the genome includes far more than a coded store of information to produce proteins.

The human genome has approximately 25,000 genes that encode the wide variety of proteins found in the human body. Reproductive or germline cells contain 1 copy (N) of this genetic complement and are **haploid,** whereas somatic (nongermline) cells contain 2 complete copies (2N) and are **diploid.** Genes are organized into long segments of DNA, which, during cell division, are compacted into intricate structures together with proteins to form chromosomes. Each somatic cell has 46 chromosomes: 22 pairs of autosomes, or nonsex chromosomes, and 1 pair of sex chromosomes (XY in a male, XX in a female). Germ cells (ova or sperm) contain 22 autosomes and 1 sex chromosome, for a total of 23. At fertilization, the full diploid chromosome complement of 46 is again realized in the embryo.

Most of the genetic material is contained in the cell's nucleus. The mitochondria (the cell's energy-producing organelles) contain their own unique genome. The **mitochondrial chromosome** consists of a double-stranded circular piece of DNA, which contains 16,568 base pairs (bp) of DNA and is present in multiple copies per cell. The proteins that occupy the mitochondria are produced either in the mitochondria, using information contained in the mitochondrial genome, or are produced outside of the mitochondria, using information contained in the nuclear genome and transported into the organelle. Sperm do not usually contribute mitochondria to the developing embryo, so all mitochondria are maternally derived and a child's mitochondrial genetic makeup derives exclusively from the child's biological mother.

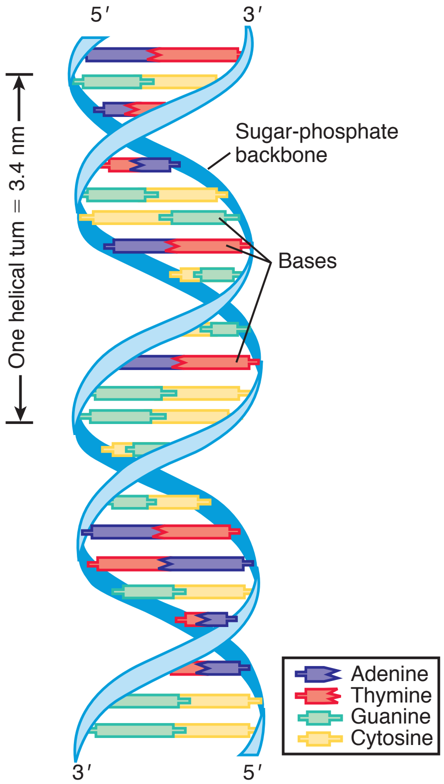

Figure 79-1 DNA double helix, with sugar-phosphate backbone and nitrogenous bases. *(From Jorde LB, Carey JC, Bamshad MJ, et al, editors:* Medical genetics, *ed 2, St. Louis, 1999, Mosby, p. 8.)*

FUNDAMENTALS OF MOLECULAR GENETICS

The central tenet of molecular genetics is that information encoded in DNA, predominantly located in the cell nucleus, is transcribed into messenger RNA (mRNA), which is then transported to the cytoplasm, where it is translated into protein. A gene is a unit that includes a regulatory region and a coding region that stores information corresponding to the sequence of amino acids in a specific protein.

DNA consists of a pair of chains of a sugar-phosphate backbone linked by pyrimidine and purine bases to form a **double helix** (Fig. 79-1). The sugar in DNA is deoxyribose. The pyrimidines are cytosine (C) and thymine (T); the purines are guanine (G) and adenine (A). The bases are linked by hydrogen bonds such that A always pairs with T and G with C. Each strand of the double helix has polarity, with a free phosphate at one end (5′) and an unbonded hydroxyl on the sugar at the other end (3′). The 2 strands are oriented in opposite polarity in the double helix.

The replication of DNA follows the pairing of bases in the parent DNA strand. The original 2 strands unwind by breaking the hydrogen bonds between base pairs. Free nucleotides, consisting of a base attached to a sugar-phosphate, form new hydrogen bonds with their complementary bases on the parent strand; new phosphodiester bonds are created by the enzyme **DNA polymerase.** Replication of chromosomes begins simultaneously at multiple sites, forming replication bubbles that expand bidirectionally until the entire DNA molecule (chromosome) is replicated. Errors in DNA replication, or mutations induced by environmental mutagens such as irradiation or chemicals, are detected and potentially corrected by DNA repair systems.

A prototypical gene consists of a regulatory region, segments called **exons** that encode the amino acid sequence of a protein, and intervening segments called **introns** (Fig. 79-2). **Transcription** starts at the promoter region and continues through the entire length of the gene to form mRNA. The introns are removed and the exons spliced together to form a mature message, which is exported to the cytoplasm. There the mRNA is bound to ribosomes and translated into protein.

Transcription is initiated by attachment of RNA polymerase to the promoter site upstream of the beginning of the coding sequence. Specific proteins bind to the region to either repress or activate transcription by opening up the chromatin, which is a complex of DNA and histone proteins. It is the action of these regulatory proteins **(transcription factors)** that determines, in large part, when a gene is turned on or off. Some genes are also turned on and off by methylation of cytosine bases that are adjacent to guanines (CpG [cytosine-phosphate-guanine] bases). Methylation is an example of an **epigenetic** change, meaning a change that can affect gene expression, and possibly the characteristics of a cell or organism, but that does not involve a change in the underlying genetic sequence. Gene regulation is flexible and responsive, with genes being turned on or off during development and in response to internal and external environmental conditions and stimuli.

Transcription proceeds through the full length of the gene, synthesizing mRNA in a 5′ to 3′ direction. RNA, like DNA, is a sugar-phosphate chain with pyrimidines and purines. In RNA, the sugar is ribose and uracil replaces the thymine found in DNA. The RNA reads off 1 strand of DNA to copy a complementary RNA sequence. A "cap" consisting of 7-methylguanosine is added to the 5′ end of the RNA in a 5′-5′ bond and, for most transcripts, several hundred adenine bases are enzymatically added to the 3′ end after transcription.

mRNA **processing** occurs in the nucleus and consists of excision of the introns and splicing together of the exons. Specific sequences at the start and end of introns mark the sites where the splicing machinery will act on the transcript. In some cases, there may be tissue-specific

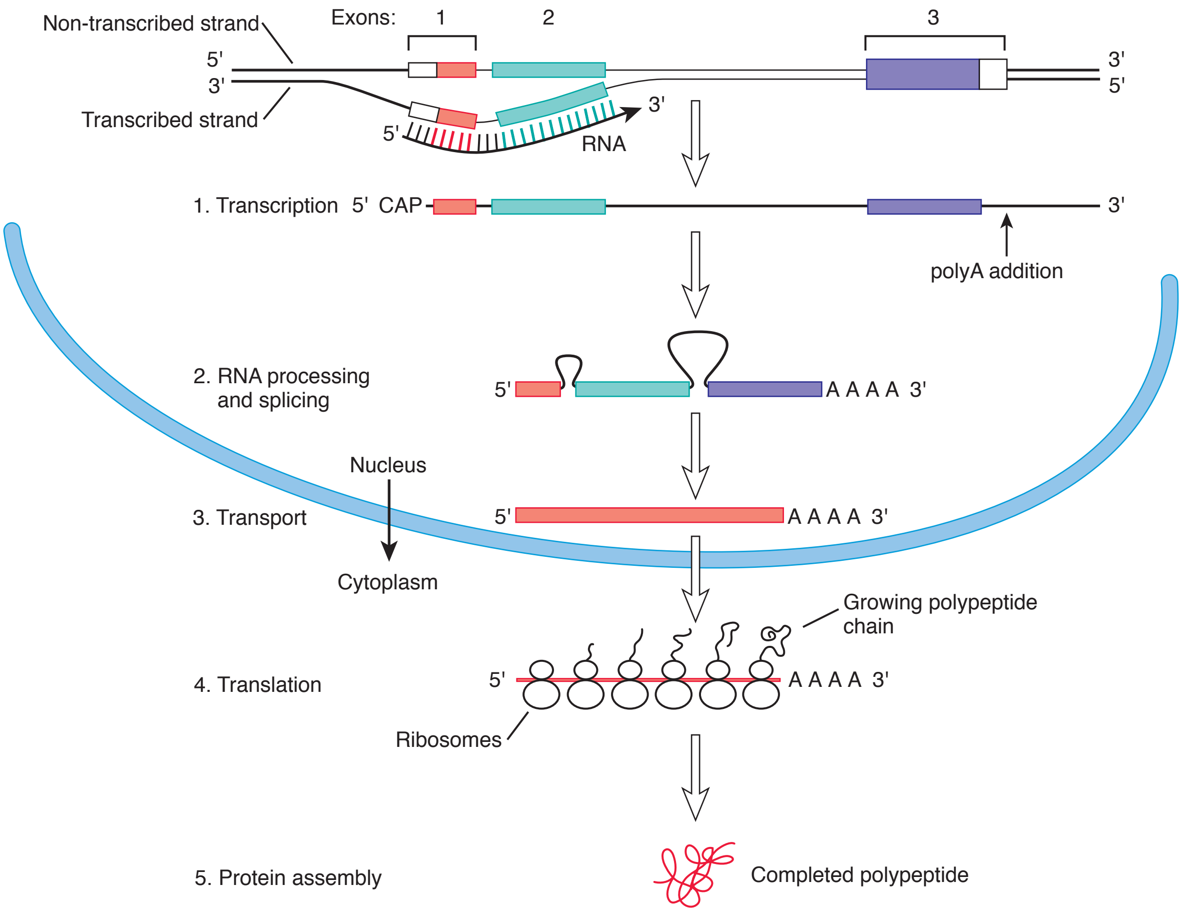

Figure 79-2 **Flow of information from DNA to RNA to protein for a hypothetical gene with three exons and two introns.** Within the exons, blue indicates the coding sequences. Steps include transcription, RNA processing and splicing, RNA transport from the nucleus to the cytoplasm, and translation. *(From Nussbaum RL, McInnis RR, Willard HF, Hamosh A, editors:* Thompson & Thompson genetics in medicine, *ed 7, Philadelphia, 2007, Saunders/Elsevier,* Fig 3.5, *p. 31.)*

patterns to splicing, so that the same primary transcript can produce multiple distinct proteins.

The processed transcript is next exported to the cytoplasm, where it binds to ribosomes, which are complexes of protein and RNA. The genetic code is then read in triplets of bases, each triplet corresponding with a specific amino acid or providing a signal that terminates **translation.** The triplet codons are recognized by transfer RNAs that include complementary anticodons and bind the corresponding amino acid, delivering it to the growing peptide. A new amino acid is enzymatically attached to the peptide; each time an amino acid is added, the ribosome moves one triplet codon step along the mRNA. Eventually a stop codon is reached, at which point translation ends and the peptide is released. In some proteins, there are **posttranslational modifications,** such as attachment of sugars (glycosylation); the protein is then delivered to its destination within or outside the cell by trafficking mechanisms that recognize portions of the peptide.

An emerging layer of complexity and genetic regulation is that of noncoding RNAs. This refers to RNAs that are transcribed from DNA but are not translated into proteins. Noncoding RNAs function in mediating splicing and the processing of coding RNAs in the nucleus and the translation of coding RNAs in ribosomes. The roles of large noncoding RNAs (>200 bp) and short noncoding RNAs (<200 bp) extend beyond these processes to impact a diverse set of biologic functions including regulation of gene expression. For example, microRNAs (miRNAs) are a class of small RNAs that control gene expression in the cell by directly targeting specific sets of coding RNAs by direct RNA–RNA binding. This RNA–RNA interaction can lead to degradation of the target coding RNA or inhibition of translation of the protein specified by that coding RNA. miRNAs, in general, target and regulate several hundred mRNAs.

GENETIC VARIATION

The process of producing protein from a gene is subject to disruption at multiple levels owing to alterations in the coding sequence (Fig. 79-3). Changes in the regulatory region can lead to altered gene expression, including increased or decreased rates of transcription, failure of gene activation, or activation of the gene at inappropriate times or in inappropriate cells. Changes in the coding sequence can lead to **substitution** of one amino acid for another **(missense mutation** or **nonsynonymous)** or creation of a stop codon in the place of an amino acid codon. Overall, missense or nonsense mutations are the most common (~56% of mutations); small deletions or insertions represent approximately 24% of mutations (Table 79-1). Some single-base changes do not affect the amino acid (silent or wobble mutation or synonymous), because there may be several triplet codons that correspond with a single amino acid. Amino acid substitutions can have a profound effect on protein function if the chemical properties of the substituted amino acid are markedly different from the usual one. Other substitutions can have a subtle or no effect on protein function, particularly if the substituted amino acid is chemically similar to the original one.

Genetic changes can also include **insertions** or **deletions.** Insertions or deletions of a nonintegral multiple of 3 bases into the coding sequence leads to a **frameshift,** altering the grouping of bases into triplets. This leads to translation of an incorrect amino acid sequence and often a premature stop to translation. Insertion or deletion of an

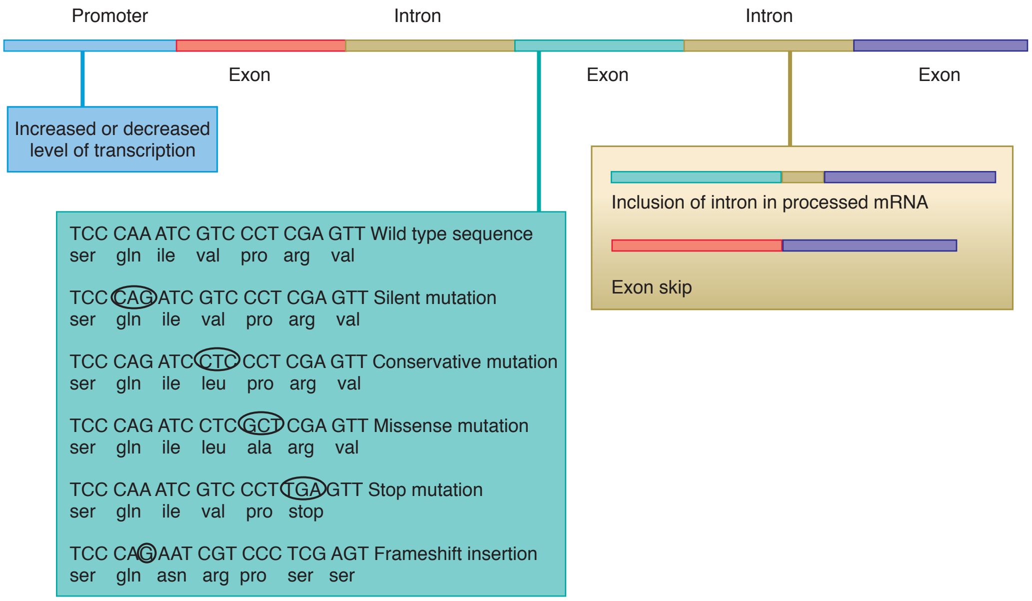

Figure 79-3 **Various types of intragenic mutations.** Promoter mutations alter rate of transcription or disrupt gene regulation. Base changes within exons can have various effects, as shown. Mutations within introns can lead to inclusion of some intronic sequence in the final processed mRNA, or it can lead to exon skipping.

Table 79-1 Main Classes, Groups, and Types of Mutation and Effects on Protein Product

CLASS	GROUP	TYPE	EFFECT ON PROTEIN PRODUCT
Substitution	Synonymous	Silent*	Same amino acid
	Nonsynonymous	Missense*	Altered amino acid—may affect protein function or stability
		Nonsense*	Stop codon—loss of function or expression from degradation of mRNA
		Splice site	Aberrant splicing—exon skipping or intron retention
		Promoter	Altered gene expression
Deletion	Multiple of 3 (codon)		In-frame deletion of 1 or more amino acid(s)—may affect protein function or stability
	Not multiple of 3	Frameshift	Likely to result in premature termination with loss of function or expression
	Large deletion	Partial gene deletion	May result in premature termination with loss of function or expression
		Whole gene deletion	Loss of expression
Insertion	Multiple of 3 (codon)		In-frame insertion of 1 or more amino acid(s)—may affect protein function or stability
	Not multiple of 3	Frameshift	Likely to result in premature termination with loss of function or expression
	Large insertion	Partial gene duplication	May result in premature termination with loss of function or expression
		Whole gene duplication	May have an effect because of increased gene dosage
	Expansion of trinucleotide repeat	Dynamic mutation	Altered gene expression or altered protein stability or function

*Some have been shown to cause aberrant splicing.
From Turnpenny P, Ellard S (Editors): Emery's elements of medical genetics, *ed 14, Philadelphia, 2012, Elsevier/Churchill Livingstone, Table 2.2, p. 23.*

integral multiple of 3 bases into the coding sequence will insert or delete a corresponding number of amino acids from the protein leading to in-frame alterations that maintain the amino acid sequence outside of the deleted or duplicated amino acids. Larger-scale insertions or deletions can disrupt a coding sequence or result in complete deletion of an entire gene or group of genes.

Mutations usually can be classified as causing a loss of function or a gain of function. **Loss-of-function mutations** cause a reduction in the level of protein function as a result of decreased expression or production of a protein that does not work as efficiently. In some cases, loss of protein function from one gene is sufficient to cause disease. **Haploinsufficiency** describes the situation in which maintenance of a normal phenotype requires the proteins produced by both copies of a gene, and a 50% decrease in gene function results in an abnormal phenotype. Hence, haploinsufficient phenotypes are, by definition, dominantly inherited. Loss-of-function mutations can also have a dominant negative effect when the abnormal protein product actively interferes with the function of the normal protein product. Both of these situations lead to diseases inherited in a dominant fashion (see Chapter 80). In other cases, loss-of-function mutation must be present in both copies of a gene before an abnormal phenotype results. This situation typically results in diseases inherited in a recessive fashion (see Chapter 80).

Gain-of-function mutations typically cause dominantly inherited diseases. These mutations can result in production of a protein molecule with an increased ability to perform a normal function or they

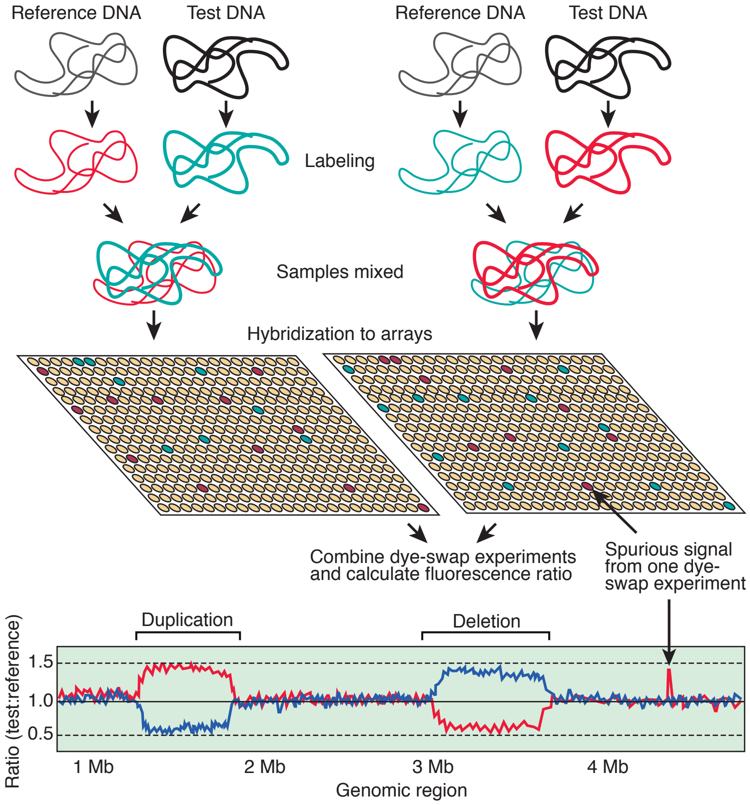

Figure 79-4 **Array comparative genomic hybridization.** Test and reference DNA samples are differentially labeled, mixed, and passed over a target array of probes (e.g., bacterial artificial chromosome clones or oligonucleotides) containing DNA fragments from across the whole human genome. The experiment is often repeated with reversal of the test and reference dyes to detect dye effects or identify spurious signals. DNA samples hybridize with their corresponding probe, and the ratio of fluorescence from each probe (test:reference) is used to detect regions that vary in copy number between the test and the reference sample (*red line:* original hybridization; *blue line:* dye-swapped hybridization). Equal copy number for both the test and reference DNA is identified by equal binding, resulting in a ratio of 1:1. Duplication in a genomic region of the test sample is identified by an increased ratio, and a deletion is identified by a decreased ratio, but a deletion in the test sample is indistinguishable from a duplication in the reference sample. These ratios are usually converted to log2 scale for further analysis. *(Adapted from Feuk L, Carson AR, Scherer SW: Structural variation in the human genome,* Nat Rev Genet *7:85–97, 2006, with permission from* Nature Reviews Genetics.*)*

can confer a novel property on the protein. The gain-of-function mutation in **achondroplasia,** the most common of the disproportionate, short-limbed short stature disorders, exemplifies the enhanced function of a normal protein. Achondroplasia results from a mutation in the fibroblast growth factor receptor 3 gene (*FGFR3*), which leads to activation of the receptor, even in the absence of fibroblast growth factor. In **sickle cell disease,** an amino acid is substituted into the hemoglobin molecule that has little effect on the ability of the protein to transport oxygen. However, sickle hemoglobin chains have a novel property. Unlike normal hemoglobin, sickle hemoglobin chains aggregate under conditions of deoxygenation, forming fibers that deform the red cells.

Other gain-of-function mutations result in overexpression or inappropriate expression of a gene product. Many cancer-causing genes **(oncogenes)** are normal regulators of cellular proliferation during development. However, expression of these genes in adult life and/or in cells in which they usually are not expressed can result in neoplasia.

In some cases, changes in gene expression are caused by changes in the number of copies of a gene that are present in the genome (Fig. 79-4). Although some **copy number variations** are common and do not appear to cause or predispose to disease, others are clearly disease causing. Charcot-Marie-Tooth disease type 1A, the most common inherited form of chronic peripheral neuropathy of childhood, is caused by duplications of the gene for peripheral myelin protein 22, resulting in overexpression as a consequence of the existence of 3 active copies of this gene. Deletions of this same gene leaving only 1 active copy are responsible for a different disorder, hereditary neuropathy with liability to pressure palsies.

Deletions and duplications can vary in their extent and can involve several genes, even when they are not visible on a traditional chromosome analysis. Such changes are commonly called **microdeletions** and **microduplications.** When deletion or duplication of 2 or more genes in the same chromosomal region each play a role in the resulting clinical features, the condition can also be referred to as a **contiguous gene disorder**.

In some cases the recognition of a specific constellation of features leads the clinician to suspect a specific microdeletion or microduplication syndrome. Examples of such disorders include Smith-Magenis, DiGeorge, and Williams syndromes. In other cases, the clinician may be alerted to this possibility by an unusually diverse array of clinical features in one patient or the presence of unusual features in a person with a known condition. Owing to the close physical proximity of a series of genes, different deletions involving the short arm of the X chromosome can produce individuals with various combinations of ichthyosis, Kallmann syndrome, ocular albinism, intellectual disability, chondrodysplasia punctata, and short stature.

DNA rearrangements can also take place in somatic cells-meaning cells that do not go on to produce ova or sperm. Rearrangements that occur in lymphoid cells are required for the formation of functional immunoglobulin in B cells and antigen-recognizing receptors on T cells. Large segments of DNA, which code for the variable and the constant regions of either immunoglobulin or the T-cell receptor, are physically joined at a specific stage in the development of an immunocompetent lymphocyte. These rearrangements take place during development of the lymphoid cell lineage in humans and result in the extensive diversity of immunoglobulin and T-cell receptor molecules. It is as a result of this postgermline DNA rearrangement that no 2 individuals, not even identical twins, are really identical, because mature lymphocytes from each will have undergone random DNA rearrangements at these loci.

Studies of the human genome sequence reveal that any 2 individuals differ in about 1 base in 1,000. Some of these differences are silent; some result in changes that explain phenotypic differences (hair or eye color, physical appearance); some have medical significance, causing single-gene disorders such as sickle cell anemia or explaining susceptibility to common pediatric disorders such as asthma. Genetic variants in a single gene that occur at a frequency of >1% in a population are often referred to as **polymorphisms.** These variations may be silent or subtle or have significant phenotypic effects.

GENOTYPE-PHENOTYPE CORRELATIONS IN GENETIC DISEASE

The term **genotype** is used to signify the internally coded, heritable information of an individual and can also be used to refer to which particular alternative version **(allele)** of a gene is present at a specific location **(locus)** on a chromosome. A **phenotype** is the observed structural, biochemical, and physiologic characteristics of an individual, determined by the genotype, and can also refer to the observed structural and functional effects of a mutant allele at a specific locus. Many mutations result in predictable phenotypes. In these cases, physicians can predict clinical outcomes and plan appropriate treatment strategies based on a patient's genotype.

The **long QT syndrome** exemplifies a disorder with predictable associations between a patient's genotype and his or her phenotype (see Chapter 435.5). Long QT syndrome is genetically heterogeneous, meaning that mutations in several different genes can cause the same disorder. The risk for cardiac events (syncope, aborted cardiac arrest, or sudden death) is higher with long QT syndrome mutations involving the *KCNQ1* gene (63%) or the *KCNH2* gene (46%) than among subjects with mutations in the *SCN5A* gene (18%). In addition, those with mutations involving *KCNQ1* experience most of their episodes during exercise and rarely during rest or sleep. In contrast, individuals with mutations in *KCNH2* and *SCN5A* are more likely to have episodes during sleep or rest, and rarely during exercise. Therefore, mutations in specific genes (genotype) are correlated with specific manifestations (phenotype) of long QT syndrome. These types of relationships are commonly referred to as *genotype–phenotype correlations.*

Mutations in the fibrillin-1 gene associated with **Marfan syndrome** represent another example of predictable genotype–phenotype correlations (see Chapter 702). Marfan syndrome is characterized by the combination of skeletal, ocular, and aortic manifestations, with the most devastating outcome being aortic root dissection and sudden death. Sixty-five exons make up the fibrillin-1 gene, and mutations have been found in almost all of these exons. The location of the mutation within the gene (genotype) might play a significant role in determining the severity of the condition (phenotype). Neonatal Marfan syndrome is caused by mutations in exons 24-27 and in exons 31 and 32, whereas milder forms are caused by mutations in exons 59-65 and in exons 37 and 41.

Genotype–phenotype correlations have also been observed in some complications of **cystic fibrosis** (CF; see Chapter 403). Although pulmonary disease is the major cause of morbidity and mortality, CF is a multisystem disorder that affects not only the epithelia of the respiratory tract but also the exocrine pancreas, intestine, male genital tract, hepatobiliary system, and exocrine sweat glands. CF is caused by mutations in the CF transmembrane conductance regulator (*CFTR*) gene. More than 1,600 different mutations have been identified. The most common is a deletion of 3 nucleotides that removes the amino acid phenylalanine (F) at the 508th position on the protein (ΔF508 mutation), which accounts for approximately 70% of all CF mutations and is associated with severe disease. The best genotype–phenotype correlations in CF are seen in the context of pancreatic function, with most common mutations being classified as either pancreatic sufficient or pancreatic insufficient. Persons with pancreatic sufficiency usually have either 1 or 2 pancreatic-sufficient alleles, indicating that pancreatic-sufficient alleles are dominant. In contrast, the genotype–phenotype correlation in pulmonary disease is much weaker, and persons with identical genotypes have wide variations in the severity of their pulmonary disease. This finding may be accounted for in part by genetic modifiers or environmental factors.

There are many disorders in which the effects of mutations on phenotype can be modified by changes in the other allele of the same gene, by changes in specific **modifier genes,** and/or variations in a number of unspecified genes **(genetic background).** When sickle cell anemia is coinherited with the gene for hereditary persistence of fetal hemoglobin, the sickle cell phenotypic expression is less severe. Modifier genes in CF can influence the development of congenital meconium ileus, or colonization with *Pseudomonas aeruginosa.* Modifier genes can also affect the manifestations of Hirschsprung disease, neurofibromatosis type 2, craniosynostosis, and congenital adrenal hyperplasia. The combination of genetic mutations producing glucose-6-phosphate dehydrogenase deficiency and longer versions of the TATAA element in the uridine diphosphate–glucuronosyltransferase gene promoter exacerbates neonatal physiologic hyperbilirubinemia.

HUMAN GENOME PROJECT

A rudimentary genetic map can be made using genetic linkage, which is based on the principle that alleles at 2 genetic loci that are located near each other segregate together in a family unless they are separated by genetic **recombination.** The frequency of recombination between the loci can be used to estimate the physical distance between points. Some of the first maps of the human genome were linkage maps based on a set of polymorphic genetic loci located along the entire human genome. Linkage analysis is still used to map the location of genetic changes responsible for phenotypic traits and genetic disorders that are inherited in a mendelian fashion.

In contrast to linkage maps, which are based on recombination frequencies, physical maps rely on overlapping DNA fragments to determine the location of loci with respect to one another. Several strategies can be used to create physical maps of a chromosomal region. In one strategy, segments of the region of interest with lengths from hundreds or thousands to a few million base pairs are isolated and placed in microorganisms such as bacteria or yeast. Common regions contained in different organism can then be identified and this information can be used to piece together a map composed of overlapping DNA pieces, each contained in a different microorganism. The pieces contained in each organism can then be sequenced to obtain the DNA sequence of the entire region. An alternative strategy involves breaking the entire genome into random fragments, sequencing the fragments, and then using a computer to order the fragments based on overlapping segments. This whole genome approach in combination with new next-generation sequencing technologies has resulted in a dramatic reduction in the cost of sequencing an individual's entire genome.

Analysis of the human genome has produced some surprising results. The number of genes is still not known precisely but appears to be around 25,000. This is fewer than had been expected and in the same range as many simpler organisms. The number of protein products encoded by the genome is greater than the number of genes. This is a result of the presence of alternative promoter regions, alternative splicing, and posttranslational modifications, which can allow a single gene to encode a number of protein products.

It is also apparent that most of the human genome does not encode protein, with <5% being transcribed and translated, though a much larger percentage may be transcribed without translation. Many transcribed sequences are not translated but represent genes that encode RNAs that serve a regulatory role. A large fraction of the genome consists of repeated sequences that are interspersed among the genes. Some of these are transposable genetic elements that can move from place to place in the genome. Others are static elements that were expanded and dispersed in the past during human evolution. Other repeated sequences might play a structural role. There are also regions of genomic duplications. Such duplications are substrate for evolution, allowing genetic motifs to be copied and modified to serve new roles in the cell. Duplications can also play a role in chromosomal rearrangement, permitting nonhomologous chromosome segments to pair during meiosis and exchange material. This is another source of evolutionary change and a potential source of chromosomal instability leading to congenital anomalies or cancer. Low copy repeats also play an important role in causing genomic disorders. When low copy repeats flank unique genomic segments, these regions can be duplicated or deleted through a process known as *nonallelic homologous recombination.*

Availability of the entire human genomic sequence permits the study of large groups of genes, looking for patterns of gene expression or genome alteration. Microarrays permit the expression of thousands of genes to be analyzed on a small glass chip. Increasingly, studies of gene expression are being performed using next generation sequencing

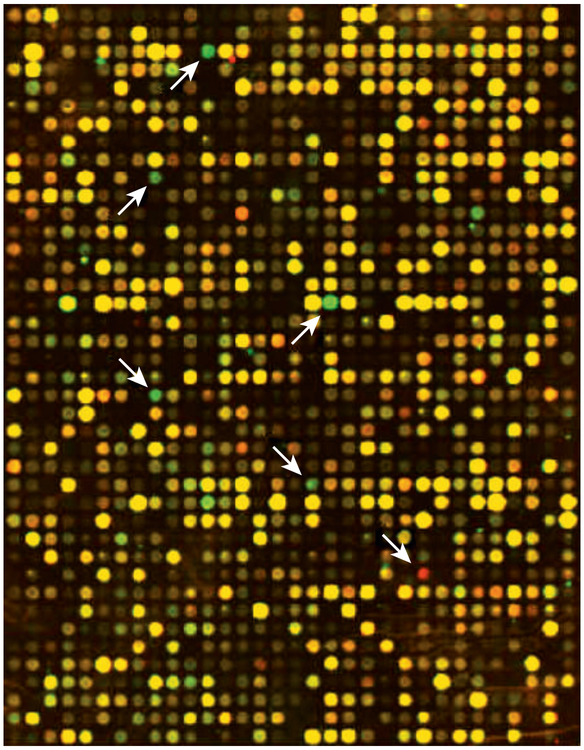

Figure 79-5 Microarray containing 36,000 oligonucleotides. The microarray was exposed to RNA from normal fibroblasts (labeled in *red*; see *arrows*) and fibroblasts from a patient with Niemann-Pick disease, type C (labeled *green*). Arrows point to regions in which there was a strong hybridization signal with either normal or disease RNA. This microarray was used to search for genes that are highly expressed in the fibroblasts of patients. *(From Jorde LB, Carey JC, Bamshad MJ, et al, editors:* Medical genetics, *ed 3, St. Louis, 2006, Mosby, p. 116.)*

techniques to obtain information about all of the RNA transcripts in a tissue sample. In some cases the patterns of gene expression provide signatures for particular disease states, such as cancer, or change in response to therapy (Fig. 79-5).

Chapter 80

Patterns of Genetic Transmission

Daryl A. Scott and Brendan Lee

FAMILY HISTORY AND PEDIGREE NOTATION

The family history remains the most important screening tool for pediatricians in identifying a patient's risk for developing a wide range of diseases, from multifactorial conditions, such as diabetes and attention-deficit disorder, to single-gene disorders such as sickle cell anemia and cystic fibrosis. Through a detailed family history the physician can often ascertain the mode of genetic transmission and the risks to family members. Because not all familial clustering of disease is caused by genetic factors, a family history can also identify common environmental and behavioral factors that influence the occurrence of disease. The main goal of the family history is to identify genetic susceptibility, and the cornerstone of the family history is a systematic and standardized pedigree.

A **pedigree** provides a graphic depiction of a family's structure and medical history. It is important when taking a pedigree to be systematic and use standard symbols and configurations (Figs. 80-1 to 80-4) so that anyone can read and understand the information. In the pediatric setting, the **proband** is typically the child or adolescent who is being evaluated. The proband is designated in the pedigree by an arrow.

A 3 to 4–generation pedigree should be obtained for every new patient as an initial screen for genetic disorders segregating within the family. The pedigree can provide clues to the inheritance pattern of these disorders and can aid the clinician in determining the risk to the proband and other family members. The closer the relationship of the proband to the person in the family with the genetic disorder, the greater is the shared genetic complement. **First-degree** relatives, such as a parent, full sibling, or child, share ½ their genetic information on average; first cousins share ⅛. Sometimes the person providing the family history may mention a distant relative who is affected with a genetic disorder. In such cases a more extensive pedigree may be needed to identify the risk to other family members. For example, a history of a distant maternally related cousin with mental retardation caused by fragile X syndrome can still place a male proband at an elevated risk for this disorder.

MENDELIAN INHERITANCE

There are 3 classic forms of genetic inheritance: **autosomal dominant, autosomal recessive,** and **X-linked.** These are referred to as *mendelian inheritance forms,* after Gregor Mendel, the 19th-century monk whose experiments led to the laws of **segregation of characteristics, dominance,** and **independent assortment.** These remain the foundation of single-gene inheritance.

Autosomal Dominant Inheritance

Autosomal dominant inheritance is determined by the presence of 1 abnormal gene on 1 of the autosomes (chromosomes 1-22). Autosomal genes exist in pairs, with each parent contributing 1 copy. In an autosomal dominant trait, a change in 1 of the paired genes has an effect on the phenotype; this can refer to physical manifestations, behavioral characteristics, or differences detectable only through laboratory tests, even though the other copy of the gene is functioning correctly.

The pedigree for an autosomal dominant disorder (Fig. 80-5) demonstrates certain characteristics. The disorder is transmitted in a vertical (parent-to-child) pattern and can appear in multiple generations. This is illustrated by individual I.1 (see Fig. 80-5) passing on the changed gene to II.2 and II.5. An affected individual has a 50% (1 in 2) chance of passing on the deleterious gene in *each* pregnancy and, therefore, of having a child affected by the disorder. This is referred to as the **recurrence risk** for the disorder. Unaffected individuals (family members who do not manifest the trait) do not pass the disorder to their children. Males and females are equally affected. Although not a characteristic per se, the finding of male-to-male transmission essentially confirms autosomal dominant inheritance. Vertical transmission can also be seen with X-linked traits. However, because a father passes on his Y chromosome to a son, male-to-male transmission cannot be seen with an X-linked trait. Therefore, male-to-male transmission eliminates X-linked inheritance as a possible explanation. Although male-to-male transmission can occur with Y-linked genes as well, there are very few Y-linked disorders compared with thousands having the autosomal dominant inheritance pattern.

Although parent-to-child transmission is a characteristic of autosomal dominant inheritance, for many patients with an autosomal dominant disorder there is no history of an affected family member. There are several possible reasons: First, the patient may represent a **new mutation** that occurred in the DNA of the egg or sperm that came together to form that individual. Second, many autosomal dominant conditions demonstrate **incomplete penetrance,** meaning that not all individuals who carry the mutation have phenotypic manifestations. In a pedigree this can appear as a **skipped generation,** in which an

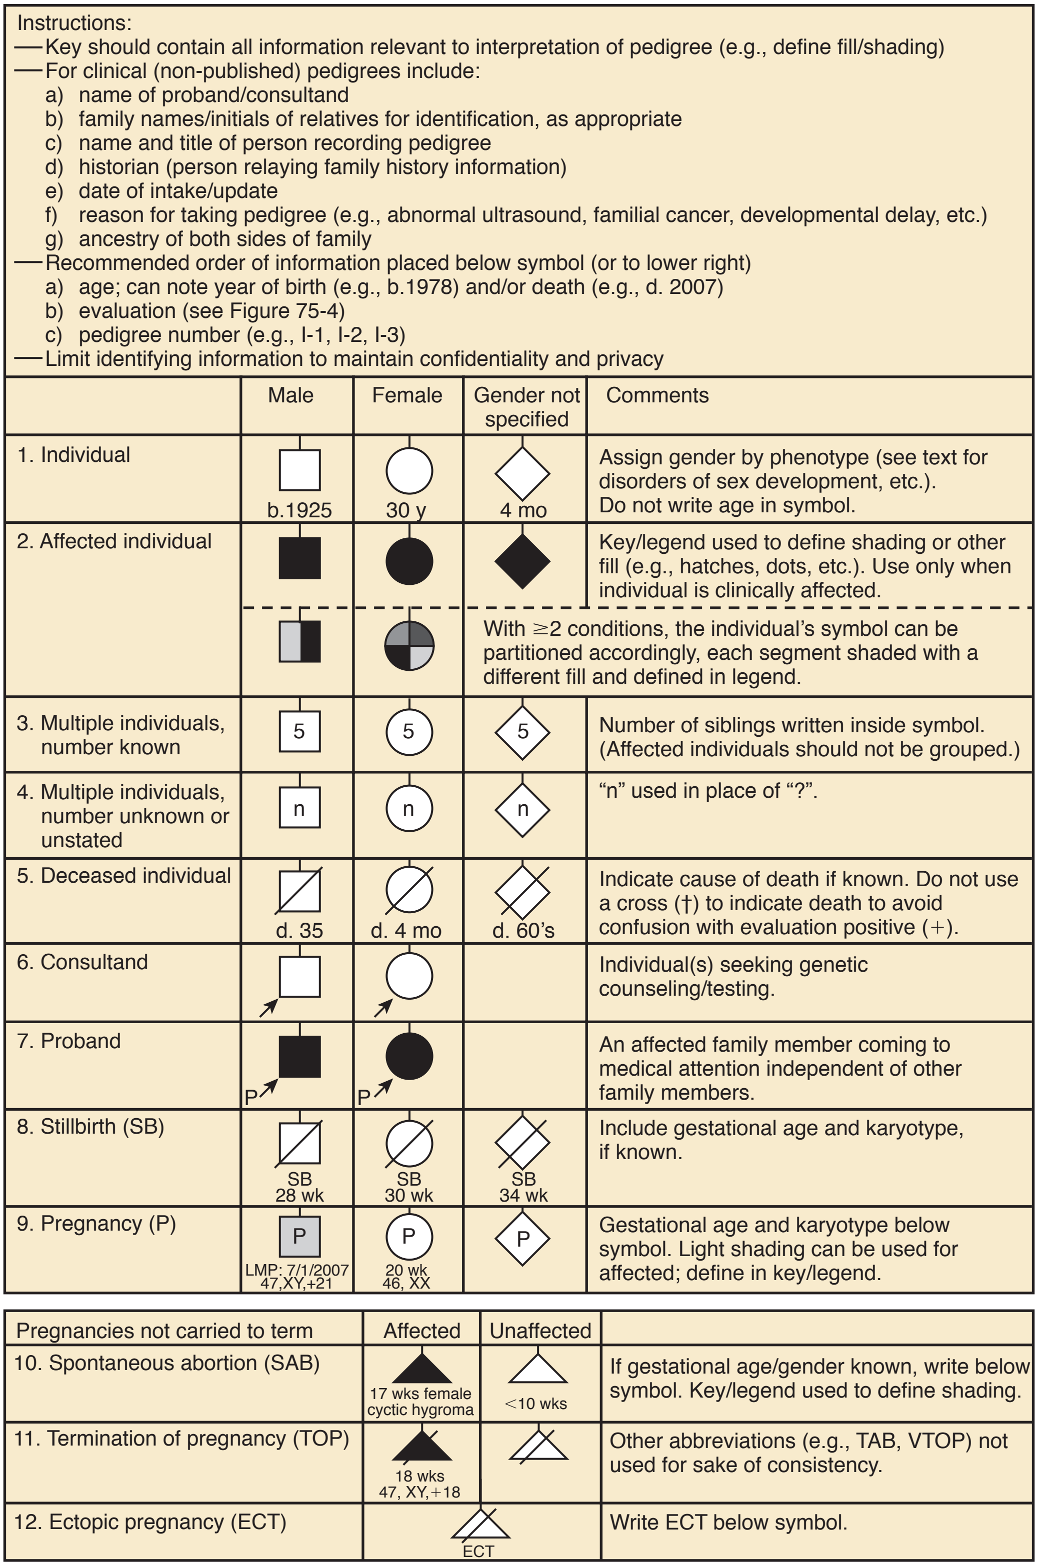

Figure 80-1 Common pedigree symbols, definitions, and abbreviations. *(From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors,* J Genet Couns *17:424–433, 2008.)*

unaffected individual links 2 affected persons (Fig. 80-6). There are many potential reasons that a disorder exhibits incomplete penetrance, including the effect of modifier genes, environmental factors, gender, and age. Third, individuals with the same autosomal dominant mutation can manifest the disorder to different degrees. This is termed **variable expression** and is a characteristic of many autosomal dominant disorders. Fourth, some spontaneous genetic mutations occur not in the egg or sperm that forms a child, but rather in a cell in the developing embryo. Such events are referred to as **somatic mutations,** and because not all cells are affected, the change is said to be *mosaic.* The

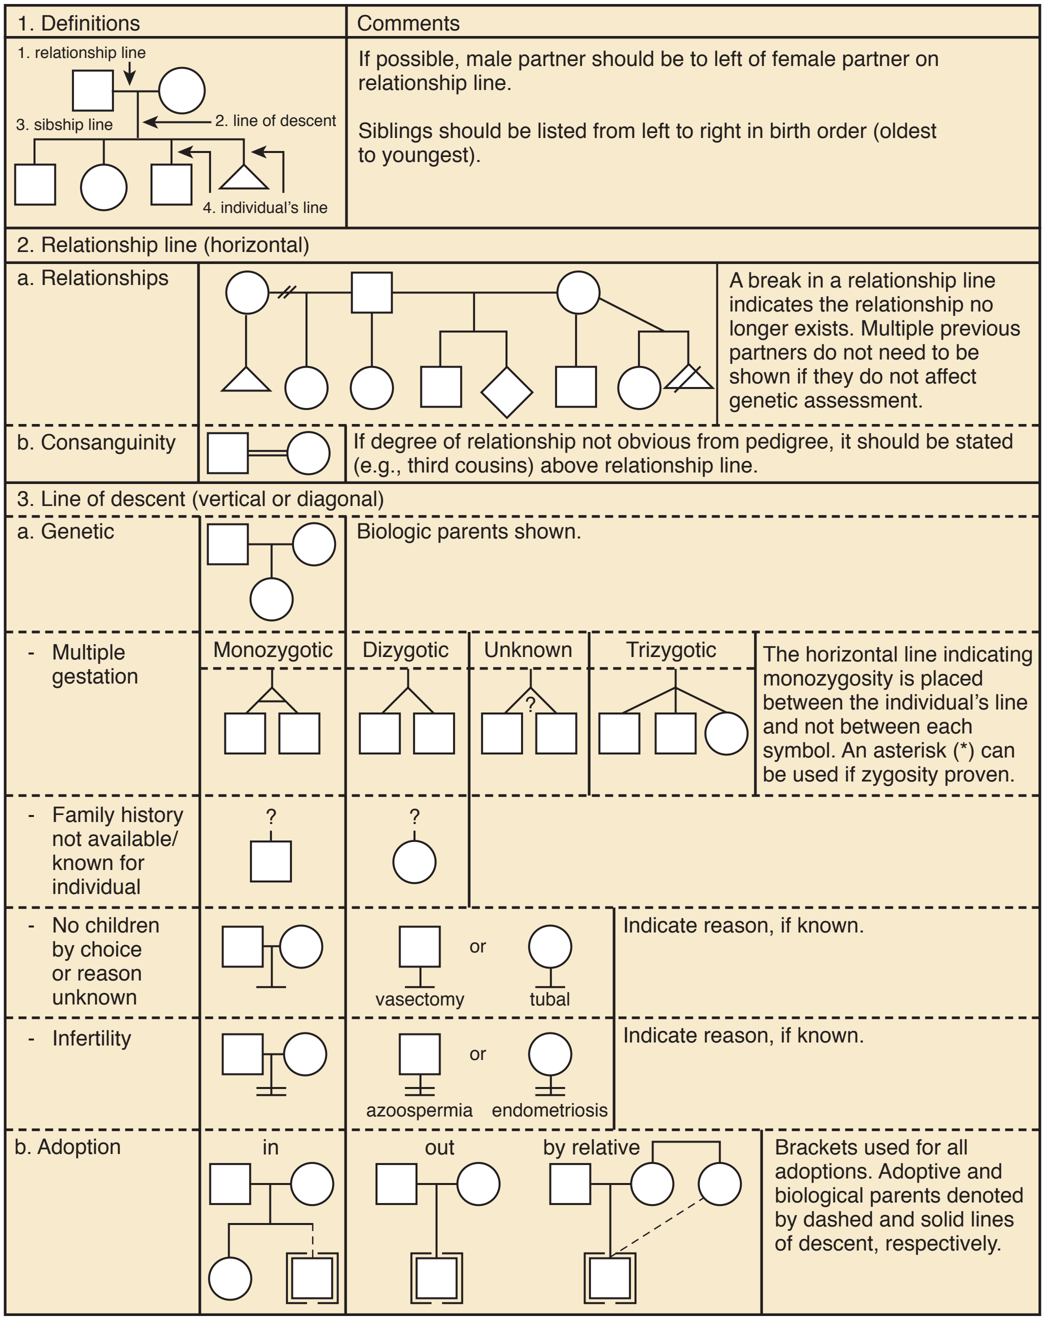

Figure 80-2 Pedigree line definitions. *(From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, J Genet Couns 17:424–433, 2008.)*

resulting phenotype caused by a somatic mutation can be varied, but it is usually milder than if all cells contain the mutation. In **germline mosaicism,** the mutation occurs in cells that populate the germline that produce eggs or sperm. A germline mosaic might not have any manifestations of the disorder but might produce multiple eggs or sperm that carry the mutation.

Autosomal Recessive Inheritance

Autosomal recessive inheritance involves mutations in both copies of a gene. Examples of autosomal recessive diseases are cystic fibrosis and sickle cell disease. Characteristics of autosomal recessive traits (Fig. 80-7) include **horizontal transmission,** the observation of multiple affected members of a kindred in the same generation, but no affected family members in other generations; recurrence risk of 25% for parents with a previous affected child; males and females being equally affected, although some traits exhibit different expression in males and females and increased incidence, particularly for rare traits, in the offspring of consanguineous parents. **Consanguinity** refers to the existence of a relationship by a common ancestor and increases the chance that both parents carry a gene affected by an identical mutation that they inherited. Consanguinity between parents of a child with a suspected genetic disorder implies (but does not prove) autosomal recessive inheritance. Although consanguineous unions are uncommon in Western society, in other parts of the world (southern India, Japan, and the Middle East) they are common; the incidence may be as high as 50%. The risk of a genetic disorder for the offspring of a first-cousin marriage (6-8%) is about double the risk in the general population (3-4%).

Every individual probably has several rare, harmful, recessive mutations. Because most mutations carried in the general population occur

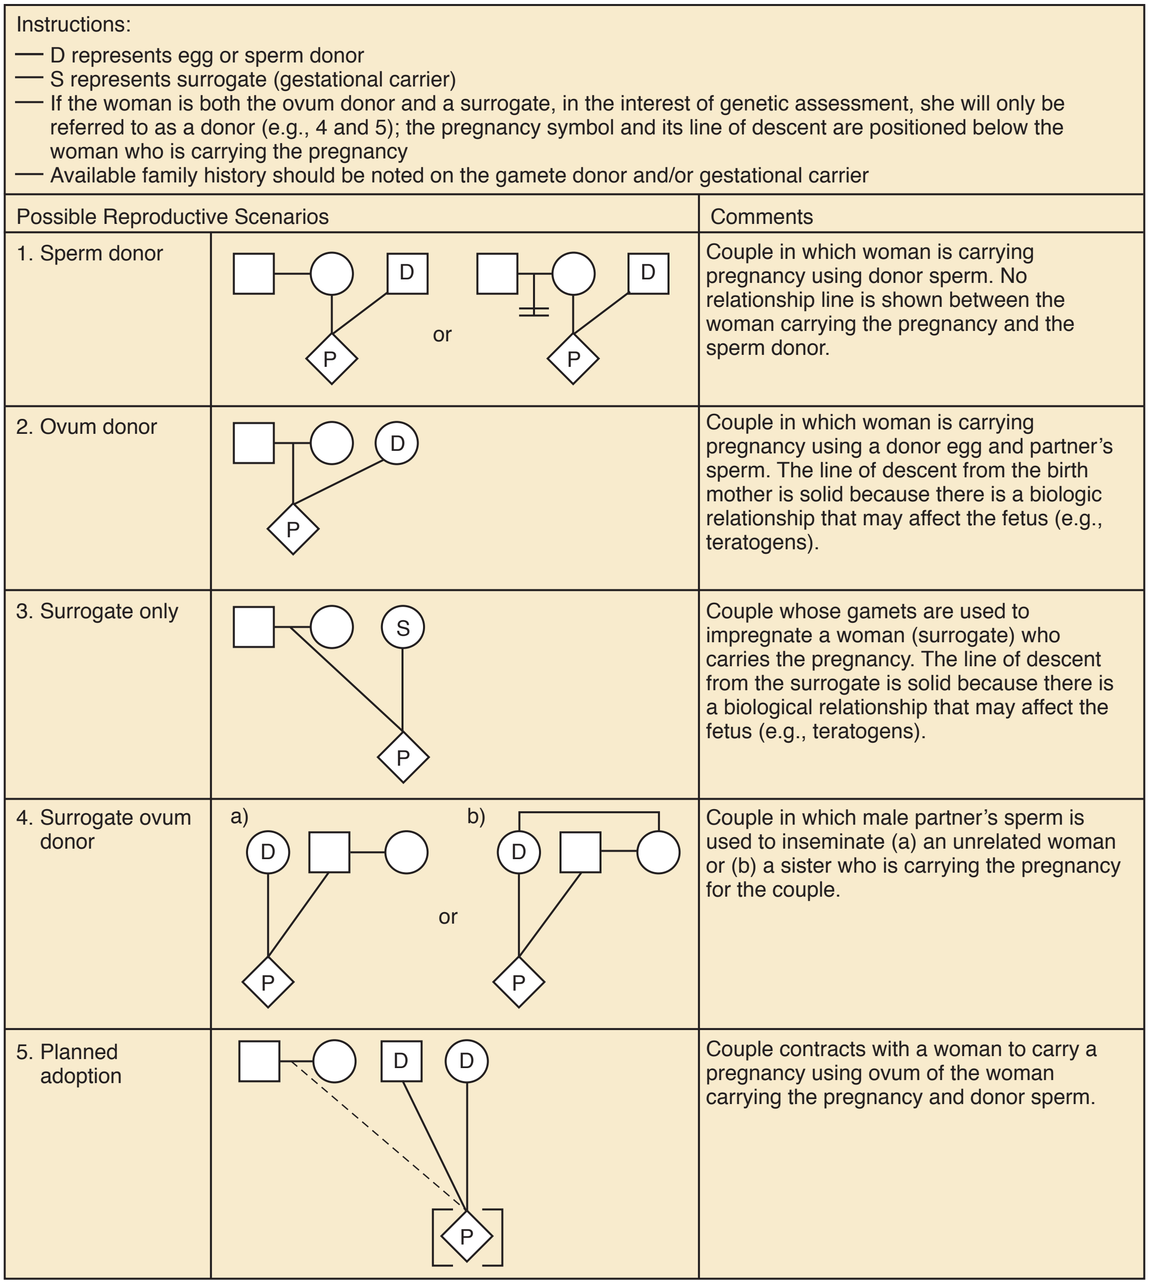

Figure 80-3 Assisted reproductive technology symbols and definitions. *(From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors,* J Genet Couns *17:424–433, 2008.)*

at a very low frequency, it does not make economic sense to screen the entire population in order to identify the small number of persons who carry these mutations. As a result, these mutations typically remain undetected unless an affected child is born to a couple who both carry mutations affecting the same gene.

However, in some genetic isolates (small populations separated by geography, religion, culture, or language) certain rare recessive mutations are far more common than in the general population. Even though there may be no known consanguinity, couples from these genetic isolates have a greater chance of sharing mutant alleles inherited from a common ancestor. Screening programs have been developed among some such groups to detect persons who carry common disease-causing mutations and therefore are at increased risk for having affected children. For example, a variety of autosomal recessive conditions are more common among Ashkenazi Jews than in the general population. Couples of Ashkenazi Jewish ancestry should be offered prenatal or preconception screening for Gaucher disease type 1 (carrier rate 1:14), cystic fibrosis (1:25), Tay-Sachs disease (1:25), familial dysautonomia (1:30), Canavan disease (1:40), glycogen storage disease type 1A (1:71), maple syrup urine disease (1:81), Fanconi anemia type C (1:89), Niemann-Pick disease type A (1:90), Bloom syndrome (1:100), mucolipidosis IV (1:120), and possibly neonatal familial hyperinsulinemic hypoglycemia.

The prevalence of carriers of certain autosomal recessive genes in some larger populations is unusually high. In such cases, heterozygote advantage is postulated. For example, the carrier frequencies of sickle cell disease in the African population and of cystic fibrosis in the northern European population are much higher than would be expected from new mutations. It is possible that heterozygous carriers have had an advantage in terms of survival and reproduction over

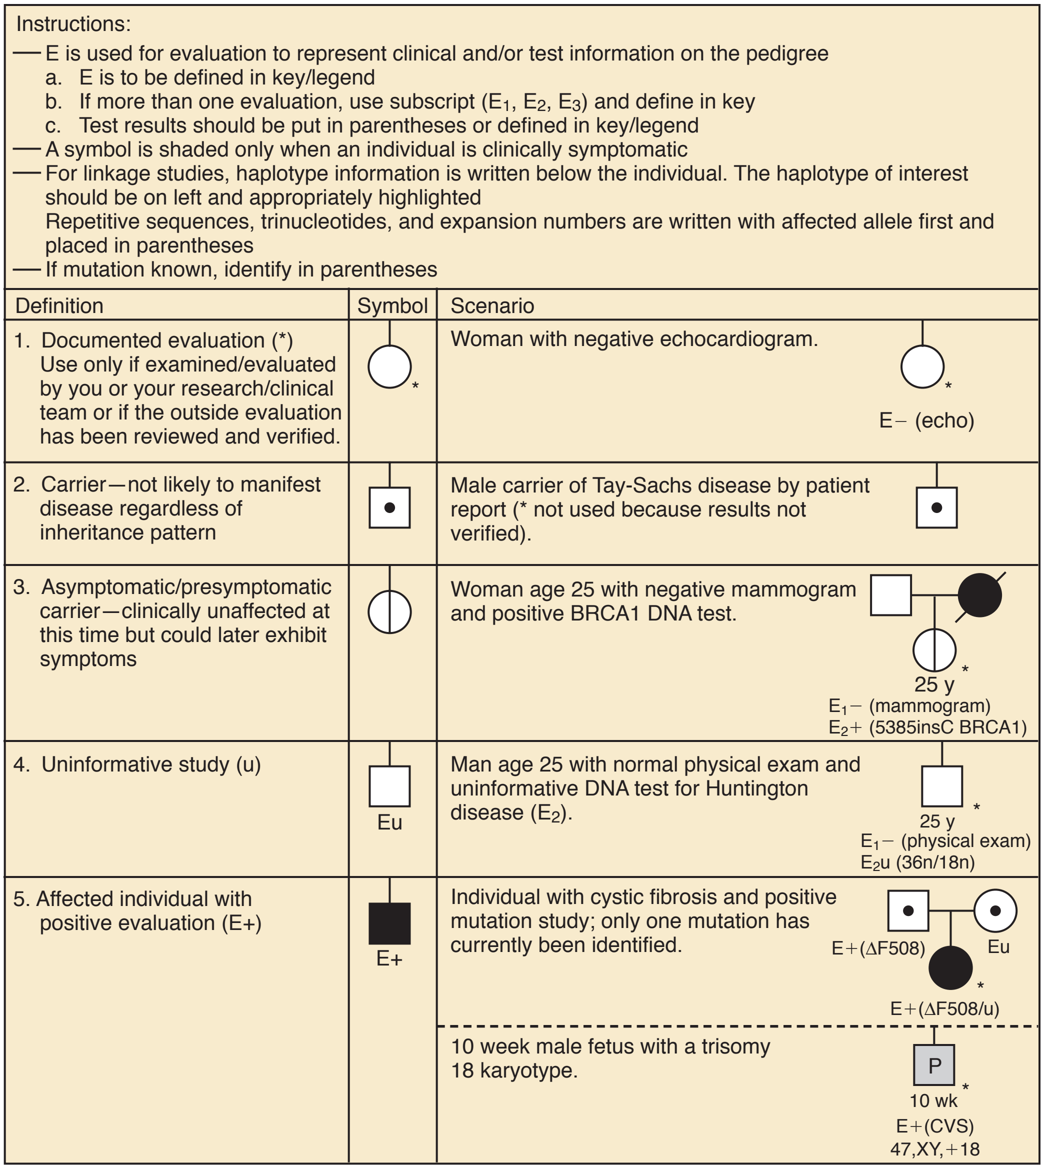

Figure 80-4 **Pedigree symbols of genetic evaluation and testing information.** *(From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, J Genet Couns 17:424–433, 2008.)*

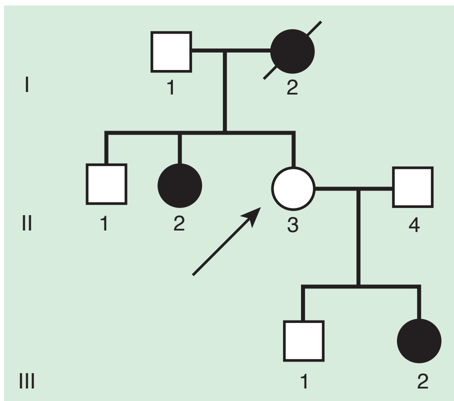

Figure 80-6 **Incomplete penetrance.** This family segregates a familial cancer syndrome, familial adenomatous polyposis. Individual II.3 is an obligate carrier, but there are no findings to suggest the disorder. This disorder is nonpenetrant in this individual.

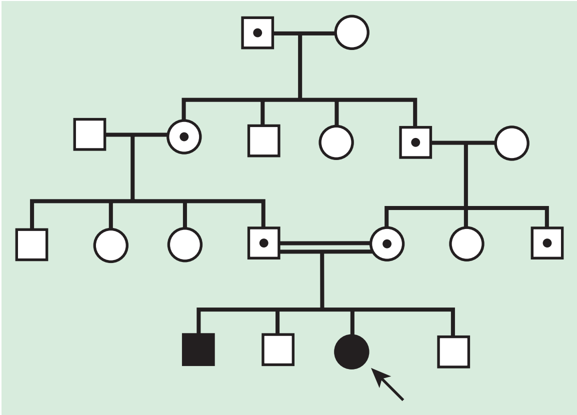

Figure 80-7 Autosomal recessive pedigree with parental consanguinity. *Central dot,* carriers; *black,* affected patients.

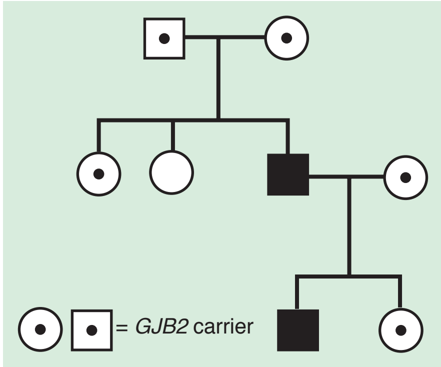

Figure 80-8 Pseudodominant inheritance. *Black,* affected (deaf); *central dot* shows carrier who is asymptomatic (unaffected).

noncarriers. In sickle cell disease, the carrier state might confer some resistance to malaria; in cystic fibrosis, the carrier state has been postulated to confer resistance to cholera or enteropathogenic *Escherichia coli* infections. Population-based carrier screening for cystic fibrosis is recommended for persons of northern European and Ashkenazi Jewish ancestry; population-based screening for sickle cell disease is recommended for persons of African ancestry.

If the frequency of an autosomal recessive disease is known, the frequency of the heterozygote or carrier state can be calculated from the **Hardy-Weinberg formula:**

$$p^2 + 2pq + q^2 = 1$$

where *p* is the frequency of one of a pair of alleles and *q* is the frequency of the other. For example, if the frequency of cystic fibrosis among white Americans is 1 in 2,500 (p^2), then the frequency of the heterozygote (2pq) can be calculated: If $p^2 = 1/2{,}500$, then $p = 1/50$ and $q = 49/50$; $2pq = 2 \times (1/50) \times (49/50) = 98/2500$ or 3.92%.

Pseudodominant Inheritance

Pseudodominant inheritance refers to the observation of apparent dominant (parent to child) transmission of a known autosomal recessive disorder (Fig. 80-8). This occurs when a homozygous affected individual has a partner who is a heterozygous carrier, and it is most likely to occur for relatively common traits, such as sickle cell anemia or nonsyndromic autosomal recessive hearing loss because of mutations in *GJB2*, the gene that encodes Connexin 26.

X-Linked Inheritance

Characteristics of X-linked inheritance (Fig. 80-9) include the following:

- Males are more commonly and more severely affected than females.
- Female carriers are generally unaffected, or if affected, they are affected more mildly than males.
- Female carriers have a 25% risk for having an affected son, a 25% risk for a carrier daughter, and a 50% chance of having a child that does not inherit the mutated X-linked gene.
- Affected males have carrier daughters and unaffected sons because they pass their X chromosome to all of their daughters and their Y chromosome to all of their sons. Male-to-male transmission excludes X-linkage but is seen with autosomal dominant and Y-linked inheritance.

A female occasionally exhibits signs of an X-linked trait similarly to a male. This occurs rarely owing to homozygosity for an X-linked trait or the presence of a sex chromosome abnormality (45,X or 46,XY female) or skewed or nonrandom X-inactivation. **X chromosome inactivation** occurs early in development and involves random and irreversible inactivation of most genes on one X chromosome in female

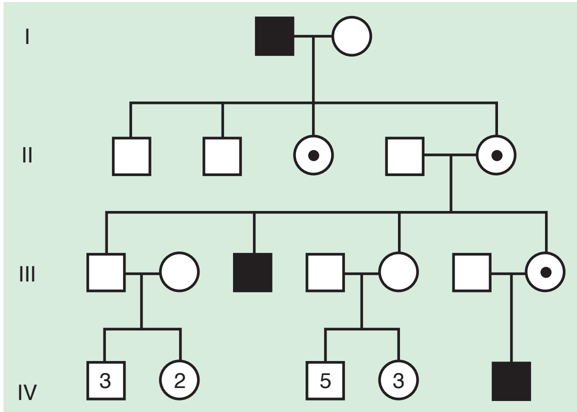

Figure 80-9 Pedigree demonstrating X-linked recessive inheritance.

cells (Fig. 80-10). In some cases, a preponderance of cells inactivates the same X chromosome, resulting in phenotypic expression of an X-linked mutation if it resides on the active chromosome. This can occur owing to chance, selection against cells that have inactivated the X chromosome carrying the normal gene, or X chromosome abnormalities that result in inactivation of the X chromosome carrying the normal gene.

Some X-linked disorders are inherited in an **X-linked dominant** fashion in which female carriers typically manifest abnormal findings. An affected man will have only affected daughters and unaffected sons, and half of the offspring of an affected woman will be affected (Fig. 80-11). Some X-linked dominant conditions are lethal in a high percentage of males. An example is incontinentia pigmenti (see Chapter 596.7). The pedigree shows only affected females and an overall ratio of 2 : 1 females to males with an increased number of miscarriages (Fig. 80-12).

Y-LINKED INHERITANCE

There are few Y-linked traits. These demonstrate *only* male-to-male transmission, and only males are affected (Fig. 80-13). Most Y-linked genes are related to male sex determination and reproduction and are associated with infertility. Therefore, it is rare to see familial transmission of a Y-linked disorder. However, advances in assisted reproductive technologies might make it possible to have familial transmission of male infertility.

Of special note are the pseudoautosomal regions on the Y chromosome that have homology that is shared by both Xp and Yp. Very few genes reside in this region. One of the few is *SHOX*. Heterozygous *SHOX* mutations cause **Leri-Weil dyschondrosteosis,** a rare skeletal dysplasia that involves bilateral bowing of the forearms with

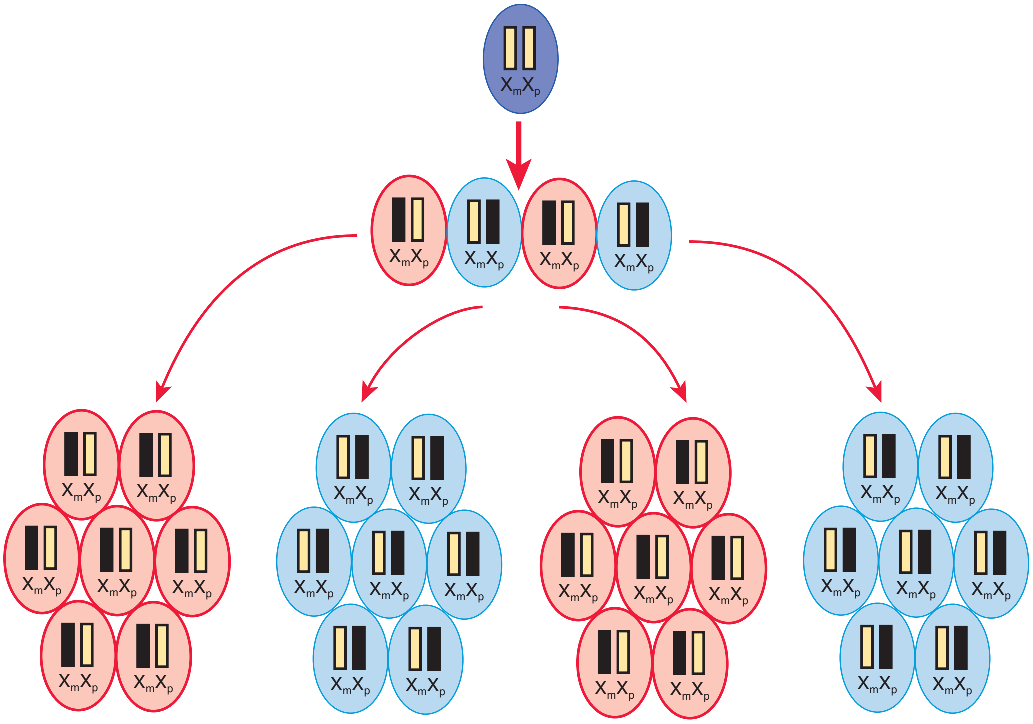

Figure 80-10 X-inactivation. *Black* marks the active X chromosome. Color of the cell represents its active X chromosome is paternally (X_p, *blue*) or maternally (X_m, *pink*) derived.

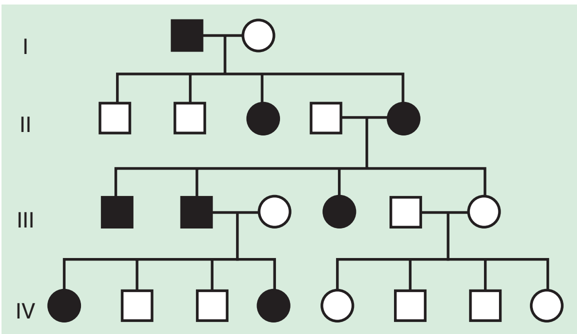

Figure 80-11 Pedigree pattern demonstrating X-linked dominant inheritance. Note there is no father-to-son transmission in this situation, and hemizygosity (i.e., X-linked gene in a male) is not lethal. In some X-linked dominant conditions, X-linked males have a more severe phenotype and might not survive. In that case, only females manifest the disease (see Fig. 80-12).

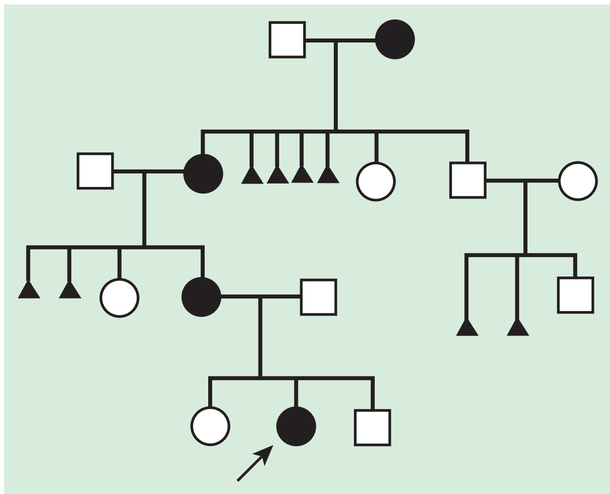

Figure 80-12 Pedigree of an X-linked dominant disorder with male lethality, such as incontinentia pigmenti.

dislocations of the ulna at the wrist and generalized short stature. Homozygous mutations cause the much more severe **Langer mesomelic dwarfism.**

DIGENIC INHERITANCE

Digenic inheritance explains the occurrence of **retinitis pigmentosa** (RP) in children of parents who each carry a mutation in a different RP-associated gene. Both parents have normal vision, as would be expected, but their offspring who are **double heterozygotes**—having inherited both mutations—develop RP. Digenic pedigrees (Fig. 80-14) can exhibit characteristics of both autosomal dominant (vertical transmission) and autosomal recessive inheritance (1 in 4 recurrence risk). For example, a couple in which the 2 unaffected partners are carriers for mutation in 2 different RP-associated genes that show digenic inheritance have a 1 in 4 risk of having an affected child similar to what is seen in autosomal recessive inheritance. However, their affected

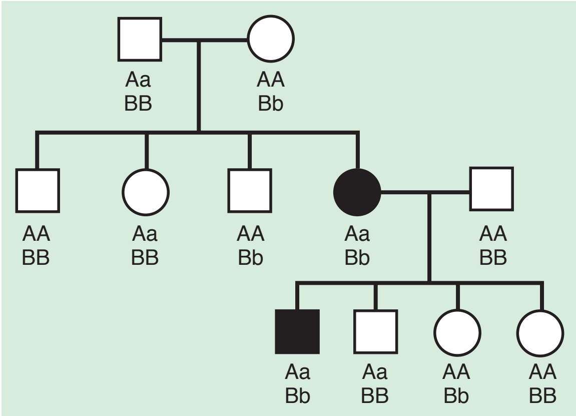

Figure 80-14 Digenic pedigree. Here, the disease alleles are *a* and *b* and they reside on distinct genetic loci or genes. For a person to have the disease, heterozygosity for mutant alleles in both genes (A/a;B/b) is required.

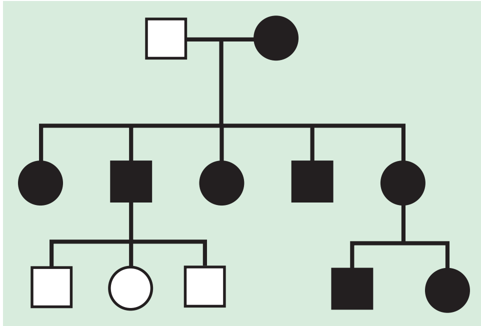

Figure 80-15 Pedigree of a mitochondrial disorder, exhibiting maternal inheritance. *Black,* affected patient.

children, and affected children in subsequent generations, have a 1 in 4 risk of transmitting both mutations to their offspring, who would be affected (vertical transmission).

PSEUDOGENETIC INHERITANCE AND FAMILIAL CLUSTERING

Sometimes nongenetic reasons for the occurrence of a particular disease in multiple family members can produce a pattern that mimics genetic transmission. These nongenetic factors can include identifiable environmental factors, teratogenic exposures, or as yet undetermined and/or undefined factors. Examples of identifiable factors might include multiple siblings in a family having asthma as a result of exposure to cigarette smoke from their parents or having failure to thrive, developmental delay, and unusual facial appearance caused by exposure to alcohol during pregnancy.

In some cases the disease is sufficiently common in the general population that some familial clustering occurs simply by chance. Breast cancer affects 11% of all women, and it is possible that several women in a family will develop breast cancer even in the absence of a genetic predisposition. However, hereditary breast cancer associated with mutations in *BRCA1* and *BRCA2* should be suspected in any individual who has a personal history of breast cancer with onset before age 50 yr, early-onset breast and ovarian cancer at any age, bilateral or multifocal breast cancer, a family history of breast cancer or breast and ovarian cancer consistent with autosomal dominant inheritance, and/or a personal or family history of male breast cancer.

NONTRADITIONAL INHERITANCE

Some genetic disorders are inherited in a manner that does not follow classical Mendelian patterns. Nontraditional inheritance includes mitochondrial disorders, triplet repeat expansion diseases, and imprinting defects.

Mitochondrial Inheritance

An individual's mitochondrial genome is entirely derived from the mother because sperm contain few mitochondria, which are typically shed upon fertilization. It follows that mitochondrial disorders exhibit maternal inheritance. A woman with a mitochondrial genetic disorder can have affected offspring of either sex, but an affected father cannot pass on the disease to his offspring (Fig. 80-15). Mitochondrial DNA mutations are often deletions or point mutations; overall, 1:400 people has a maternally inherited pathogenic mitochondrial DNA mutation.

In individual families, mitochondrial inheritance may be difficult to distinguish from autosomal dominant or X-linked inheritance, but in many cases, paying close attention to the sex of the transmitting and nontransmitting parents can suggest a mitochondrial basis (Table 80-1).

The mitochondria are the cell's suppliers of energy, and it is not surprising that the organs that are most affected by the presence of abnormal mitochondria are those that have the greatest energy requirements, such as the brain, muscle, heart, and liver (see Chapters 87.4, 361, 598.2, and 611.4). Common manifestations include developmental delay, seizures, cardiac dysfunction, decreased muscle strength and tone, and hearing and vision problems. Examples of mitochondrial disorders include **MELAS** (*m*yopathy, *e*ncephalopathy, *l*actic *a*cidosis, and *s*trokelike episodes), **MERRF** (*m*yoclonic *e*pilepsy associated with *r*agged *r*ed *f*ibers), and **Kearns-Sayre syndrome** (ophthalmoplegia, pigmentary retinopathy, and cardiomyopathy) (see Chapter 598.2 and 611.4).

Mitochondrial diseases can be highly variable in clinical manifestation. This is partly because cells can contain multiple mitochondria, each bearing several copies of the mitochondrial genome. Thus, a cell can have a mixture of normal and abnormal mitochondrial genomes, which is referred to as **heteroplasmy.** Unequal segregation of mitochondria carrying normal and abnormal genomes and replicative advantage can result in varying degrees of heteroplasmy in the cells of an affected individual, including the individual ova of an affected female. Because of this, a mother may be asymptomatic and yet have children who are severely affected. The level of heteroplasmy at which disease symptoms typically appear can also vary based on the type of mitochondrial mutation. Detection of mitochondrial genome mutations can require sampling of the affected tissue for DNA analysis; testing for mitochondrial DNA mutations may in some tissues, such as blood, be inadequate because the mutation may be found primarily in affected tissues such as muscle.

Triplet Repeat Expansion Disorders

Triplet repeat expansion disorders are distinguished by the special dynamic nature of the disease-causing mutation. Triplet repeat expansion disorders include fragile X syndrome, myotonic dystrophy, Huntington disease, spinocerebellar ataxias, and several others (Table 80-2). These disorders are caused by expansion in the number of 3-bp repeats. The **fragile X gene,** *FMR1,* normally has 5-40 CGG triplets. An error in replication can result in expansion of that number to a level in the gray zone between 41 and 58 repeats, or to a level referred to as **premutation,** which comprises 59-200 repeats. Some male carriers of the premutation develop fragile X–associated tremor/ataxia syndrome (FXTAS) as adults, and female carriers of the premutation are at risk for fragile X-associated primary ovarian insufficiency (*FXPOI*). Persons with a premutation are also at risk for having the gene expand further in subsequent meiosis, hence crossing into the range of full mutation in offspring. In fragile X, the threshold for clinical diagnosis is above 200 repeats. With this number of repeats, the *FMR1* gene becomes hypermethylated, and protein production is lost.

Some triplet expansions associated with other genes can cause disease through a mechanism other than decreased protein production. In **Huntington disease,** the expansion causes the gene product

Table 80-1 Representative Examples of Disorders Caused by Mutations in Mitochondrial DNA and Their Inheritance

DISEASE	PHENOTYPE	MOST FREQUENT MUTATION IN MTDNA MOLECULE	HOMOPLASMY VS. HETEROPLASMY	INHERITANCE
Leber hereditary optic neuropathy	Rapid optic nerve death, leading to blindness in young adult life	Substitution Arg340His in *ND1* gene of complex I of electron transport chain; other complex I missense mutations	Homoplasmic (usually)	Maternal
NARP, Leigh disease	Neuropathy, ataxia, retinitis pigmentosa, developmental delay, mental retardation, lactic acidemia	Point mutations in ATPase subunit 6 gene	Heteroplasmic	Maternal
MELAS	Mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; may manifest only as diabetes mellitus	Point mutation in $tRNA^{Leu}$	Heteroplasmic	Maternal
MERRF	Myoclonic epilepsy, ragged red fibers in muscle, ataxia, sensorineural deafness	Point mutation in $tRNA^{Lys}$	Heteroplasmic	Maternal
Deafness	Progressive sensorineural deafness, often induced by aminoglycoside antibiotics	A1555G mutation in 12S rRNA	Homoplasmic	Maternal
	Nonsyndromic sensorineural deafness	A7445G mutation in 12S rRNA	Homoplasmic	Maternal
Chronic progressive external ophthalmoplegia (CPEO)	Progressive weakness of extraocular muscles	The common MELAS point mutation in $tRNA^{Lys}$; large deletions similar to KSS	Heteroplasmic	Maternal if point mutations
Pearson syndrome	Pancreatic insufficiency, pancytopenia, lactic acidosis	Large deletions	Heteroplasmic	Sporadic, somatic mutations
Kearns-Sayre syndrome (KSS)	PEO of early onset with heart block, retinal pigmentation	5 kb large deletion	Heteroplasmic	Sporadic, somatic mutations

Table 80-2 Diseases Associated with Polynucleotide Repeat Expansions

DISEASE	DESCRIPTION	REPEAT SEQUENCE	NORMAL RANGE	ABNORMAL RANGE	PARENT IN WHOM EXPANSION USUALLY OCCURS	LOCATION OF EXPANSION
CATEGORY 1						
Huntington disease	Loss of motor control, dementia, affective disorder	CAG	6-34	36-100 or more	More often through father	Exon
Spinal and bulbar muscular atrophy	Adult-onset motor-neuron disease associated with androgen insensitivity	CAG	11-34	40-62	More often through father	Exon
Spinocerebellar ataxia type 1	Progressive ataxia, dysarthria, dysmetria	CAG	6-39	41-81	More often through father	Exon
Spinocerebellar ataxia type 2	Progressive ataxia, dysarthria	CAG	15-29	35-59	—	Exon
Spinocerebellar ataxia type 3 (Machado-Joseph disease)	Dystonia, distal muscular atrophy, ataxia, external ophthalmoplegia	CAG	13-36	68-79	More often through father	Exon
Spinocerebellar ataxia type 6	Progressive ataxia, dysarthria, nystagmus	CAG	4-16	21-27	—	Exon
Spinocerebellar ataxia type 7	Progressive ataxia, dysarthria, retinal degeneration	CAG	7-35	38-200	More often through father	—
Spinocerebellar ataxia type 17	Progressive ataxia, dementia, bradykinesia, dysmetria	CAG	29-42	47-55	—	Exon
Dentatorubral-pallidoluysian atrophy/Haw River syndrome	Cerebellar atrophy, ataxia, myoclonic epilepsy, choreoathetosis, dementia	CAG	7-25	49-88	More often through father	Exon

Continued

Table 80-2 Diseases Associated with Polynucleotide Repeat Expansions—cont'd

DISEASE	DESCRIPTION	REPEAT SEQUENCE	NORMAL RANGE	ABNORMAL RANGE	PARENT IN WHOM EXPANSION USUALLY OCCURS	LOCATION OF EXPANSION
CATEGORY 2						
Pseudoachondroplasia, multiple epiphyseal dysplasia	Short stature, joint laxity, degenerative joint disease	GAC	5	6-7	—	Exon
Oculopharyngeal muscular dystrophy	Proximal limb weakness, dysphagia, ptosis	GCG	6	7-13	—	Exon
Cleidocranial dysplasia	Short stature, open skull sutures with bulging calvaria, clavicular hypoplasia, shortened fingers, dental anomalies	GCG, GCT, GCA	17	27 (expansion observed in 1 family)	—	Exon
Synpolydactyly	Polydactyly and syndactyly	GCG, GCT, GCA	15	22-25	—	Exon
CATEGORY 3						
Myotonic dystrophy (DM1; chromosome 19)	Muscle loss, cardiac arrhythmia, cataracts, frontal balding	CTG	5-37	100 to several thousand	Either parent, but expansion to congenital form through mother	3′ untranslated region
Myotonic dystrophy (DM2; chromosome 3)	Muscle loss, cardiac arrhythmia, cataracts, frontal balding	CCTG	<75	75-11,000	—	3′ untranslated region
Friedreich ataxia	Progressive limb ataxia, dysarthria, hypertrophic cardiomyopathy, pyramidal weakness in legs	GAA	7-2	200-900 or more	Autosomal recessive inheritance, so disease alleles are inherited from both parents	Intron
Fragile X syndrome (FRAXA)	Mental retardation, large ears and jaws, macroorchidism in males	CGG	6-52	200-2,000 or more	Exclusively through mother	5′ untranslated region
Fragile site (FRAXE)	Mild mental retardation	GCC	6-35	>200	More often through mother	5′ untranslated region
Spinocerebellar ataxia type 8	Adult-onset ataxia, dysarthria, nystagmus	CTG	16-37	107-127	More often through mother	3′ untranslated region
Spinocerebellar ataxia type 10	Ataxia and seizures	ATTCT	12-16	800-4,500	More often through father	Intron
Spinocerebellar ataxia type 12	Ataxia, eye movement disorders; variable age at onset	CAG	7-28	66-78	—	5′ untranslated region
Progressive myoclonic epilepsy type 1	Juvenile-onset convulsions, myoclonus, dementia	12-bp repeat motif	2-3	30-75	Autosomal recessive inheritance, so transmitted by both parents	5′ untranslated region

From Jorde LB, Carey JC, Bamshad MJ, et al: Medical genetics, ed 3, St. Louis, 2006, Mosby, p. 82.

to have a new, toxic effect on the neurons of the basal ganglia. For most triplet-repeat disorders, there is a clinical correlation to the size of the expansion, with a greater expansion causing more severe symptoms and/or earlier age of onset for the disease. The observation of increasing severity of disease and early age at onset in subsequent generations is termed **genetic anticipation** and is a defining characteristic of many triplet-repeat expansion disorders (Fig. 80-16).

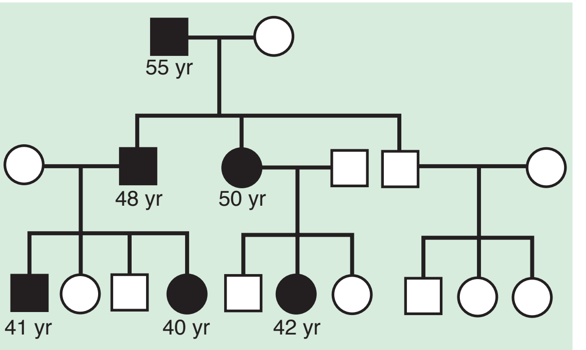

Figure 80-16 Myotonic dystrophy pedigree illustrating anticipation. In this case, the age at onset for family members affected with an autosomal dominant disease is lower in more recent generations. *Black,* affected patients.

Genetic Imprinting

The 2 copies of most autosomal genes are functionally equivalent. However, in some cases only 1 copy of a gene is transcribed and the other copy is silenced. This gene silencing is typically associated with methylation of DNA, which is an **epigenetic modification**, meaning it does not change the nucleotide sequence of the DNA (Fig. 80-17). In **imprinting**, gene expression depends on the parent of origin of the chromosome (see Chapter 81.8). Imprinting disorders result from an imbalance of active copies of a given gene, which can occur for several reasons. **Prader-Willi** and **Angelman syndromes**, two distinct disorders associated with developmental impairment, are illustrative. Both

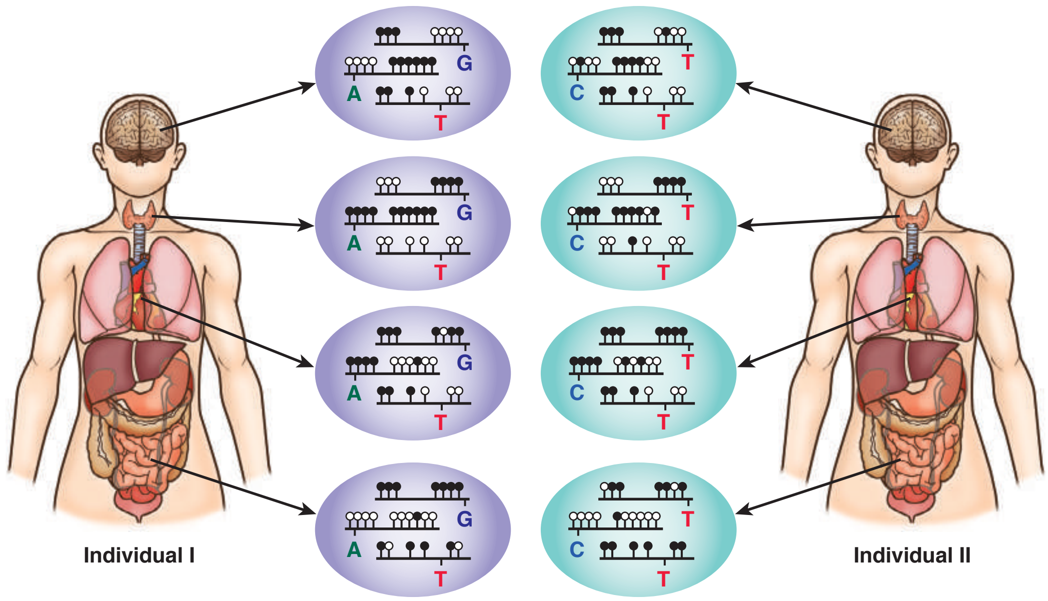

Figure 80-17 Tissue-specific DNA methylation and epigenetic heterogeneity among individuals. A subset of the DNA methylation patterns within a cell is characteristic of that cell type. Cell type–specific and tissue-specific DNA methylation are illustrated by organ-to-organ variations in the clusters of methylated CpGs within the same individual. Despite overall consistency in tissue-specific DNA methylation patterns, variations in these patterns exist among different individuals. Methylated CpGs are indicated by a *filled circle* and unmethylated CpGs by an *open circle*. SNPs are indicated by the corresponding base. *(Redrawn from Brena RM, Huang THM, Plass C: Toward a human epigenome*, Nat Genet *38:1359–1360, 2006.)*

can be caused by microdeletions of chromosome 15q11-12. The microdeletion in Prader-Willi syndrome is always on the paternally derived chromosome 15, whereas in Angelman syndrome it is on the maternal copy. *UBE3A* is the gene responsible for Angelman syndrome. The paternal copy of *UBE3A* is transcriptionally silenced in the brain and the maternal copy continues to be transcribed. If an individual has a maternal deletion, an insufficient amount of *UBE3A* protein is produced in the brain, resulting in the neurologic deficits seen in Angelman syndrome.

Uniparental disomy (UPD), the rare occurrence of a child inheriting both copies of a chromosome from the same parent, is another genetic mechanism that can cause Prader-Willi and Angelman syndromes. Inheriting both chromosomes 15 from the mother is functionally the same as deletion of the paternal 15q12 and results in Prader-Willi syndrome. Approximately 30% of cases of Prader-Willi syndrome is caused by paternal UPD15, whereas maternal UPD15 accounts for only 3% of Angelman syndrome (see Chapter 81.8).

A mutation in an imprinted gene is another cause. Mutations in *UBEA3* account for almost 11% of patients with Angelman syndrome and also result in familial transmission. The most uncommon cause is a mutation in the imprinting center, which results in an inability to correctly imprint the *UBE3A*. In a woman, the inability to reset the imprinting on her paternally inherited chromosome 15 imprint results in a 50% risk of passing on an incorrectly methylated copy of *UBE3A* to a child who would then develop Angelman syndrome.

Beside 15q12, other imprinted regions of clinical interest include the short arm of chromosome 11, where the genes for Beckwith-Wiedemann syndrome and nesidioblastosis map, and the long arm of chromosome 7 with maternal UPD of 7q, which has been associated with some cases of idiopathic short stature and Russell-Silver syndrome.

Imprinting of a gene can occur during gametogenesis or early embryonic development (reprogramming). Genes can become inactive or active by various mechanisms including DNA methylation or demethylation or histone acetylation or deacetylation, with different patterns of (de)methylation noted on paternal or maternal imprintable chromosome regions. Some genes demonstrate tissue-specific imprinting (see Fig. 80-17). Several studies suggest that there may be a small but significantly increased incidence of imprinting disorders, specifically Beckwith-Wiedemann and Angelman syndrome, associated with assisted reproductive technologies such as in vitro fertilization and intracytoplasmic sperm injection. However, the overall incidence of these disorders in children conceived using assisted reproductive technologies is likely to be <1%.

MULTIFACTORIAL AND POLYGENIC INHERITANCE

Multifactorial inheritance refers to traits that are caused by a combination of inherited, environmental, and stochastic factors (Fig. 80-18). Multifactorial traits differ from polygenic inheritance, which refers to traits that result from the additive effects of multiple genes. Multifactorial traits segregate within families but do not exhibit a consistent or recognizable inheritance pattern. Characteristics include the following:

- There is a similar rate of recurrence among all 1st-degree relatives (parents, siblings, offspring of the affected child). It is unusual to find a substantial increase in risk for relatives related more distantly than 2nd degree to the index case.
- The risk of recurrence is related to the incidence of the disease.
- Some disorders have a sex predilection, as indicated by an unequal male : female incidence. Pyloric stenosis, for example, is more common in males, whereas congenital dislocation of the hips is more common in females. Where there is an altered sex ratio, the risk is higher for the relatives of an index case whose gender is less commonly affected than relatives of an index case of the more commonly affected gender. For example, the risk to the son of an affected female with infantile pyloric stenosis is 18%, compared with the 5% risk for the son of an affected male. An affected female presumably has a greater genetic susceptibility, which she can then pass on to her offspring.
- The likelihood that both identical twins will be affected with the same malformation is less than 100% but much greater than the chance that both members of a nonidentical twin pair will be affected. This is in contrast with the pattern seen in mendelian

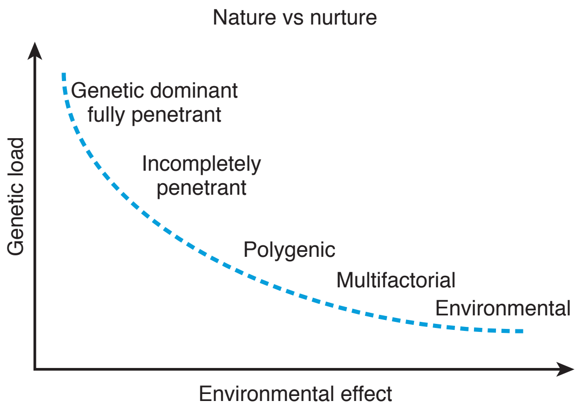

Figure 80-18 **The progressive decrease in the genetic load contributing to the development of a disease creates a smooth transition in the distribution of illnesses on an etiologic diagram.** In theory, no diseases are completely free from the influence of both genetic and environmental factors. *(From Bomprezzi R, Kovanen PE, Martin R: New approaches to investigating heterogeneity in complex traits,* J Med Genet *40:553–559, 2003. Reproduced with permission from the BMJ Publishing Group.)*

inheritance, in which identical twins almost always share fully penetrant genetic disorders.

- The risk of recurrence is increased when multiple family members are affected. A simple example is that the risk of recurrence for unilateral cleft lip and palate is 4% for a couple with 1 affected child and increases to 9% with 2 affected children. It is sometimes difficult to distinguish between a multifactorial and mendelian etiology in families with multiple affected individuals.
- The risk of recurrence may be greater when the disorder is more severe. For example, an infant who has long-segment Hirschsprung disease has a greater chance of having an affected sibling than the infant who has short-segment Hirschsprung disease.

There are 2 types of multifactorial traits. One exhibits continuous variation, with "normal" individuals falling within a statistical range—often defined as having a value 2 SDs above and/or below the mean—and "abnormals" falling outside that range. Examples include such traits as intelligence, blood pressure, height, and head circumference. For many of these traits, offspring values can be estimated based on a modified average of their parental values, with nutritional and environmental factors playing an important role.

With other multifactorial traits, the distinction between normal and abnormal is based on the presence or absence of a particular trait. Examples include pyloric stenosis, neural tube defects, congenital heart defects, and cleft lip and cleft palate. Such traits follow a threshold model (see Fig. 80-15). A distribution of liability because of genetic and nongenetic factors is postulated in the population. Individuals who exceed a threshold liability develop the trait, and those below the threshold do not.

The balance between genetic and environmental factors is demonstrated by **neural tube defects.** Genetic factors are implicated by the increased recurrence risk for parents of an affected child compared with the general population, yet the recurrence risk is about 3%, less than what would be expected if the trait was caused by a single, fully penetrant mutation. The role of nongenetic environmental factors can be seen in the fact that the recurrence risk can be lowered by up to 87% if the mother-to-be takes 4 mg of folic acid per day starting 3 mo before conception.

Many adult-onset diseases behave as if they are caused by multifactorial inheritance. Diabetes, coronary artery disease, and schizophrenia are examples.

Chapter 81

Cytogenetics

Carlos A. Bacino and Brendan Lee

Clinical cytogenetics is the study of chromosomes: their structure, function, inheritance, and abnormalities. Chromosome abnormalities are very common and occur in approximately 1-2% of live births, 5% of stillbirths, and 50% of early fetal losses in the 1st trimester of pregnancy (Table 81-1). Chromosome abnormalities are more common among persons with intellectual disability and they play a significant role in the development of some neoplasias.

Chromosome analyses are indicated in persons presenting with multiple congenital anomalies, dysmorphic features, and/or intellectual disability. The specific indications for studies include advanced maternal age (>35 yr) or multiple abnormalities on fetal ultrasound (prenatal testing), multiple congenital anomalies, unexplained growth restriction in the fetus or postnatal problems in growth and development, ambiguous genitalia, unexplained intellectual disability with or without associated anatomic abnormalities, primary amenorrhea or infertility, recurrent miscarriages (≥3) or prior history of stillbirths and neonatal deaths, a 1st-degree relative with a known or suspected structural chromosome abnormality, clinical findings consistent with a known anomaly, some malignancies, and chromosome breakage syndromes (e.g., Bloom syndrome, Fanconi anemia).

Table 81-1 Incidence of Chromosomal Abnormalities in Newborn Surveys

TYPE OF ABNORMALITY	NUMBER	APPROXIMATE INCIDENCE
SEX CHROMOSOME ANEUPLOIDY		
Males (43,612 newborns)		
47,XXY	45	1/1,000
47,XYY	45	1/1,000
Other X or Y aneuploidy	32	1/1,350
Total	**122**	**1/360 male births**
Females (24,547 newborns)		
45,X	6	1/4,000
47,XXX	27	1/900
Other X aneuploidy	9	1/2,700
Total	**42**	**1/580 female births**
AUTOSOMAL ANEUPLOIDY (68,159 NEWBORNS)		
Trisomy 21	82	1/830
Trisomy 18	9	1/7,500
Trisomy 13	3	1/22,700
Other aneuploidy	2	1/34,000
Total	**96**	**1/700 live births**
STRUCTURAL ABNORMALITIES (68,159 NEWBORNS)		
Balanced rearrangements		
Robertsonian	62	1/1,100
Other	77	1/885
Unbalanced rearrangements		
Robertsonian	5	1/13,600
Other	38	1/1,800
Total	**182**	**1/375 live births**
All Chromosome Abnormalities	442	1/154 live births

Data from Hsu LYF: Prenatal diagnosis of chromosomal abnormalities through amniocentesis. In Milunsky A, editor: Genetic disorders and the fetus, *ed 4, Baltimore, 1998, Johns Hopkins University Press, pp. 179-248.*

81.1 Methods of Chromosome Analysis

Carlos A. Bacino and Brendan Lee

Cytogenetic studies are usually performed on peripheral blood lymphocytes, although cultured fibroblasts may also be used. Prenatal (fetal) chromosome studies are performed with cells obtained from the amniotic fluid, chorionic villus tissue, and fetal blood or, in the case of preimplantation diagnosis, by analysis of a blastomere. Cytogenetic studies of bone marrow have an important role in tumor surveillance, particularly among patients with leukemia. These are useful to determine induction of remission and success of therapy or, in some cases, the occurrence of relapses.

Chromosome anomalies include abnormalities of number and structure and are the result of errors during cell division. There are 2 types of cell division: mitosis, which occurs in most somatic cells, and meiosis, which is limited to the germ cells. In **mitosis,** 2 genetically identical daughter cells are produced from a single parent cell. DNA duplication has already occurred during **interphase** in the S phase of the cell cycle (DNA synthesis). Therefore, at the beginning of mitosis the chromosomes consist of 2 double DNA strands joined together at the centromere known as *sister chromatids.* Mitosis can be divided into 4 stages: **prophase**, **metaphase**, **anaphase**, and **telophase**. Prophase is characterized by condensation of the DNA. Also during prophase, the nuclear membrane and the nucleolus disappear and the mitotic spindle forms. In metaphase, the chromosomes are maximally compacted and are clearly visible as distinct structures. The chromosomes align at the center of the cell and spindle fibers connect to the centromere of each chromosome and extend to centrioles at the 2 poles of the mitotic figure. In anaphase, the chromosomes divide along their longitudinal axes to form 2 daughter chromatids, which then migrate to opposite poles of the cell. Telophase is characterized by formation of 2 new nuclear membranes and nucleoli, duplication of the centrioles, and cytoplasmic cleavage to form the 2 daughter cells.

Meiosis begins in the female oocyte during fetal life and is completed years to decades later. In males, it begins in a particular spermatogonial cell sometime between adolescence and adult life and is completed in a few days. Meiosis is preceded by DNA replication so that at the outset each of the 46 chromosomes consists of 2 chromatids. In meiosis, a **diploid cell** (2n = 46 chromosomes) divides to form **haploid cells** (n = 23 chromosomes). Meiosis consists of 2 major rounds of cell division. In meiosis I, each of the homologous chromosomes pair precisely so that **genetic recombination,** involving exchange between 2 DNA strands **(crossing over),** can occur. This results in a reshuffling of the genetic information on the recombined chromosomes and allows further genetic diversity. Each daughter cell then receives 1 of each of the 23 homologous chromosomes. In oogenesis, 1 of the daughter cells receives most of the cytoplasm and becomes the egg, whereas the other smaller cell becomes the first polar body. Meiosis II is similar to a mitotic division but without a preceding round of DNA duplication (replication). Each of the 23 chromosomes divides longitudinally, and the homologous chromatids migrate to opposite poles of the cell. This produces 4 spermatogonia in males, or an egg cell and a second polar body in females, each with a haploid (n = 23) set of chromosomes. Consequently, meiosis fulfills 2 crucial roles: It reduces the chromosome number from diploid (46) to haploid (23) so that upon fertilization a diploid number is restored, and it allows genetic recombination.

Two errors of cell division commonly occur during meiosis or mitosis, and either can result in an abnormal number of chromosomes. The first is **nondisjunction,** in which 2 chromosomes fail to separate during meiosis and thus migrate together into 1 of the new cells, producing 1 cell with 2 copies of the chromosome and another with no copy. The second is **anaphase lag,** in which a chromatid or chromosome is lost during mitosis because it fails to move quickly enough during anaphase to become incorporated into 1 of the new daughter cells (Fig. 81-1).

For chromosome analysis, cells are cultured (for varying periods depending on cell type), with or without stimulation, and then artificially arrested in mitosis during metaphase (or prometaphase), later on subjected to a hypotonic solution to allow disruption of the nuclear cell membrane and proper dispersion of the chromosomes for analysis, fixed, banded, and finally stained. The most commonly used banding and staining method is the GTG banding (G-bands trypsin Giemsa), also known as G banding, which produces a unique combination of dark (G-positive) and light (G-negative) bands that permits recognition of all individual 23 chromosome pairs for analysis.

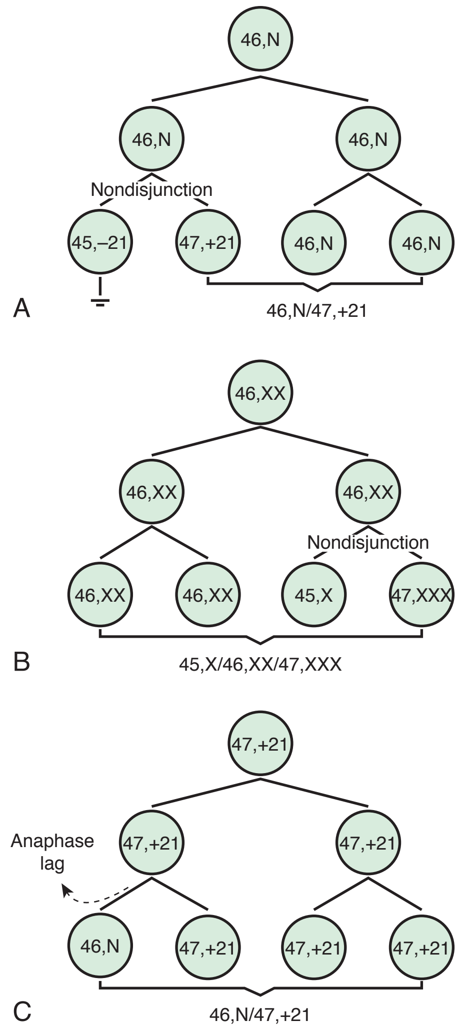

Figure 81-1 Generation of mosaicism. *A,* Postzygotic nondisjunction in an initially normal conceptus. In this example, 1 cell line (monosomic 21) is subsequently lost, with the final karyotype 46,N/47,+21. *B,* Postzygotic nondisjunction in an initially 46,XX conceptus, resulting in 45,X/46,XX/47,XXX mosaicism. *C,* Postzygotic anaphase lag in an initially 47,+21 conceptus. *(From Gardner RJM, Sutherland GR.* Chromosome abnormalities and genetic counseling, *ed 3 New York, 2003, Oxford University Press, p. 33, Figure 43.1. By permission of Oxford University Press, Inc.,* www.oup.com.*)*

Other banding techniques, such as Q-banding using quinacrine, reverse banding (R-banding) using acridine orange, and C-banding (constitutive heterochromatin) using barium hydroxide, are available for use in certain circumstances but are losing ground to molecular technologies. Metaphase chromosome spreads are first evaluated microscopically, and then their images are photographed or captured by a video camera and stored on a computer to be later analyzed. Humans have 46 chromosomes or 23 pairs, which are classified as autosomes for chromosomes 1 to 22, and the sex chromosomes, often referred as sex complement: XX for females and XY for males. The homologous chromosomes from a metaphase spread can then be paired and arranged systematically to assemble a karyotype according to well-defined standard conventions like those established by International

System for Human Cytogenetic Nomenclature (ISCN), with chromosome 1 being the largest and 22 the smallest. According to nomenclature, the description of the karyotype includes the total number of chromosomes followed by the sex chromosome constitution. A normal karyotype is 46,XX for females and 46,XY for males (Fig. 81-2). Abnormalities are noted after the sex chromosome complement.

Although the internationally accepted system for human chromosome classification relies largely on the length and banding pattern of each chromosome, the position of the centromere relative to the ends of the chromosome also is a useful distinguishing feature (Fig. 81-3). The centromere divides the chromosome in 2, with the short arm designated as the **p arm** and the long arm designated as the **q arm**. A plus or minus sign before the number of a chromosome indicates that there is an extra or missing chromosome, respectively. Table 81-2 lists some of the abbreviations used for the descriptions of chromosomes and their abnormalities. A metaphase chromosome spread usually shows 450-550 bands. Prophase and prometaphase chromosomes are longer, are less condensed, and often show 550-850 bands. High-resolution analysis is useful for detecting subtle chromosome abnormalities that might otherwise go unrecognized.

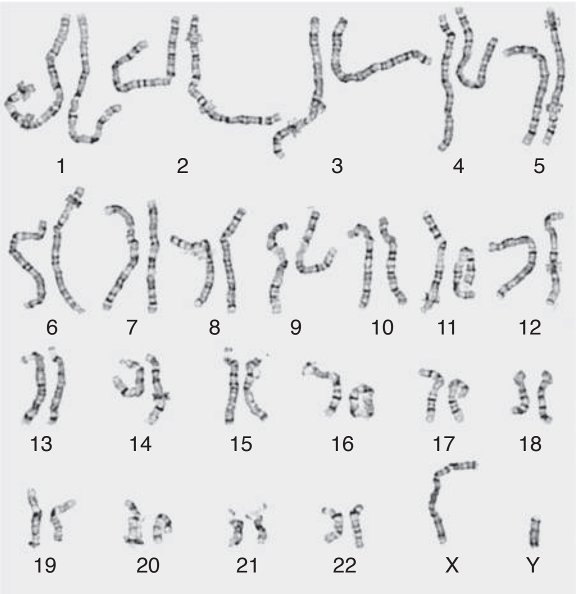

Figure 81-2 **Karyotype of a normal male at the 550-600 band level.** The longer the chromosomes are captured at metaphase or sometimes prometaphase, the more bands that can be visualized.

Molecular techniques such as fluorescence in situ hybridization (FISH) and array comparative genomic hybridization studies (conventional CGH and array CGH [aCGH]) have filled a significant void for the diagnosing cryptic chromosomal abnormalities. These techniques identify subtle abnormalities that are often below the resolution of standard cytogenetic studies. **FISH** is used to identify the presence, absence, or rearrangement of *specific* DNA segments and is performed with gene- or region-specific DNA probes. Several FISH probes are used in the clinical setting: unique sequence or single-copy probes, repetitive-sequence probes (alpha satellites in the pericentromeric regions), and multiple-copy probes (chromosome specific or painting) (Fig. 81-4*A* and *B*). FISH involves using a unique known DNA sequence or probe labeled with a fluorescent dye that is complementary to the studied region of disease interest. The labeled probe is exposed to the DNA on a microscope slide, typically metaphase or interphase chromosomal DNA. When the probe pairs with its complementary DNA sequence, it can be then visualized by fluorescence microscopy (Fig. 81-5). In metaphase chromosome spreads, the exact chromosomal

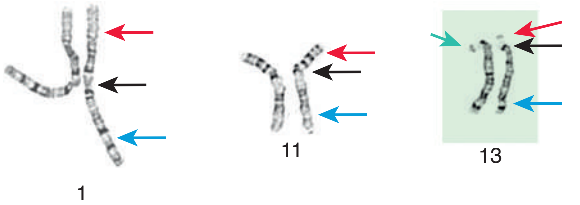

Figure 81-3 **Example of different chromosome types according to the position of the centromere.** On the *left* is a chromosome 1 pair with the centromere equidistant from the short and long arm (also known as metacentric). In the center is a chromosome 11 pair that is submetacentric. On the right is a chromosome 13 pair that is an example of an acrocentric chromosome. Acrocentric chromosomes contain a very small short arm, stalks, and satellite DNA. The *black arrow* indicates the position of the centromere. The *blue arrow* shows the long arm of a chromosome. The *red arrow* shows the short arm of a chromosome. The *green arrow* highlights the satellite region, which is made of DNA repeats. The *light area* between the short arm and the satellite is known as the stalk.

Table 81-2 Some Abbreviations Used for Description of Chromosomes and Their Abnormalities

ABBREVIATION	MEANING	EXAMPLE	CONDITION
XX	Female	46,XX	Normal female karyotype
XY	Male	46,XY	Normal male karyotype
[##]	Number [#] of cells	46,XY[12]/47,XXY[10]	Number of cells in each clone, typically inside brackets Mosaicism in Klinefelter syndrome with 12 normal cells and 10 cells with an extra X chromosome
cen	Centromere		
del	Deletion	46,XY,del(5p)	Male with deletion of chromosome 5 short arm
der	Derivative	46,XX,der(2),t(2p127q13)	Female with a structurally rearranged chromosome 2 that resulted from a translocation between chromosomes 2 and 7
dup	Duplication	46,XY,dup(15)(q11-13)	Male with interstitial duplication in the long arm of chromosome 15 in the Prader-Willi/Angelman syndrome region
ins	Insertion	46,XY,ins(3)(p13q21q26)	Male with an insertion within chromosome 3 A piece between q21q26 has reinserted on p13
inv	Inversion	46,XY,inv(2)(p21q31)	Male with pericentric inversion of chromosome 2 with breakpoints at bands p21 and q31

Table 81-2 Some Abbreviations Used for Description of Chromosomes and Their Abnormalities—cont'd

ABBREVIATION	MEANING	EXAMPLE	CONDITION
ish	Metaphase FISH	46,XX.ish del(7)(q11.23q11.23)	Female with deletion in the Williams syndrome region detected by in situ hybridization
nuc ish	Interphase FISH	nuc ish(DXZ1 × 3)	Interphase in situ hybridization showing 3 signals for the X chromosome centromeric region
mar	Marker	47,XY,+mar	Male with extra, unidentified chromosome material
mos	Mosaic	mos 45,X[14]/46,XX[16]	Turner syndrome mosaicism (analysis of 30 cells showed that 14 cells were 45,X and 16 cells were 46,XX)
p	Short arm	46,XY,del(5)(p12)	Male with a deletion on the short arm of chromosome 5, band p12 (short nomenclature)
q	Long arm	46,XY,del(5)(q14)	Male with a deletion on the long arm of chromosome 5, band 14
r	Ring chromosome	46,X,r(X)(p21q27)	Female with 1 normal X chromosome and a ring X chromosome
t	Translocation	t(2;8)(q33;q24.1)	The interchange of material between chromosomes 2 and 8 with breakpoints at bands 2q33 and 8q24.1
ter	Terminal	46,XY,del(5)(p12-pter)	Male with a deletion of chromosome 5 between p12 and the end of the short arm (long nomenclature)
/	Slash	45,X/46,XY	Separate lines or clones Mosaicism for monosomy X and a male cell line
+	Gain of	47,XX,+21	Female with trisomy 21
–	Loss of	45,XY,–21	Male with monosomy 21

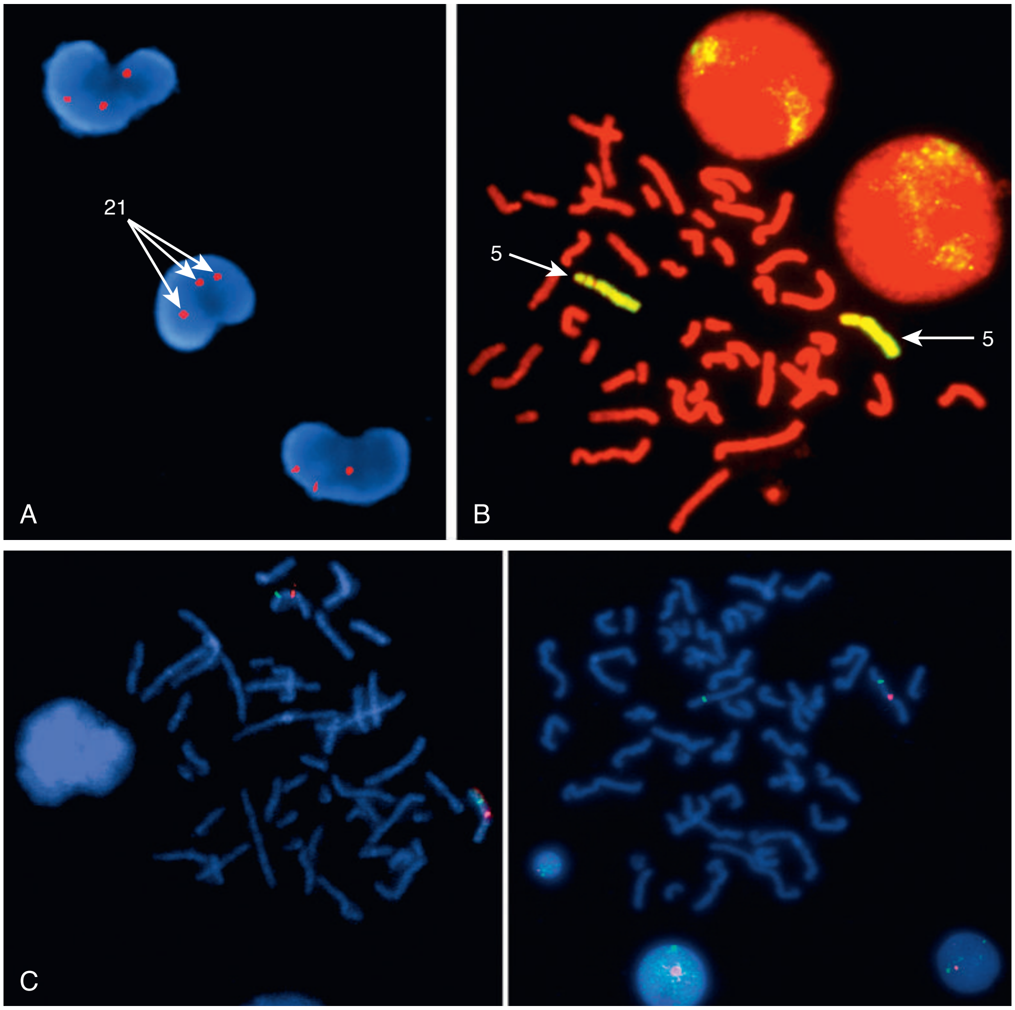

Figure 81-4 *A,* FISH analysis of interphase peripheral blood cells from a patient with Down syndrome using a chromosome 21-specific probe. The 3 red signals mark the presence of 3 chromosomes 21. *B,* FISH analysis of a metaphase chromosome spread from a clinically normal individual using a whole-chromosome paint specific for chromosome 5. Both chromosomes 5 are completely labeled *(yellow)* along their entire length. *C,* FISH on metaphase cells using a unique sequence probe that hybridizes to the elastin gene on chromosome 7q11.23, inside the Williams syndrome critical region. The elastin probe is labeled in *red*, and a control probe on chromosome 7 is labeled in *green*. The left image shows normal hybridization to chromosome 7, with 2 signals for the elastin region and 2 for the control probe. The right image shows a normal chromosome on the right with control and elastin signals, and a deleted chromosome 7 on the *left*, evidenced by a single signal for the control probe. This image corresponds to a patient with a Williams syndrome region deletion.

Continued

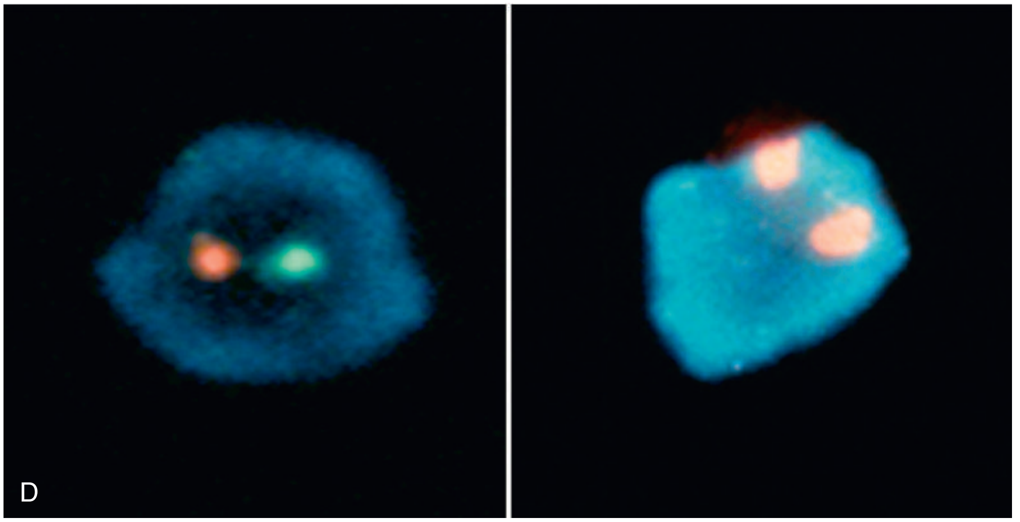

Figure 81-4, cont'd *D,* FISH in interphase cells using DNA probes that hybridize to repetitive α-satellite sequences in the pericentromeric region for the sex chromosomes. *Left,* interphase cells with 2 signals, 1 labeled in *red* for the X chromosome and *green* for the Y chromosome, consistent with a normal male chromosome complement. *Right,* interphase cell showing 2 *red* signals for the X chromosome, compatible with a normal female chromosome complement.

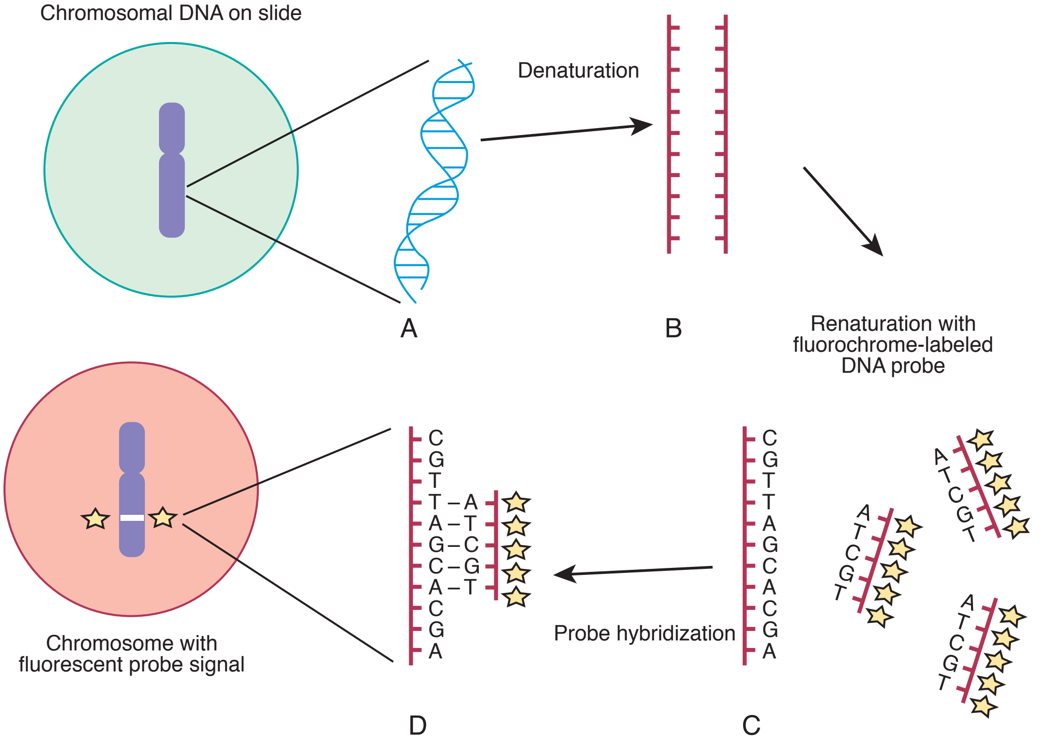

Figure 81-5 FISH involves denaturation of double-stranded DNA as present in metaphase chromosomes or interphase nuclei on cytogenetic slide preparations *(A)* into single-stranded DNA *(B).* The slide-bound (in situ) DNA is then renatured or reannealed in the presence of excess copies of a single-stranded, fluorochrome-labeled DNA base-pair sequence or probe *(C).* The probe anneals or "hybridizes" to sites of complementary DNA sequence *(D)* within the chromosomal genome. Probe signal is visualized and imaged on the chromosome by fluorescent microscopy. *(From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In Hyme HE, Greydanus D, editors:* Genetic disorders in adolescents: state of the art reviews. Adolescent medicine, *Philadelphia, 2002, Hanley and Belfus, pp. 305–313.)*

location of each probe copy can be documented and often the *number of copies* (deletions, duplications) of the DNA sequence as well. When the interrogated segments (as in genomic duplications) are close together, only interphase cells can accurately determine the presence of 2 or more copies or signals since in metaphase cells, some duplications might falsely appear as a single signal.

With high-resolution chromosome analysis it is very difficult to recognize deletions of <5 million bp (5 Mbp); FISH can reliably detect deletions as small as 50-200 kb of DNA. This has allowed the clinical characterization of a number of *microdeletion syndromes*. Other probes hybridize to repetitive sequences located to the pericentromeric regions. Pericentromeric probes are still widely used for the rapid identification of certain trisomies in interphase cells of blood smears, or even in the rapid analysis of prenatal samples from cells obtained through amniocentesis. Such probes are available for chromosomes 13, 18, and 21 and for the sex pair X and Y (see Fig. 81-4*C* and *D*). With regards to the detection of genomic disorders, FISH is no longer the first line of testing, and its role has also mostly changed to the confirmation of microarray findings.

Spectral karyotyping and **multicolor FISH** are similar molecular cytogenetic techniques that use 24 different chromosome painting probes and 5 fluorochromes to simultaneously visualize every chromosome in a metaphase spread. Each of the 24 different chromosome paints is labeled with a different combination of the 5 fluorescent dyes, which emit at different wavelengths. Each of the 22 autosomes and the X and Y chromosomes has its own unique spectrum of wavelengths of fluorescence. Special filters, cameras, and image-processing software are required to identify each chromosome. Spectral karyotyping and multicolor FISH are especially useful for identifying the complex chromosome rearrangements found in many tumors. This technique requires very special and costly equipment and is being displaced by comparative aCGH.

CGH is a molecular-based technique that involves differentially labeling the patient's DNA with a fluorescent dye (green) and a normal reference DNA with another fluorescent dye (red; Fig. 81-6). Equal amounts of the 2-label DNA samples are mixed and then used as a painting probe for FISH with normal metaphase chromosomes. The ratio of green : red fluorescence is measured along each chromosome. Regions of amplification of the patient's DNA display an excess of green fluorescence, and regions of loss show excess red fluorescence. If the patient's and the control DNA are equally represented, the green : red ratio is 1 : 1 and the chromosomes appear yellow.

A modified version of this technology, aCGH, uses DNA spotted onto a slide or **microarray** grid. In this case, instead of metaphase

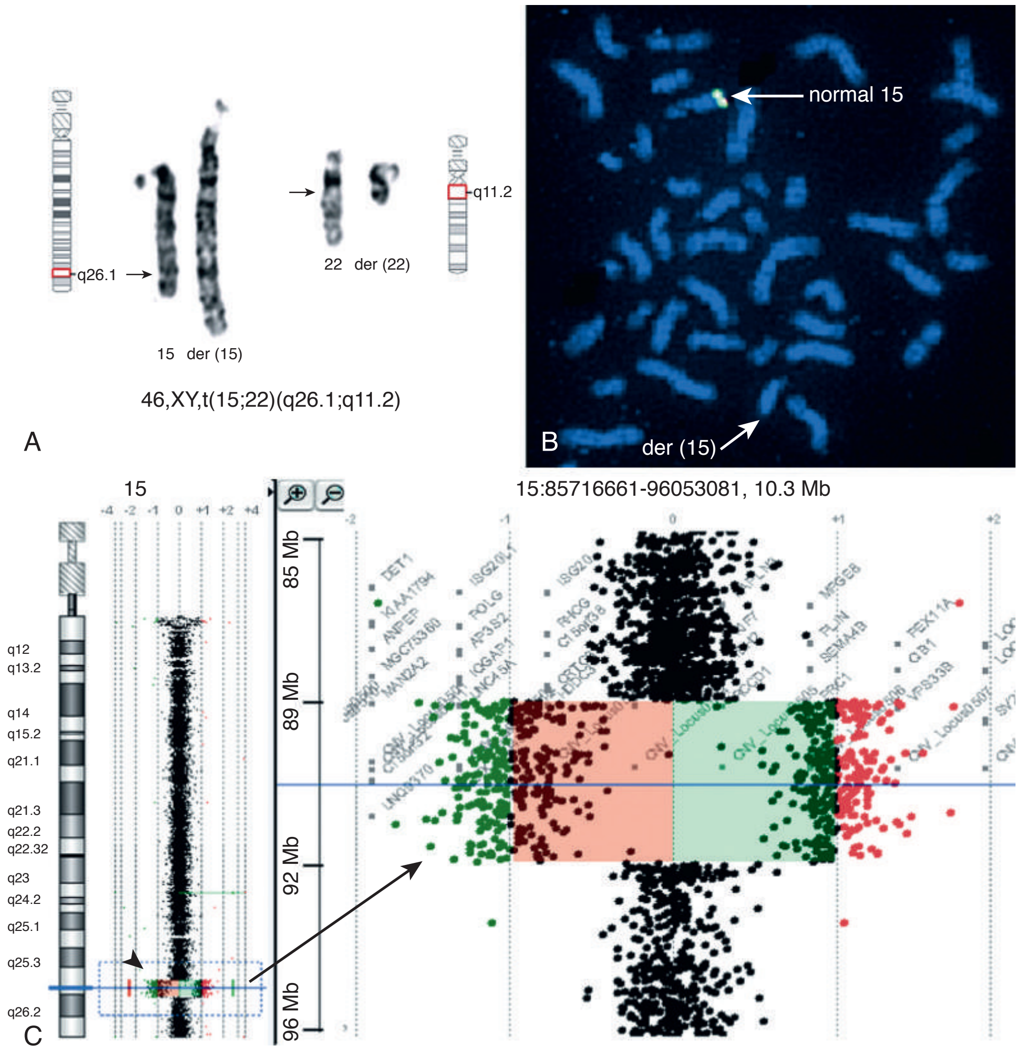

Figure 81-6 An example of a cryptic microdeletion at a translocation breakpoint of an apparently balanced translocation in a patient with DD and growth defect. *A*, Partial karyotype shows t(15;22)(q26.1;q11.2). *B*, FISH with clones 2O19 *(green)* and 354M14 *(red)* at 15q26.1; *arrows* indicate signals only present on the normal chromosome 15, suggesting a deletion on the der(15). *C*, Two-color aCGH with dye swap with 244 K oligo probes; *arrowhead* indicates a 3.3-Mbp deletion at chromosome 15q26.1-q26.2, *arrow* points to the close-up view of the deletion. *(From Li MM, Andersson HC: Clinical application of microarray-based molecular cytogenetics: an emerging new era of genomic medicine,* J Pediatr *155:311-317, 2009, with permission of the authors and publisher.)*

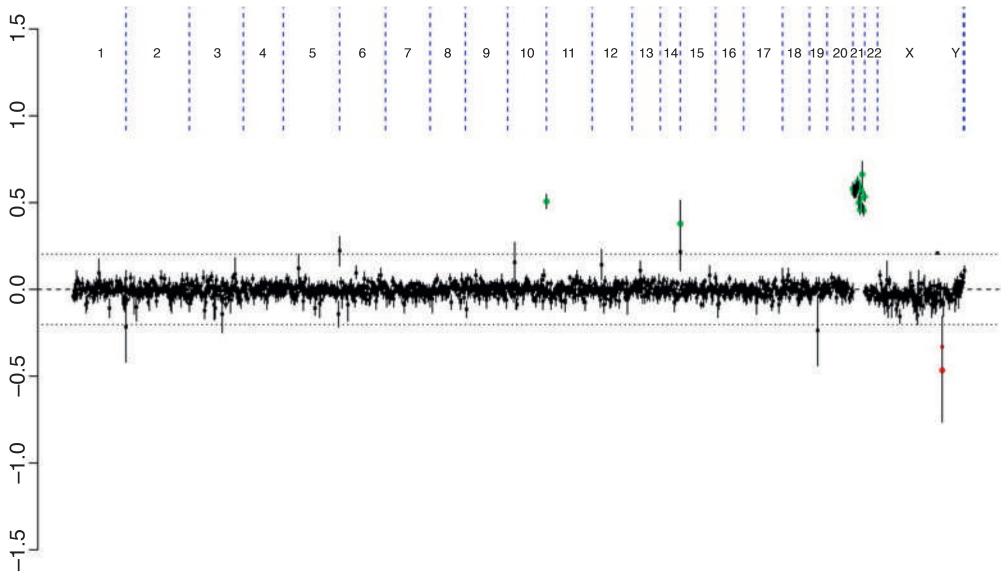

Figure 81-7 aCGH in a female patient with Down syndrome. Each *black dot* represents a piece of DNA segment specific for different chromosome location. Most of the dots displayed between the 0.0 and 0.2 axis are considered within normal range. Exceptions are often a result of polymorphic variations. A group of dots colored in *green* clusters on chromosome 21 and above 0.5. Those represent a *gain* in copy number of DNA segments for chromosome 21 as seen in Down syndrome and consistent with trisomy 21.

chromosomes, segments of DNA are represented by oligonucleotides (short DNA segments) distributed in a microarray that resembles the chromosomes in a metaphase. The detection is currently possible at the single exon resolution level depending on the arrays employed.

There are many advantages of aCGH. It can test all critical disease-causing regions in the genome at once; FISH requires the clinical knowledge and tests only 1 area at a time. aCGH can detect duplications and deletions not currently recognized as recurrent disease-causing regions probed by FISH. aCGH can detect single and contiguous gene deletion syndromes. aCGH does not always require cell culture to generate sufficient DNA, something that may be important in the context of prenatal testing because of timing. There are disadvantages to aCGH: It does not detect balanced translocations, inversions, or very low-levels of mosaicism.

There are different types of aCGH; some of them are more targeted while others have whole-genome coverage. **Targeted aCGH** is an effective and efficient technique for detecting clinically known cryptic chromosomal aberrations, which are typically associated with known disease phenotypes; many of these arrays have expanded detection to areas potentially susceptible to recurring deletion or duplication. **Whole-genome arrays** target the entire genome. The advantage of this latter technique is that it allows better and denser coverage of the entire genome in evenly spaced portions; its disadvantage is that interpretation of deletions or duplications may be difficult if it involves areas not previously known to be involved in disease. There is a new type of array being used in the clinical setting and that is the so-called single nucleotide polymorphism (SNP) array. SNPs are polymorphic variations between 2 nucleotides and when analyzed in massive parallel fashion, they can provide very valuable clinical information. Several million SNPs normally occur in the human genome. SNP arrays can help with the detection of uniparental disomies as well as consanguinity. Many arrays currently used in clinical practice combine the use of oligonucleotides for the detection of copy number variations in conjunction with SNPs.

There are many **copy number variations** causing deletion or duplication in the human genome. Thus, most detected genetic abnormalities, unless associated with very well-known clinical phenotypes, require *parental investigations* because a detected copy number variation that is inherited might turn out to be an incidental polymorphic variant. A de novo abnormality (i.e., one found only in the child and not the parents) is often more significant if it is associated with an abnormal phenotype found only in the child and if it involves genes with important functions. aCGH is a very valuable technology alone or when combined with FISH and conventional chromosome studies (Fig. 81-7).

Bibliography is available at Expert Consult.

81.2 Down Syndrome and Other Abnormalities of Chromosome Number

Brendan Lee

ANEUPLOIDY AND POLYPLOIDY

Human cells contain a multiple of 23 chromosomes (n = 23). A haploid cell (n) has 23 chromosomes (typically in the ovum or sperm). If a cell's chromosomes are an exact multiple of 23 (46, 69, 92 in humans), those cells are referred to as euploid. **Polyploid** cells are euploid cells with more than the normal **diploid** number of 46 (2n) chromosomes: 3n, 4n. Polyploid conceptions are usually not viable, but the presence of mosaicism with a karyotypically normal line can allow survival. Mosaicism is an abnormality defined as the presence of 2 or more cell lines in a single individual. Polyploidy is a common abnormality seen in 1st-trimester pregnancy losses. **Triploid cells** are those with 3 haploid sets of chromosomes (3n) and are only viable in a mosaic form. Triploid infants can be liveborn but do not survive long. Triploidy is often the result of fertilization of an egg by 2 sperm (dispermy). Failure of 1 of the meiotic divisions, resulting in a diploid egg or sperm, can also result in triploidy. The phenotype of a triploid conception depends on the origin of the extra chromosome set. If the extra set is of **paternal** origin, it results in a partial hydatidiform mole with poor embryonic development, but triploid conceptions that have an extra set of **maternal** chromosomes results in severe embryonic retardation with a small fibrotic placenta that is typically spontaneously aborted.

Abnormal cells that do not contain a multiple of haploid number of chromosomes are termed **aneuploid** cells. Aneuploidy is the most common and clinically significant type of human chromosome abnormality, occurring in at least 3-4% of all clinically recognized pregnancies. **Monosomies** occur when only 1, instead of the normal 2, of a given chromosome is present in an otherwise diploid cell. In humans,

most autosomal monosomies appear to be lethal early in development, and survival is possible in **mosaic forms** or by means of chromosome rescue (restoration of the normal number by duplication of single monosomic chromosome). An exception to this rule is monosomy for the X chromosome (45,X), seen in Turner syndrome; it has been estimated that the majority of 45,X conceptuses are lost early in pregnancy for as yet unexplained reasons.

The most common cause of aneuploidy is **nondisjunction,** the failure of chromosomes to disjoin normally during meiosis (see Fig. 81-1). Nondisjunction can occur during meiosis I or II or during mitosis. After meiotic nondisjunction, the resulting gamete either lacks a chromosome or has 2 copies instead of 1 normal copy, resulting in a monosomic or trisomic zygote, respectively.

Trisomy is characterized by the presence of 3 chromosomes, instead of the normal 2, of any particular chromosome. Trisomy is the most common form of aneuploidy. Trisomy can occur in all cells or it may be mosaic. Most individuals with trisomy exhibit a consistent and specific phenotype depending on the chromosome involved.

FISH is a technique that can be used for rapid diagnosis in the prenatal detection of common fetal aneuploidies including chromosomes 13, 18, and 21, as well as sex chromosomes (see Fig. 81-4*C* and *D*). The most common numerical abnormalities in liveborn children include trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), and sex chromosomal aneuploidies: Turner syndrome (usually 45,X), Klinefelter syndrome (47,XXY), 47,XXX, and 47,XYY, By far the most common type of trisomy in liveborn infants is trisomy 21 (47,XX,+21 or 47,XY,+21) (see Table 81-1). Trisomy 18 and trisomy 13 are relatively less common and are associated with a characteristic set of congenital anomalies and severe intellectual disability (Table 81-3). The occurrence of trisomy 21 and other trisomies increases with advanced maternal age (≥35 yr). Owing to this increased risk, women who are ≥35 yr at the time of delivery should be offered genetic counseling and prenatal diagnosis (including serum screening, ultrasonography, and amniocentesis or chorionic villus sampling; see Chapter 96).

DOWN SYNDROME

Trisomy 21 is the most common genetic cause of moderate intellectual disability. The incidence of Down syndrome in live births is approximately 1 in 733; the incidence at conception is more than twice that rate; the difference is accounted by early pregnancy losses. In addition to cognitive impairment, Down syndrome is associated with congenital anomalies and characteristic dysmorphic features (Figs. 81-8 and 81-9; Table 81-4). Although there is variability in the clinical features, the constellation of phenotypic features is fairly consistent and permits clinical recognition of trisomy 21. Affected individuals are more prone to congenital heart defects (50%) such as atrioventricular septal defects, ventricular septal defects, isolated secundum atrial septal defects,

Table 81-3 Chromosomal Trisomies and Their Clinical Findings

SYNDROME	INCIDENCE	CLINICAL MANIFESTATIONS
Trisomy 13, Patau syndrome	1/10,000 births	Cleft lip often midline; flexed fingers with postaxial polydactyly; ocular hypotelorism, bulbous nose; low-set, malformed ears; microcephaly; cerebral malformation, especially holoprosencephaly; microphthalmia, cardiac malformations; scalp defects; hypoplastic or absent ribs; visceral and genital anomalies Early lethality in most cases, with a median survival of 7 days; ~91% die by 1 year. Survivors have significant neurodevelopmental delay
Trisomy 18, Edwards syndrome	1/6,000 births	Low birthweight, closed fists with index finger overlapping the 3rd digit and the 5th digit overlapping the 4th, narrow hips with limited abduction, short sternum, rocker-bottom feet, microcephaly, prominent occiput, micrognathia, cardiac and renal malformations, and intellectual disability ~92% of children die in the first year; with full support ~25% may survive 1 yr. Survivors have significant neurodevelopmental delay
Trisomy 8, mosaicism	1/20,000 births	Long face, high prominent forehead, wide upturned nose, thick everted lower lip, microretrognathia, low-set ears, high arched, sometimes cleft, palate; osteoarticular anomalies common (camptodactyly of 2nd to 5th digits, small patella); deep plantar and palmar creases; moderate intellectual disability

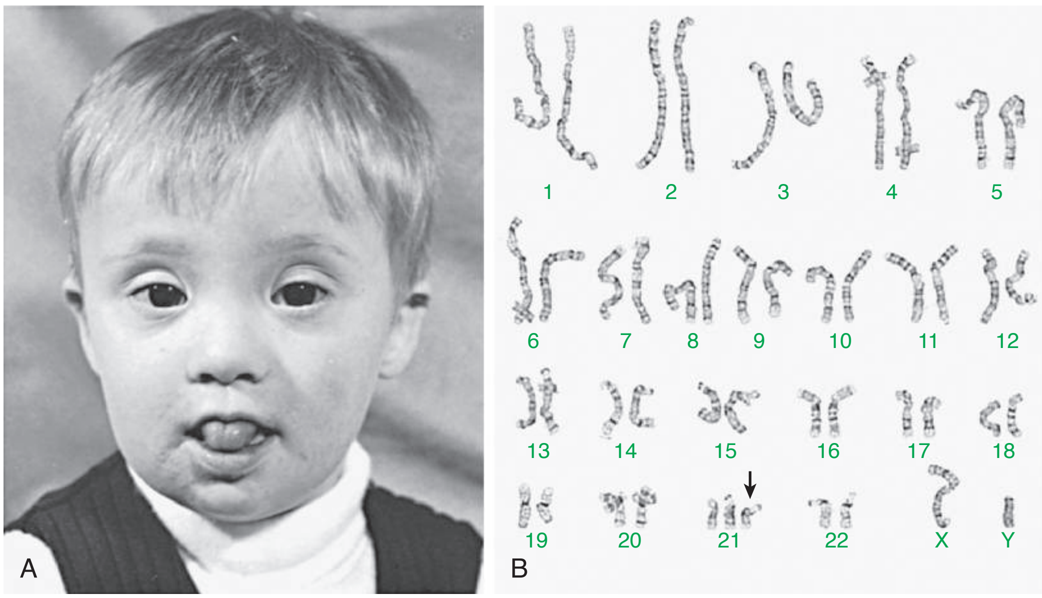

Figure 81-8 *A*, Face of a child with Down syndrome. *B*, Karyotype of a male with trisomy 21 as seen in Down syndrome. This karyotype reveals 47 chromosomes instead of 46, with an extra chromosome in pair 21.

Figure 81-9 Prehensile foot in a 1 mo old child with Down syndrome. *(From Wiedemann HR, Kunze J, Dibbern H:* Atlas of clinical syndromes: a visual guide to diagnosis, *ed 3, St. Louis, 1989, Mosby.)*

patent ductus arteriosus, and tetralogy of Fallot. Congenital and acquired gastrointestinal anomalies and hypothyroidism are common (Table 81-5). Other abnormalities include megakaryoblastic leukemia, immune dysfunction, diabetes mellitus, and problems with hearing and vision (Table 81-5). Alzheimer disease–like dementia is a known complication that occurs as early as the 4th decade and has an incidence 2-3 times higher than sporadic Alzheimer disease. Most males with Down syndrome are sterile, but some females have been able to reproduce, with a 50% chance of having trisomy 21 pregnancies. Two genes (*DYRK1A, DSCR1*) in the putative critical region of chromosome 21 may be targets for therapy.

Developmental delay is universal (Tables 81-6 and 81-7; Fig. 81-10). Cognitive impairment does not uniformly affect all areas of development. Social development is relatively spared, but children with Down syndrome have considerable difficulty using expressive language. Understanding these individual developmental strengths will maximize the educational process for children with Down syndrome. Persons with Down syndrome often benefit from programs aimed at stimulation, development, and education. These programs are most effective in addressing social skills that often appear advanced for the intellectual delay. Children with Down syndrome also benefit from anticipatory guidance, which establishes the protocol for screening, evaluation, and care for patients with genetic syndromes and chronic disorders (Table 81-8). Up to 15% of children with Down syndrome have misalignment of cervical vertebra C1, which places them at risk for spinal cord injury with neck hyperextension or extreme flexion. Special Olympics recommends sports participation and training but requires x-ray examination (full extension and flexion views) of the neck prior to participation in sports that may result in hyperextension or radical flexion or pressure on the neck or upper spine; sports include diving starts in swimming, butterfly stroke, diving, pentathlon, high jump, equestrian sports, gymnastics, football, soccer, alpine skinning, and warm up exercises placing stress on the head and neck. If atlantoaxial instability is diagnosed, Special Olympics will permit participation if the parents or guardians request so and only after obtaining written certification from a physician and acknowledgment of the risks by the parent or guardian.

The majority of children with Down syndrome do not have behavior problems. It is estimated that psychiatric comorbidity is 18-38% in this population. These estimates are higher than in unaffected children, but they are lower than in children with similar levels of intellectual disability from other etiologies. All maladaptive behaviors in persons with Down syndrome are thought to be inherently linked to cognitive impairment. Common behavioral difficulties that occur in children with Down syndrome include inattentiveness, stubbornness, and a need for routine and sameness. Aggression and self-injurious behavior are less common in this population. All of these behaviors can respond to educational or pharmacologic interventions.

The life expectancy for children with Down syndrome is reduced and is approximately 50-55 yr. Little prospective information about the secondary medical problems of adults with Down syndrome is known. Retrospective studies have shown premature aging and an increased risk of Alzheimer disease in adults with Down syndrome. These studies have also shown unexpected negative associations between Down syndrome and other medical comorbidities. Persons with Down syndrome have fewer than expected deaths caused by solid tumors and ischemic heart disease. This same study reported increased risk of adult deaths due to congenital heart disease, seizures, and leukemia. In one large study, leukemias accounted for 60% of all cancers in people with Down

syndrome and 97% of all cancers in children with Down syndrome. There was decreased risk of solid tumors in all age groups, including neuroblastomas and nephroblastomas in children with Down syndrome and epithelial tumors in adults with Down syndrome.

Most adults with Down syndrome are able to perform activities of daily living. However, most adults with Down syndrome have difficulty with complex financial, legal, or medical decisions. In most circumstances, a conservator is appointed for the adult with Down syndrome.

The risk of having a child with trisomy 21 is highest in women who conceive at >35 yr of age. Even though younger women have a lower risk, they represent half of all mothers with babies with Down syndrome because of their higher overall birth rate. *All women should be offered screening for Down syndrome* in their 2nd trimester by means of 4 maternal serum tests (free β-human chorionic gonadotropin [β-hCG], unconjugated estriol, inhibin, and α-fetoprotein). This is

Table 81-8 Health Supervision for Children with Down Syndrome

CONDITION	TIME TO SCREEN	COMMENT
Congenital heart disease	Birth; by pediatric cardiologist Young adult for acquired valve disease	50% risk of congenital heart disease; increased risk for pulmonary hypertension
Strabismus, cataracts, nystagmus	Birth or by 6 mo; by pediatric ophthalmologist **Check vision annually**	Cataracts occur in 15%, refractive errors in 50%
Hearing impairment or loss	Birth or by 3 mo with auditory brainstem response or otoacoustic emission testing; check hearing q6mo up to 3 yr if tympanic membrane is not visualized; **annually thereafter**	Risk for congenital hearing loss plus 50-70% risk of serous otitis media
Constipation	Birth	Increased risk for Hirschsprung disease
Celiac disease	At 2 yr or with symptoms	Screen with IgA and tissue transglutaminase antibodies
Hematologic disease	At birth and in adolescence or if symptoms develop	Increased risk for neonatal polycythemia (18%), leukemoid reaction, leukemia (<1%)
Hypothyroidism	Birth; repeat at 6-12 mo and **annually**	Congenital (1%) and acquired (5%)
Growth and development	At each visit Use Down syndrome growth curves	Discuss school placement options Proper diet to avoid obesity
Obstructive sleep apnea	Start at ~1 yr and at each visit	Monitor for snoring, restless sleep
Atlantoaxial subluxation or instability (incidence 10-30%)	At each visit by history and physical exam Radiographs at 3-5 yr or when planning to participate in contact sports Radiographs indicated wherever neurologic symptoms are present even if transient (neck pain, torticollis, gait disturbances, weakness) Many are asymptomatic	Special Olympics recommendations are to screen for high-risk sports, e.g., diving, swimming, contact sports
Gynecologic care	Adolescent girls	Menstruation and contraception issues
Recurrent infections	When present	Check IgG subclass and IgA levels
Psychiatric, behavioral disorders	At each visit	Depression, anxiety, obsessive-compulsive disorder, schizophrenia seem in 10-17% Autism spectrum disorder in 5-10% Early-onset Alzheimer disease

IgA, immunoglobulin A; IgG, immunoglobulin G.

Data from Committee on Genetics: Health supervision for children with Down syndrome, Pediatrics *107:442-449, 2001; and Baum RA, Spader M, Nash PL, et al: Primary care of children and adolescents with Down syndrome: an update,* Curr Probl Pediatr Adolesc Health Care *38:235–268, 2008.*

known as the *quad screen;* it can detect up to 80% of Down syndrome pregnancies compared to 70% in the triple screen. Both tests have a 5% false-positive rate. There is a method of screening during the 1st trimester using fetal nuchal translucency (NT) thickness that can be done alone or in conjunction with maternal serum β-hCG and pregnancy-associated plasma protein-A (PAPP-A). In the 1st trimester, NT alone can detect ≤70% of Down syndrome pregnancies, but with β-hCG and PAPP-A, the detection goes up to 87%. If both 1st and 2nd trimester screens are combined using NT and biochemical profiles (integrated screen), the detection rate goes up to 95%. If only 1st trimester quad screening is done, maternal serum α-fetoprotein (which is decreased in affected pregnancies) is recommended as a 2nd trimester follow-up.

Detection of cell free fetal DNA in maternal plasma is also diagnostic. The noninvasive detection of fetal trisomy 21 by analyzing cell-free fetal DNA in maternal serum is an important advance in prenatal diagnosis of Down syndrome. Next-generation DNA sequencing has reduced the cost of this procedure, which has a high degree of accuracy (98% detection rate) and applicability. The prenatal screens are also useful for other trisomies, although the detection rates may be different from those given for Down syndrome.

In approximately 95% of the cases of Down syndrome there are 3 copies of chromosome 21. The origin of the supernumerary chromosome 21 is maternal in 97% of the cases as a result of errors in meiosis. The majority of these occur in maternal meiosis I (90%). Approximately 1% of persons with trisomy 21 are mosaics, with some cells having 46 chromosomes, and another 4% have a **translocation** that involves chromosome 21. The majority of translocations in Down syndrome are fusions at the centromere between chromosomes 13, 14, 15, 21, and 22 known as *Robertsonian translocations.* The translocations can be de novo or inherited. Very rarely is Down syndrome diagnosed in a patient with only a part of the long arm of chromosome 21 in triplicate **(partial trisomy).** Isochromosomes and ring chromosomes are other rarer causes of trisomy 21. Down syndrome patients without a visible chromosome abnormality are the least common. It is not possible to distinguish the phenotypes of persons with full trisomy 21 and those with a translocation. Representative genes on chromosome 21 and their potential effects on development are noted in Table 81-9. Patients who are mosaic tend to have a milder phenotype.

Chromosome analysis is indicated in every person suspected of having Down syndrome. If a translocation is identified, parental chromosome studies must be performed to determine whether one of the parents is a translocation carrier, which carries a high recurrence risk for having another affected child. That parent might also have other family members at risk. Translocation (21;21) carriers have a 100% recurrence risk for a chromosomally abnormal child, and other Robertsonian translocations, such as t(14;21), have a 5-7% recurrence risk when transmitted by females. Genomic dosage imbalance contributes through direct and indirect pathways to the Down syndrome phenotype and its phenotypic variation.

Tables 81-10 and 81-11 provide more information on other aneuploidies and partial autosomal aneuploidies (Figs. 81-11 to 81-14).

Bibliography is available at Expert Consult.

Table 81-9 Genes Localized to Chromosome 21 That Possibly Affect Brain Development, Neuronal Loss, and Alzheimer Type Neuropathology

SYMBOL	NAME	POSSIBLE EFFECT IN DOWN SYNDROME	FUNCTION
SIM2	Single-minded homolog 2	Brain development	Required for synchronized cell division and establishment of proper cell lineage
DYRK1A	Dual-specificity tyrosine-(Y)-phosphorylation regulated kinase 1A	Brain development	Expressed during neuroblast proliferation Believed important homolog in regulating cell-cycle kinetics during cell division
GART	Phosphoribosylglycinamide formyltransferase Phosphoribosylglycinamide synthetase Phosphoribosylaminoimidazole synthetase	Brain development	Expressed during prenatal development of the cerebellum
PCP4	Purkinje cell protein 4	Brain development	Function unknown but found exclusively in the brain and most abundantly in the cerebellum
DSCAM	Down syndrome cell adhesion molecule	Brain development and possible candidate gene for congenital heart disease	Expressed in all molecule regions of the brain and believed to have a role in axonal outgrowth during development of the nervous system
GRIK1	Glutamate receptor, ionotropic kainite1	Neuronal loss	Function unknown, found in the cortex in fetal and early postnatal life and in adult primates, most concentrated in pyramidal cells in the cortex
APP	Amyloid beta (A4) precursor protein (protease nexin-II, Alzheimer disease)	Alzheimer type neuropathy	Seems to be involved in plasticity, neurite outgrowth, and neuroprotection
S100B	S100 calcium binding protein β (neural)	Alzheimer type neuropathy	Stimulates glial formation
SOD1	Superoxide dismutase 1, soluble (amyotrophic lateral sclerosis, adult)	Accelerated aging?	Scavenges free superoxide molecules in the cell and might accelerate aging by producing hydrogen peroxide and oxygen

Table 81-10 Other Rare Aneuploidies and Partial Autosomal Aneuploidies

DISORDER	KARYOTYPE	CLINICAL MANIFESTATIONS
Trisomy 8	47,XX/XY,+8	Growth and mental deficiency are variable The majority of patients are mosaics Deep palmar and plantar furrows are characteristic
Trisomy 9	47,XX/XY,+9	The majority of patients are mosaics Clinical features include craniofacial (high forehead, microphthalmia, low-set malformed ears, bulbous nose) and skeletal (joint contractures) malformations and heart defects (60%)
Trisomy 16	47,XX/XY,+16	The most commonly observed autosomal aneuploidy in spontaneous abortion; the recurrence risk is negligible
Tetrasomy 12p	46,XX[12]/46,XX, +i(12p)[8] (mosaicism for an isochromosome 12p)	Known as Pallister-Killian syndrome. Sparse anterior scalp hair, eyebrows, and eyelashes, prominent forehead, chubby cheeks, long philtrum with thin upper lip and cupid-bow configuration, polydactyly, and streaks of hyper- and hypopigmentation

81.3 Abnormalities of Chromosome Structure

Carlos A. Bacino and Brendan Lee

TRANSLOCATIONS

Translocations, which involve the transfer of material from 1 chromosome to another, occur with a frequency of 1 in 500 liveborn human infants. They may be inherited from a carrier parent or appear de novo, with no other affected family member. Translocations are commonly reciprocal or Robertsonian, involving 2 chromosomes (Fig. 81-15).

Reciprocal translocations are the result of breaks in nonhomologous chromosomes, with reciprocal exchange of the broken segments. Carriers of a reciprocal translocation are usually phenotypically normal but are at an increased risk for miscarriage caused by transmission of unbalanced reciprocal translocations and for bearing chromosomally abnormal offspring. Unbalanced translocations are the result of abnormalities in the segregation or crossover of the translocation carrier chromosomes in the germ cells.

Robertsonian translocations involve 2 acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) that fuse near the centromeric region with a subsequent loss of the short arms. Because the short arms of all 5 pairs of acrocentric chromosomes have multiple copies of genes for ribosomal RNA, loss of the short arm of 2 acrocentric chromosomes has no deleterious effect. The resulting karyotype has only 45 chromosomes, including the translocated chromosome that is made up of the long arms of the 2 fused chromosomes. Carriers of Robertsonian translocations are usually phenotypically normal.

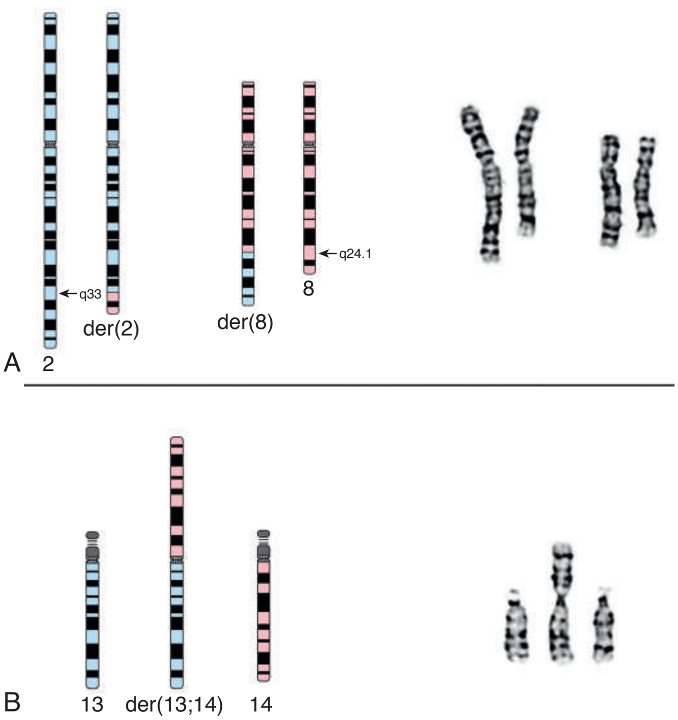

Figure 81-15 *A,* Schematic diagram *(left)* and partial G-banded karyotype *(right)* of a reciprocal translocation between chromosome 2 *(blue)* and chromosome 8 *(pink)*. The breakpoints are on the long *(q)* arm of both chromosomes at bands 2q33 and 8q24.1, with the reciprocal exchange of material between the derivative *(der)* chromosomes 2 and 8. This translocation is balanced, with no net gain or loss of material. The nomenclature for this exchange is t(2;8)(q33:q24.1). *B,* Schematic diagram *(left)* and partial G-banded karyotype *(right)* of a Robertsonian translocation between chromosomes 13 *(blue)* and 14 *(pink)*. The breakpoints are at the centromere (band q10) of both chromosomes, with fusion of the long arms into a single derivative chromosome and loss of the short *(p)* arm material. The nomenclature for this exchange is der(13;14)(q10;q10).

However, they are at increased risk for miscarriage and unbalanced translocations in phenotypically abnormal offspring.

In some rare instances, translocations can involve 3 or more chromosomes, as seen in complex rearrangements. Another, less common type is the insertional translocation. Insertional translocations result from a piece of chromosome material that breaks away and later is reinserted inside the same chromosome at a different site or inserted in another chromosome.

INVERSIONS

An inversion requires that a single chromosome break at 2 points; the broken piece is then inverted and joined into the same chromosome. Inversions occur in 1 in 100 live births. There are 2 types of inversions: pericentric and paracentric. In **pericentric inversions,** the breaks are in the 2 opposite arms of the chromosome and include the centromere. They are usually discovered because they change the position of the centromere. The breaks in **paracentric inversions** occur in only 1 arm. Carriers of inversions are usually phenotypically normal, but they are at increased risk for miscarriages, typically in paracentric inversions, and chromosomally abnormal offspring in pericentric inversions.

DELETIONS AND DUPLICATIONS

Deletions involve loss of chromosome material and, depending on their location, they can be classified as **terminal** (at the ends of chromosomes) or **interstitial** (within the arms of a chromosome). They may be isolated or they may occur along with a duplication of another chromosome segment. The latter typically occurs in unbalanced reciprocal chromosomal translocation secondary to abnormal crossover or segregation in a translocation or inversion carrier.

A carrier of a deletion is monosomic for the genetic information of the missing segment. Deletions are usually associated with intellectual disability and malformations. The most commonly observed deletions in routine chromosome preparations include 1p–, 4p–, 5p–, 9p–, 11p–, 13q–, 18p–, 18q–, and 21q– (Table 81-12 and Fig. 81-16), all distal or terminal deletions of the short or the long arms of chromosomes. Deletions may be observed in routine chromosome preparations, and deletions and translocations larger than 5-10 Mbp are usually visible microscopically.

High-resolution banding techniques, FISH, and molecular studies like aCGH can reveal deletions that are too small to be seen in ordinary or routine chromosome spreads (see Fig. 81-7). **Microdeletions** involve loss of small chromosome regions, the largest of which are detectable only with prophase chromosome studies and/or molecular methods. For submicroscopic deletions, the missing piece can only be detected using molecular methodologies such as DNA-based studies like aCGH or FISH. The presence of extra genetic material from the same chromosome is referred to as **duplication.** Duplications can also be sporadic or result from abnormal segregation in translocation or inversion carriers.

Microdeletions and microduplications usually involve regions that include several genes, so that the affected individuals can have a distinctive phenotype depending on the number of genes involved. When such a deletion involves more than a single gene, the condition is referred to as a **contiguous gene deletion syndrome** (Table 81-13). With the advent of clinically available aCGH, a large number of duplications, most of them microduplications, have been uncovered. Most of those **microduplication syndromes** are the reciprocal duplications of the known deletions or microdeletion counterparts and have distinctive clinical features (Table 81-14).

Subtelomeric regions are often involved in chromosome rearrangements that cannot be visualized using routine cytogenetics. Telomeres, which are the distal ends of the chromosomes, are gene-rich regions. The distal structure of the telomeres is essentially common to all chromosomes, but proximal to those, there are unique regions known as subtelomeres, which typically involved in deletions and most other chromosome rearrangements. Small subtelomeric deletions, duplications, or rearrangements (translocations, inversions) may be relatively common in nonspecific intellectual disability with minor anomalies. Subtelomeric rearrangements have been found in 3-7% of children

Table 81-12 Common Deletions and Their Clinical Manifestations

DELETION	CLINICAL ABNORMALITIES
4p–	Wolf-Hirschhorn syndrome. The main features are a typical “Greek helmet” facies secondary to ocular hypertelorism, prominent glabella, and frontal bossing; microcephaly, dolichocephaly, hypoplasia of the orbits, ptosis, strabismus, nystagmus, bilateral epicanthic folds, cleft lip and palate, beaked nose with prominent bridge, hypospadias, cardiac malformations, and intellectual disability.
5p–	Cri-du-chat syndrome. The main features are hypotonia, short stature, characteristic shrill cry in the first few weeks of life (cat-like cry), microcephaly with protruding metopic suture, hypertelorism, bilateral epicanthic folds, high arched palate, wide and flat nasal bridge, and intellectual disability.
9p–	The main features are craniofacial dysmorphology with trigonocephaly, slanted palpebral fissures, discrete exophthalmos secondary to supraorbital hypoplasia, arched eyebrows, flat and wide nasal bridge, short neck with low hairline, genital anomalies, long fingers and toes with extra flexion creases, cardiac malformations, and intellectual disability.
13q–	The main features are low birthweight, failure to thrive, microcephaly, and severe intellectual disability. Facial features include high wide nasal bridge, hypertelorism, ptosis, micrognathia. Ocular malformations are common (retinoblastoma). The hands have hypoplastic or absent thumbs and syndactyly.
18p–	A few patients (15%) are severely affected and have cephalic and ocular malformations: holoprosencephaly, cleft lip and palate, ptosis, epicanthal folds, and varying degrees of intellectual disability. Most (80%) have only minor malformations and mild intellectual disability.
18q–	Growth deficiency, hypotonia with “frog-like” position with the legs flexed, externally rotated, and in hyperabduction. The face is characteristic with depressed midface and apparent protrusion of the mandible, deep-set eyes, short upper lip, everted lower lip (“carp-like” mouth); antihelix of the ears is very prominent; varying degrees of intellectual disability and belligerent personality. Myelination abnormalities in the central nervous system.

Table 81-13 Microdeletion and Contiguous Gene Syndromes and Their Clinical Manifestations

DELETION	SYNDROME	CLINICAL MANIFESTATIONS
1p36	1p deletion	Growth restriction, dysmorphic features with midface hypoplasia, straight thin eyebrows, pointy chin, sensorineural hearing loss, progressive cardiomyopathy, hypothyroidism, seizures, intellectual disability
5q35	Sotos (50% are deletions of *NSD1* gene in Asians but only 6% in whites)	Overgrowth, macrocephaly, prominent forehead, prominence of extraaxial fluid spaces on brain imaging, large hands and feet, hypotonia, clumsiness, mental disabilities
6p25	Axenfeld-Rieger	Axenfeld-Rieger malformation, hearing loss, congenital heart defects, dental anomalies, developmental delays, facial dysmorphism
7q11.23	Williams	Round face with full cheeks and lips, long philtrum, stellate pattern in iris, strabismus, supravalvular aortic stenosis and other cardiac malformations, varying degrees of intellectual disability, friendly personality
8p11	8p11	Kallmann syndrome 2 (hypogonadotropic hypogonadism and anosmia), spherocytosis (deletions of ankyrin 1), multiple congenital anomalies, intellectual disability
8q24.1-q24.13	Langer-Giedion or trichorhinophalangeal type II	Sparse hair, multiple cone-shaped epiphyses, multiple cartilaginous exostoses, bulbous nasal tip, thickened alar cartilage, upturned nares, prominent philtrum, large protruding ears, mild intellectual disability
9q22	Gorlin	Multiple basal cell carcinomas, odontogenic keratocysts, palmoplantar pits, calcification falx cerebri
9q34	9q34 deletion	Distinct face with synophrys, anteverted nares, tented upper lip, protruding tongue, midface hypoplasia, conotruncal heart defects, intellectual disability
10p12-p13	DiGeorge 2	Many of the DiGeorge 1 and velocardiofacial 1 features (conotruncal defects, immunodeficiency, hypoparathyroidism, dysmorphic features)
11p11.2	Potocki-Shaffer	Multiple exostoses, parietal foramina, craniosynostosis, facial dysmorphism, syndactyly, intellectual disability
11p13	WAGR	Hypernephroma (Wilms tumor), aniridia, male genital hypoplasia of varying degrees, gonadoblastoma, long face, upward slanting palpebral fissures, ptosis, beaked nose, low-set poorly formed auricles, intellectual disability
11q24.1-11qter	Jacobsen	Growth restriction, intellectual disability, cardiac and digit anomalies, thrombocytopenia
15q11-q13 (paternal)	Prader-Willi	Severe hypotonia and feeding difficulties at birth, voracious appetite and obesity in infancy, short stature (responsive to growth hormone), small hands and feet, hypogonadism, intellectual disability

Table 81-13 Microdeletion and Contiguous Gene Syndromes and Their Clinical Manifestations—cont'd

DELETION	SYNDROME	CLINICAL MANIFESTATIONS
15q11-q13 (maternal)	Angelman	Hypotonia, feeding difficulties, gastroesophageal reflux, fair hair and skin, midface hypoplasia, prognathism, seizures, tremors, ataxia, sleep disturbances, inappropriate laughter, poor or absent speech, severe intellectual disability
16p13.3	Rubinstein-Taybi	Microcephaly, ptosis, beaked nose with low-lying philtrum, broad thumbs and large toes, intellectual disability
17p11.2	Smith-Magenis	Brachycephaly, midfacial hypoplasia, prognathism, myopia, cleft palate, short stature, severe behavioral problems, intellectual disability
17p13.3	Miller-Dieker	Microcephaly, lissencephaly, pachygyria, narrow forehead, hypoplastic male external genitals, growth restriction, seizures, profound intellectual disability
20p12	Alagille syndrome	Bile duct paucity with cholestasis; heart defects, particularly pulmonary artery stenosis; ocular abnormalities (posterior embryotoxon); skeletal defects such as butterfly vertebrae; long nose
22q11.2	Velocardiofacial-DiGeorge syndrome	Conotruncal cardiac anomalies, cleft palate, velopharyngeal incompetence, hypoplasia or agenesis of the thymus and parathyroid glands, hypocalcemia, hypoplasia of auricle, learning disabilities, psychiatric disorders
22q13.3 deletion		Hypotonia, developmental delay, normal or accelerated growth, severe expressive language deficits, autistic behavior
Xp21.2-p21.3		Duchenne muscular dystrophy, retinitis pigmentosa, adrenal hypoplasia, intellectual disability, glycerol kinase deficiency
Xp22.2-p22.3		Ichthyosis, Kallmann syndrome, intellectual disability, chondrodysplasia punctata
Xp22.3	Microphthalmia with linear defects (MLS)	Microphthalmia, linear skin defects, poikiloderma, congenital heart defects, seizures, intellectual disability

Table 81-14 Microduplications and Their Clinical Manifestations

DUPLICATION CHROMOSOME REGION	DISEASE REGION	CLINICAL FEATURES
1q21.1		Macrocephaly, DD, learning disabilities
3q29		Mild to moderate MR, microcephaly
7q11.23	Williams syndrome	DD and severe expressive language disorder, autistic features, subtle dysmorphisms
15q13.3	Prader-Willi/Angelman syndrome region	DD, MR, autistic features in duplications of maternal origin
15q24		Growth restriction, DD, microcephaly, digital anomalies, hypospadias, connective tissue abnormalities
16p11.2		FTT, severe DD, short stature, GH deficiency, dysmorphic features
17p11.2	Potocki-Lupski syndrome	Hypotonia, cardiovascular anomalies, FTT, DD, verbal apraxia, autism, anxiety
17q21.31		Severe DD, microcephaly, short and broad digits, dysmorphic features
22q11.2	Velocardiofacial-DiGeorge syndrome	Cardiovascular defects, velopharyngeal insufficiency
Xq28	*MECP2* gene region (Rett syndrome)	In males: infantile hypotonia, immune deficiency, dysmorphic features, DD, speech delay, autistic behavior, regression in childhood

DD, developmental delay; ID, intellectual disability; FTT, failure to thrive; GH, growth hormone; MR, mental retardation.

with moderate to mild intellectual disability and 0.5% of children with mild intellectual disability.

Clinical features (>30%) include short stature, microcephaly, hypertelorism, nose and ear abnormalities, and cryptorchidism. This group is also characterized by a family history of intellectual disability and an increased likelihood of restricted growth beginning in the prenatal period. Telomere mutations have also been associated with dyskeratosis congenita and other aplastic anemia syndromes as well as pulmonary or hepatic fibrosis. Both the subtelomeric rearrangements and the microdeletion and microduplication syndromes are typically diagnosed by molecular techniques like aCGH, FISH, and multiple ligation-dependent primer amplification. Recent studies show that aCGH can detect 14-18% of abnormalities in patients who are previously known to have normal chromosome studies.

INSERTIONS

Insertions occur when a piece of a chromosome broken at 2 points is incorporated into a break in another part of a chromosome. A total of 3 breakpoints are then required, and they can occur between 2 or within 1 chromosome. A form of nonreciprocal translocation, insertions are rare. Insertion carriers are at risk of having offspring with deletions or duplications of the inserted segment.

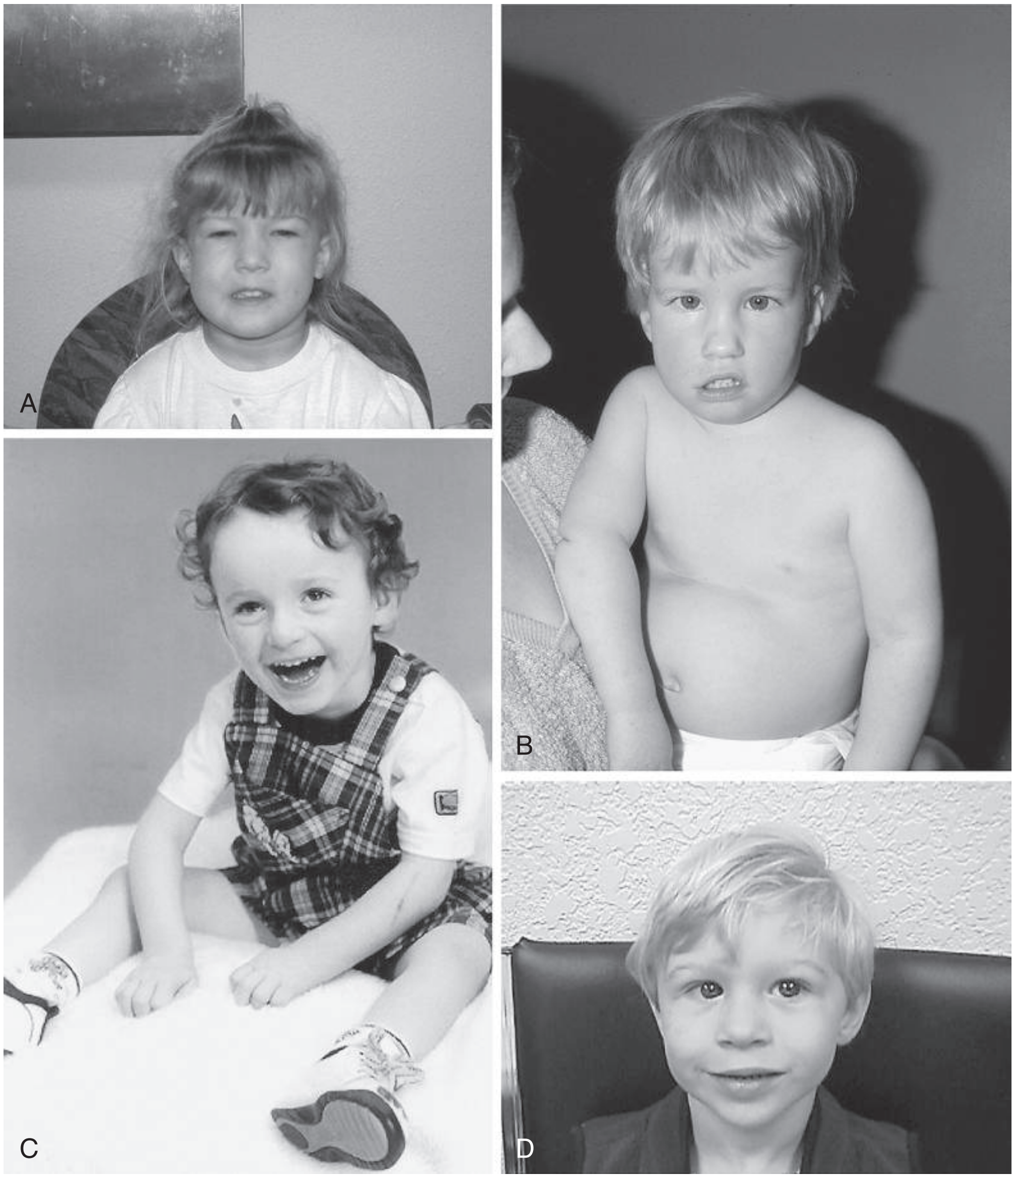

Figure 81-16 *A*, Child with velocardiofacial syndrome (deletion 22q11.2). *B*, Child with Prader-Willi syndrome (deletion 15q11-13). *C*, Child with Angelman syndrome (deletion 15q11-13). *D*, Child with Williams syndrome (deletion 7q11.23). *(From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In Hyme HE, Greydanus D, editors:* Genetic disorders in adolescents: state of the art reviews. Adolescent medicine, *Philadelphia, 2002, Hanley and Belfus, pp. 305–313.)*

ISOCHROMOSOMES

Isochromosomes consist of 2 copies of the same chromosome arm joined through a single centromere and forming mirror images of one another. The most commonly reported autosomal isochromosomes tend to involve chromosomes with small arms. Some of the more common chromosome arms involved in this formation include 5p, 8p, 9p, 12p, 18p, and 18q. There is also a common isochromosome abnormality seen in long arm of the X chromosome, and associated with Turner syndrome. Individuals who have 1 isochromosome within 46 chromosomes are monosomic for genes in the lost short arm and trisomic for the genes present in the long arm of the X chromosome.

MARKER AND RING CHROMOSOMES

Marker chromosomes are rare and are usually chromosome fragments that are too small to be identified by conventional cytogenetics; they usually occur in addition to the normal 46 chromosomes. Most are sporadic (70%); mosaicism is often (50%) noted because of the mitotic instability of the marker chromosome. The incidence in newborn infants is 1 in 3,300, and the incidence in persons with intellectual disability is 1 in 300. The associated phenotype ranges from normal to severely abnormal depending on the amount of chromosome material and number of genes associated with the fragment.

Ring chromosomes, which are found for all human chromosomes, are rare. A ring chromosome is formed when both ends of a chromosome are deleted and the ends are then joined to form a ring. Depending on the amount of chromosome material that is lacking or in excess (if the ring is in addition to the normal chromosomes), a patient with a ring chromosome can appear normal or nearly normal or can have intellectual disability and multiple congenital anomalies.

Marker and ring chromosomes can be found in the cells of solid tumors of children the cells of whose organs do not contain this additional chromosomal material.

81.4 Sex Chromosome Aneuploidy

Carlos A. Bacino and Brendan Lee

About 1 in 400 males and 1 in 650 females have some form of sex chromosome abnormality. Considered together, sex chromosome abnormalities are the most common chromosome abnormalities seen in liveborn infants, children, and adults. Sex chromosome abnormalities can be either structural or numerical and can be present in all cells or in a mosaic form. Those affected with these abnormalities might have few or no physical or developmental problems (Table 81-15).

TURNER SYNDROME

Turner syndrome is a condition characterized by complete or partial monosomy of the X chromosome and defined by a combination of phenotypic features (Table 81-16). Half of the patients with Turner syndrome have a 45,X chromosome complement. The other half exhibits mosaicism and varied structural abnormalities of the X or Y chromosome. Maternal age is not a predisposing factor for children with 45,X. Turner syndrome occurs in approximately 1 in 5,000 female live births. In 75% of patients, the lost sex chromosome is of paternal origin (whether an X or a Y). 45,X is one of the chromosome abnormalities most often associated with spontaneous abortion. It has been estimated that 95-99% of 45,X conceptions are miscarried.

Clinical findings in the newborns can include small size for gestational age, webbing of the neck, protruding ears, and lymphedema of the hands and feet, although many newborns are phenotypically normal (Fig. 81-17). Older children and adults have short stature and exhibit variable dysmorphic features. Congenital heart defects (40%) and structural renal anomalies (60%) are common. The most common heart defects are bicuspid aortic valves, coarctation of the aorta, aortic stenosis, and mitral valve prolapse. The gonads are generally streaks of fibrous tissue **(gonadal dysgenesis).** There is primary amenorrhea and lack of secondary sex characters. These children should receive regular endocrinologic testing (see Chapter 586). Most patients tend to be of normal intelligence, but intellectual disability is seen in up to 6% of affected children. They are also at increased risk for behavioral problems and deficiencies in spatial and motor perception. Guidelines for health supervision for children with Turner syndrome are published by the American Academy of Pediatrics and include pubertal induction, as well as treatment with growth hormone and oxandrolone.

Patients with **45,X/46,XY mosaicism,** can have Turner syndrome, although this form of mosaicism can also be associated with male pseudohermaphroditism, male or female genitalia in association with

Table 81-15 Sex Chromosome Abnormalities

DISORDER	KARYOTYPE	APPROXIMATE INCIDENCE
Klinefelter syndrome	47,XXY 48,XXXY Other (48,XXYY; 49,XXXYY; mosaics)	1/575-1/1,000 males 1/50,000-1/80,000 male births
XYY syndrome	47,XYY	1/800-1,000 males
Other X or Y chromosome abnormalities		1/1,500 males
XX males	46,XX	1/20,000 males
Turner syndrome	45,X Variants and mosaics	1/2,500-1/5,000 females
Trisomy X	47,XXX 48,XXXX and 49,XXXXX	1/1,000 females Rare
Other X chromosome abnormalities		1/3,000 females
XY females	46,XY	1/20,000 females

Table 81-16 Signs Associated with Turner Syndrome

Short stature
Congenital lymphedema
Horseshoe kidneys
Patella dislocation
Increased carrying angle of elbow (cubitus valgus)
Madelung deformity (chondrodysplasia of distal radial epiphysis)
Congenital hip dislocation
Scoliosis
Widespread nipples
Shield chest
Redundant nuchal skin (in utero cystic hygroma)
Low posterior hairline
Coarctation of aorta
Bicuspid aortic valve
Cardiac conduction abnormalities
Hypoplastic left-heart syndrome and other left-heart abnormalities
Gonadal dysgenesis (infertility, primary amenorrhea)
Gonadoblastoma (increased risk if Y chromosome material is present)
Learning disabilities (nonverbal perceptual motor and visuospatial skills) (in 70%)
Developmental delay (in 10%)
Social awkwardness
Hypothyroidism (acquired in 15-30%)
Type 2 diabetes mellitus (insulin resistance)
Strabismus
Cataracts
Red-green color blindness (as in males)
Recurrent otitis media
Sensorineural hearing loss
Inflammatory bowel disease
Celiac disease (increased incidence)

Figure 81-17 Redundant nuchal skin *(A)* and puffiness of the hands *(B)* and feet *(C)* in Turner syndrome. *(From Sybert VP, McCauley E: Turner's syndrome,* N Engl J Med *351:1227–1238, 2004. Copyright © 2004 Massachusetts Medical Society.)*

mixed gonadal dysgenesis, or a normal male phenotype. This variant is estimated to represent approximately 6% of patients with mosaic Turner syndrome. Some of the patients with Turner syndrome phenotype and a Y cell line exhibit masculinization. Phenotypic females with 45,X/46,XY mosaicism have a 15-30% risk of developing **gonadoblastoma.** The risk for the patients with a male phenotype and external testes is not so high, but tumor surveillance is nevertheless recommended. The American Academy of Pediatrics has recommended the use of FISH analysis to look for Y-chromosome mosaicism in all 45,X patients. If Y chromosome material is identified, laparoscopic gonadectomy is recommended.

Noonan syndrome shares many clinical features with Turner syndrome (old name was pseudo-Turner syndrome), although it is an autosomal dominant disorder resulting from mutations in several genes that are involved in the RAS-MAPK (mitogen-activated protein kinase) pathway. The most common of these is *PTPN11* (50%), which encodes a protein-tyrosine phosphatase (SHP-2) on chromosome 12q24.1. Other genes include *SOS1* in 10-13%, *RAF1* in 3-17%, *KRAS* <5%, *BRAF* <2%, and *MAP2K* <2%. Overlapping phenotypes are seen in LEOPARD (lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness) syndrome, cardiofaciocutaneous syndrome, and Costello syndrome; these are Noonan-related disorders. Features common to Noonan syndrome include short stature, low posterior hairline, shield chest, congenital heart disease, and a short or webbed neck (Table 81-17). In contrast to Turner syndrome, Noonan syndrome affects both sexes and has a different pattern of congenital heart disease, typically involving right-sided lesions.

KLINEFELTER SYNDROME

Persons with Klinefelter syndrome are phenotypically male; this syndrome is the most common cause of hypogonadism and infertility in males and the most common sex chromosome aneuploidy in humans (see Chapter 583). Eighty percent of children with Klinefelter syndrome have a male karyotype with an extra chromosome X-47,XXY; the remaining 20% have multiple sex chromosome aneuploidies (48,XXXY; 48,XXYY; 49,XXXXY), mosaicism (46,XY/47,XXY), or structurally abnormal X chromosomes. The greater the aneuploidy, the more severe the mental impairment and dysmorphism. Early studies showed that the birth prevalence is approximately 1 in 1,000 males. The current prevalence of 47,XXY appears to have increased to approximately 1 in 580 liveborn boys; the reasons for this are still unknown. Errors in paternal nondisjunction in meiosis I account for half of the cases.

Puberty occurs at the normal age, but the testes remain small. Patients develop secondary sex characters late; 50% develop gynecomastia. They have taller stature. Because many patients with Klinefelter syndrome are phenotypically normal until puberty, the syndrome often goes undiagnosed until they reach adulthood, when their infertility aids in their clinical identification. Patients with 46,XY/47,XXY have a better prognosis for testicular function. Their intelligence shows variability and ranges from above to below average. Persons with Klinefelter syndrome can show behavioral problems, learning disabilities, and deficits in language. Problems with self-esteem are often the case with adolescents and adults. Substance abuse, depression, and anxiety have been reported in adolescents with Klinefelter syndrome. Those who have higher X chromosome counts show impaired cognition. It has been estimated that each additional X chromosome reduces the IQ by 10-15 points, when comparing these persons with their normal siblings. The main effect is seen in language skills and social domains.

47,XYY

The incidence of 47,XYY is approximately 1 in 800-1,000 males, with many cases remaining undiagnosed, because most affected individuals have a normal appearance and normal fertility. The extra Y is the result of nondisjunction at paternal meiosis II. Those with this abnormality have normal intelligence but are at risk for learning disabilities. Behavioral abnormalities including hyperactive behavior, pervasive developmental disorder, and aggressive behavior have been reported. Early reports that assigned stigmata of criminality to this disorder have long been disproved.

Nevi, lentigines, café-au-lait spots
Cryptorchidism
Small penis
Delayed puberty
Bleeding disorders, including thrombocytopenia and factor deficiencies
Leukemia, myeloproliferative disorders, other malignancies
Cognitive delay (*KRAS* mutation)

81.5 Fragile Chromosome Sites

Carlos A. Bacino and Brendan Lee

Fragile sites are regions of chromosomes that show a tendency for separation, breakage, or attenuation under particular growth conditions. They appear as a gap in the staining. At least 120 chromosomal loci, many of them heritable, have been identified as fragile sites in the human genome (see Table 80-2).

One fragile site that has clinical significance is the one on the distal long arm of chromosome Xq27.3 associated with the **fragile X syndrome.** Fragile X accounts for 3% of males with intellectual disability. There is another fragile site on the X chromosome (FRAXE on Xq28) that has also been implicated in mild intellectual disability. The FRA11B (11q23.3) breakpoints are associated with Jacobsen syndrome (condition caused by deletion of the distal long arm of chromosome 11). Fragile sites can also play a role in tumorigenesis. CGG repeat expansion silences the gene producing fragile X mental retardation protein (FMRP) that regulates the translation of multiple mRNAs to specific proteins, thus affecting synaptic function. FMRP deficiency upregulates the metabotropic glutamate receptor (mGluR) 5 pathway. FMRP deficiency also alters the expression of matrix metalloproteinase (MMP) 9.

The main **clinical manifestations** of fragile X syndrome in affected males are intellectual disability, autistic behavior, macroorchidism, hyperextensible finger joints, and characteristic facial features (Table 81-18). The macroorchidism may not be evident until puberty. The facial features, which include a long face, large ears, and a prominent square jaw, become more obvious with age. Females affected with

fragile X show varying degrees of intellectual disability and/or learning disabilities. Diagnosis of fragile X is possible by DNA testing that shows an expansion of a triplet DNA repeat inside the *FMR1* gene on the X chromosome larger than 200 repeats. The expansion involves an area of the gene that contains a variable number of trinucleotide (CGG) repeats. The larger the triplet repeat expansion, the more significant the intellectual disability. In cases where the expansion is large, females can also manifest different degrees of intellectual disability. Males with premutation triple repeat expansions (50-200 repeats), have been found to have an adult, late onset progressive neurodegenerative disorder known as **fragile X-associated tremor/ataxia syndrome**. Therapy of the diverse neuropsychiatric manifestations associated with fragile X syndrome is noted in Table 81-19. Inhibitors of the mGluR (overexpressed in fragile X) are undergoing clinical trials. In preliminary trials, minocycline (lowers MMP9) has resulted in short term improvements in anxiety, mood, and the clinical Global Impression Scale.

villus samples collected at or before the 10th wk of gestation has shown that 2% or more of all conceptions are mosaic for a chromosome abnormality. With the exception of chromosomes 13, 18, and 21, complete autosomal trisomies are usually nonviable; the presence of a normal cell line might allow these other trisomic conceptions to survive to term. Depending on the point at which the new cell line arises during early embryogenesis, mosaicism may be present in some tissues but not in others. Germline mosaicism, which refers to the presence of mosaicism in the germ cells of the gonad, may be associated with an increased risk for recurrence of an affected child whether the germ cells are affected with a chromosomal abnormality or specific gene mutation.

PALLISTER-KILLIAN SYNDROME

Pallister-Killian syndrome is characterized by coarse facies (prominent full cheeks), abnormal ear lobes, localized alopecia, pigmentary skin anomalies, diaphragmatic hernia, cardiovascular anomalies, supernumerary nipples, seizures, and profound intellectual disability. The syndrome is due to mosaicism for an isochromosome 12p. The presence of the isochromosome 12p in cells gives 4 functional copies for the short arm of chromosome 12 in the affected cells. The isochromosome 12p is preferentially cultured from fibroblasts that can be readily obtained from a skin punch biopsy and is seldom present in lymphocytes. The abnormalities seen in affected persons probably reflect the presence of abnormal cells during early embryogenesis.

HYPOMELANOSIS OF ITO

Hypomelanosis of Ito is characterized by unilateral or bilateral macular hypo- or hyperpigmented whorls, streaks, and patches (see Chapter 653). Sometimes these pigmentary defects follow the lines of Blaschko. Hair and tooth anomalies are common. Abnormalities of the eyes, musculoskeletal system (growth asymmetry, syndactyly, polydactyly, clinodactyly), and central nervous system (microcephaly, seizures, intellectual disability) may also be present. Patients with hypomelanosis of Ito might have 2 genetically distinct cell lines. The mosaic chromosome anomalies that have been observed involve both autosomes and sex chromosomes and have been demonstrated in about 50% of patients. The mosaicism might not be visible in lymphocyte-derived chromosome studies; it is more likely to be found when chromosomes are analyzed from skin fibroblasts. The distinct cell lines might not always be due to observable chromosomal anomalies but might result from single gene mutations or other mechanisms.

81.7 Chromosome Instability Syndromes

Carlos A. Bacino and Brendan Lee

Chromosome instability syndromes, formerly known as chromosome breakage syndromes, are characterized by an increased risk of malignancy and specific phenotypes. They display autosomal recessive inheritance and have an increased frequency of chromosome breakage and/or rearrangement, either spontaneous or induced. They result from specific defects in DNA repair, cell cycle control, and apoptosis. The resulting chromosomal instability leads to the increased risk of developing neoplasms. The classic chromosome instability syndromes are Fanconi anemia, ataxia telangiectasia, Nijmegen syndrome, ICF (immunodeficiency, centromere instability, and facial anomalies) syndrome, Roberts syndrome, Werner syndrome, and Bloom syndrome.

81.8 Uniparental Disomy and Imprinting

Carlos A. Bacino and Brendan Lee

UNIPARENTAL DISOMY

Uniparental disomy (UPD) occurs when both chromosomes of a pair or areas from 1 chromosome in any individual have been inherited from a single parent. UPD can be of 2 types: uniparental isodisomy or uniparental heterodisomy. **Uniparental isodisomy** means that both chromosomes or chromosomal regions are identical (typically the result of monosomy rescue by duplication). **Uniparental heterodisomy** means that the 2 chromosomes are different members of a pair, both of which were still inherited from 1 parent. This results from a trisomy that is later reduced to disomy, leaving 2 copies from 1 parent. The phenotypical result of UPD varies according to the chromosome involved, the parent who contributed the chromosomes, and whether it is isodisomy or heterodisomy. Three types of phenotypic effects are seen in UPD: those related to imprinted genes (i.e., the absence of a gene that is normally expressed only when inherited from a parent of a specific sex), those related to the uncovering of autosomal recessive disorders, and those related to a vestigial aneuploidy producing mosaicism (see Chapter 80).

In uniparental isodisomy, both chromosomes or regions (and thus the genes) in the pair are identical. This is particularly important when the parent is a carrier of an autosomal recessive disorder. If the offspring of a carrier parent has UPD with isodisomy for a chromosome that carries an abnormal gene, the abnormal gene will be present in 2 copies and the phenotype will be that of the autosomal recessive disorder; the child has an autosomal recessive disorder even though only 1 parent is a carrier of that recessive disorder. It is estimated that all human beings carry approximately 20 abnormal autosomal recessive genes. Some autosomal recessive disorders like spinal muscular atrophy, cystic fibrosis, cartilage-hair hypoplasia, α- and β-thalassemias, and Bloom syndrome have been reported in cases of UPD. The possibility of uniparental isodisomy should also be considered when a person is affected with >1 recessive disorder because the abnormal genes for both disorders could be carried on the same isodisomic chromosome. Uniparental isodisomy is a *rare* cause of recessively inherited disorders. Uniparental isodisomies can also be detected by SNP microarrays.

Maternal UPD involving chromosomes 2, 7, 14, and 15 and **paternal UPD** involving chromosomes 6, 11, 15, and 20 are associated with phenotypic abnormalities of growth and behavior. UPD of maternal chromosome 7 is associated with a phenotype similar to Russell-Silver syndrome with intrauterine growth restriction. These phenotypic effects may be related to imprinting (see under Imprinting, below) (Fig. 81-18).

UPD for chromosome 15 is seen in some cases of Prader-Willi syndrome and Angelman syndrome. In **Prader-Willi syndrome**, approximately 25-29% of cases have maternal UPD (missing the paternal chromosome 15). In **Angelman syndrome**, paternal UPD of chromosome 15 is rarer and is observed in approximately 5% of the cases (missing the maternal chromosome 15). The phenotype for Prader-Willi syndrome (Fig. 81-19) and Angelman syndrome in cases of UPD is thought to result from the lack of the functional contribution from a particular parent of chromosome 15. In Prader-Willi syndrome the paternal contribution is missing, and the maternal contribution is missing in Angelman syndrome. Prader-Willi may be due to paternal deficiency of HB11-85 snoRNAs (small nucleolar RNAs). These findings suggest that there are differences in function of certain regions of chromosome 15, depending on whether it is inherited from the mother or from the father.

UPD most commonly arises when a pregnancy starts off as a **trisomic conception followed by trisomy rescue.** Because most trisomies are lethal, the fetus can only survive if a cell line loses 1 of the extra chromosomes to revert to the disomic state. One-third of the time, the disomic cell line is uniparental. This is the typical mechanism for Prader-Willi syndrome, and it is often associated with advanced maternal age. The embryo starts off as trisomy 15 secondary to maternal meiosis I nondisjunction, followed by random loss of the paternal chromosome. In this case, the disomic cell line becomes the more viable one and outgrows the trisomic cell line. When mosaic trisomy is found at prenatal diagnosis, care should be taken to determine whether UPD has resulted and whether the chromosome involved is one of the disomies known to be associated with phenotypic abnormalities. There must always be concern that some residual cells that are trisomic are present in some tissues, leading to malformations or

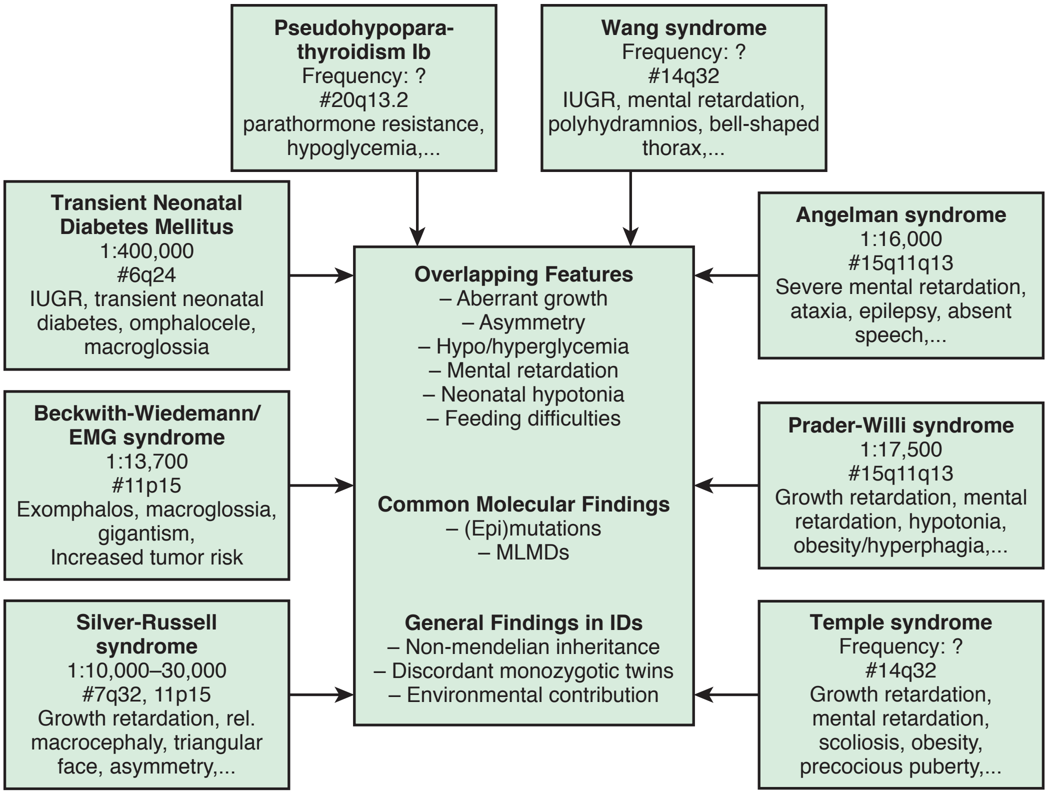

Figure 81-18 Overview of the common clinical and molecular findings in the 8 known imprinting disorders, including specific features, frequencies, and major chromosomal localization. *#6q24*, chromosome 6q24; *EMG*, exomphalos-macroglossia-gigantism; *IUGR*, intrauterine growth restriction. *(From Eggermann T, Elbracht M, Schröder C, et al: Congenital imprinting disorders: a novel mechanism linking seemingly unrelated disorders.* J Pediatr *163:1202-1207, 2013, Fig. 2, p. 1204).*

dysfunction. The presence of aggregates of trisomic cells might account for the spectrum of abnormalities seen in persons with UPD.

IMPRINTING

Traditional genetics has for many years suggested that most genes are equally expressed when inherited from maternal versus paternal lineages. The only exception to this rule were genes on the X chromosome that are subject to inactivation, and the immunoglobulin genes subject to allelic exclusion, a phenomenon that results in monoallelic expression of a particular immunoglobulin chain by switching on and off expression of parental alleles. Genomic imprinting occurs when the phenotypic expression of a gene depends on the parent of origin for certain genes or in some cases entire chromosome regions. Whether the genetic material is expressed or not depends on the sex of the parent from whom it was derived. Genomic imprinting can be suspected in some cases on the basis of a pedigree. In these pedigrees, the disease is always transmitted from 1 sex and could be passed on silently for several generations by the opposite sex (Figs. 81-20 and 81-21). Imprinting probably occurs in many different parts of the human genome and is thought to be particularly important in gene expression related to development, growth, cancer, and even behavior; over 60 genes have been classified as imprintable. Imprinting disorders may arise from UPD, deletions or duplications, epigenetic aberrant methylation patterns, or point mutations in a specific gene.

A classic example of imprinting disorder is seen in Prader-Willi syndrome and Angelman syndrome, 2 very different clinical conditions. These syndromes are usually associated with deletion of the same region in the proximal long arm of chromosome 15. A deletion on the paternally derived chromosome causes Prader-Willi syndrome, in which the maternally derived copy is still intact but some of the imprinted genes within this region normally remain silent. In contrast, a maternal deletion of the same region causes Angelman syndrome, leaving intact the paternal copy that in this case has genes that are also normally silent. In other situations, UPD can lead to the same diagnosis. Maternal UPD for chromosome 15 results in Prader-Willi syndrome due to lack of the paternal chromosome 15 contribution. In contrast, in Angelman syndrome, the UPD is always paternal, with no maternal contribution (Table 81-20). Many other disorders are associated with this type of parent of origin effect, as in some cases of Beckwith-Wiedemann syndrome, Russell-Silver syndrome, and neonatal diabetes.

Table 81-20 Molecular Mechanisms Causing Prader-Willi and Angelman Syndromes

	PRADER-WILLI SYNDROME	ANGELMAN SYNDROME
15q11-q13 deletion	~70% (paternal)	~70% (maternal)
Uniparental disomy	~30% (maternal)	~5% (paternal)
Single-gene mutation	None detected	E6-AP ubiquitin-protein ligase (10% of total but seen only in familial cases)
Imprinting center mutation	5%	5%
Unidentified	<1%	10-15%

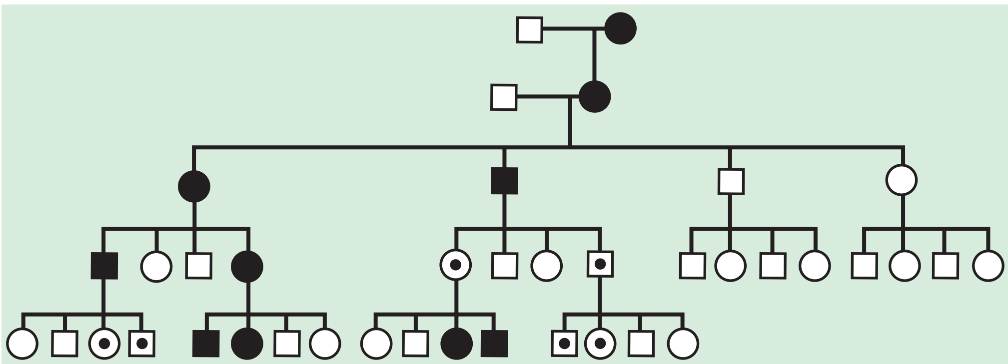

Figure 81-20 **In this hypothetical pedigree suggestive of imprinting, phenotypic effects occur only when the mutated gene is transmitted from the mother, but not when it is transmitted from the father, that is, maternal deficiency.** Equal numbers of males and females can be affected and not affected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; that is, in maternal deficiency disorders (also termed paternal imprinting), there are "skipped" nonmanifesting females. This is theoretical, because in most clinical scenarios of maternal deficiency, such as Angelman syndrome, affected persons do not reproduce.

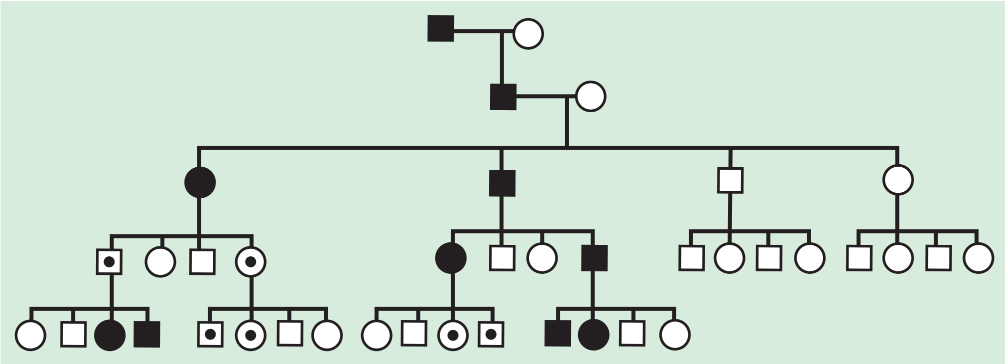

Figure 81-21 **In theoretical pedigrees suggestive of paternal deficiency (maternal imprinting), phenotypic effects occur only when the mutated gene is transmitted from the father, but not when transmitted from the mother.** Equal numbers of males and females can be affected and not affected phenotypically in each generation. In a theoretical situation, a nonmanifesting transmitter gives a clue to the sex of the parent who passes on the expressed genetic information; that is, in paternal deficiency (also known as maternal imprinting), there are "skipped" nonmanifesting males. In real-life clinical instances of Prader-Willi syndrome, affected persons do not reproduce.

Chapter 82

Genetics of Common Disorders

John W. Belmont and Brendan Lee

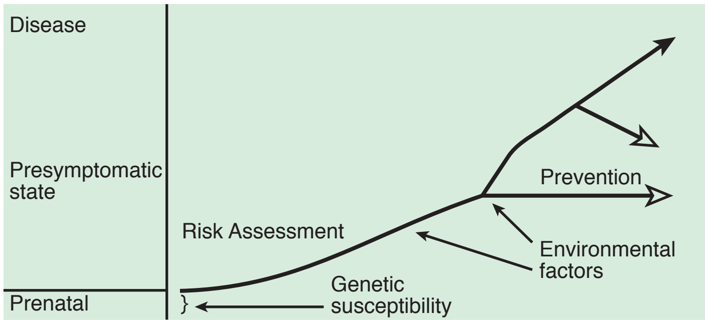

Figure 82-1 Model for the influence of genetics on health. Everyone inherits some genetic liability for disease risk, but for multifactorial disorders this is insufficient to produce disease on its own. Over time, exposure to environmental factors leads from a presymptomatic to a disease state. Identifying the genes responsible for risk can lead to prevention strategies or treatments.

Genetic studies are useful in diagnosing and treating rare pediatric conditions, often alleviating suffering, extending life, and, in the case of neonatal metabolic and presymptomatic screening, preventing injury before symptoms develop. Genetic studies can also contribute to the understanding of more common diseases, such as asthma and diabetes. An understanding of the complex and potentially multiple pathways leading to disease is crucial for the development of new therapies and prevention strategies.

Common pediatric diseases are often multifactorial, and the combination of many genes and environmental factors triggers a complex sequence of events leading to disease. Each individual has variations in his or her set of genes; the cumulative effect of the individual's gene variants with each other and with the environment influence susceptibility to disease, response to various medications, and susceptibility to specific drug toxicities. The complexity of the combination of contributing factors increases the challenge of finding genetic variants that cause disease. Genetic tools include the completed human genome sequence, public databases of genetic variants, and the human haplotype map. In addition to public genetic databases, dramatic reduction in the cost of genotyping and DNA sequencing has allowed very large numbers of genetic variants to be efficiently tested in large numbers of patients. Most of these studies focus on common variants (those with frequencies >5%). New technologies for DNA sequencing are already allowing whole exome sequencing in many individuals at very low cost. This technology is being used to investigate the role of rare coding sequence variants in common diseases. The incorporation of these tools into large, well-designed population studies is the field of **genetic epidemiology.** Many new methods for analyzing genetic data have been developed, stimulating a renaissance in applied population genetics. So far, these methods of investigation have been used less extensively in pediatric diseases than in adult-onset conditions. This is a consequence of the relative lack of large-scale DNA sample sets for many common diseases of children.

We can now project that in the near future it will become routine to carry out "genomic profiling" by one technique or another for individual children. These methods will find clinical utility in decision algorithms for disease screening and initiation of treatment, drug selection, and targeted preventive strategies. The results will be of an unprecedented complexity, so that physicians and parents will increasingly rely on the coupling of genetic data to clinical decision support tools linked to the electronic health record.

82.1 Major Genetic Approaches to the Study of Common Pediatric Disorders

John W. Belmont and Brendan Lee

Figure 82-1 shows a model for the genetic contribution to health. Genetic variation that can have an impact on disease susceptibility is present in every person. Sometimes single-gene mutations cause a condition, as is the case for cystic fibrosis or sickle cell anemia. But other kinds of genetic variations can contribute much less strongly to the emergence of specific medical conditions, and the effect can depend upon exposure to certain environmental factors. One goal in medical genetics is to identify genes that contribute to disease in the hope of preventing the occurrence of disease, either by avoiding inciting environmental factors or by instituting interventions that reduce risk. For persons who cross the threshold of disease, the goal is to better understand the pathogenesis in the hope that this will suggest better approaches to treatment. Common genetic variation can also influence response to medications and the risk of toxicities of various medications and environmental toxins.

Complex traits may be inherently difficult to study if there are problems with the precision of clinical diagnosis. This is particularly true of neurobehavioral traits. A starting point in the genetic analysis of a complex trait is to obtain evidence in support of a genetic contribution and to estimate the relative strength of genetic and environmental factors. Complex traits typically exhibit familial clustering, but are not transmitted in a regular pattern like autosomal dominant or recessive inheritance. Complex traits often show variation among different ethnic or racial groups, possibly reflecting the differences in gene variants among these groups.

Assessing the potential genetic contribution begins by determining whether the trait is seen among related individuals more often than in the general population. A common measure of **familiality** is the first-degree relative risk (usually designated by the symbol λ_s), which is equal to the ratio of the prevalence rate in siblings and/or parents to the prevalence rate in the general population. For example, the λ_s for type 1 diabetes is about 15. The relative strength of genetic and nongenetic risk factors can be estimated by variance components analysis, and the **heritability** of a trait is the estimate of the fraction of the total variance contributed by genetic factors (Fig. 82-2).

It is not uncommon for a minority of cases of common diseases like diabetes to be caused by single-gene mutations (mendelian inheritance), chromosomal disorders, and other genomic disorders. These less-common causes of the disease can often provide important insight into the most important molecular pathways involved. Chromosomal regions with genes that might contribute to disease susceptibility could theoretically be located with **linkage mapping,** which locates regions of DNA that are inherited in families with the specific disease. But practically, this has turned out to be quite difficult for most complex traits either because of a dearth of families or because the effect of individual genetic loci is weak.

Phenotypic variance		Genetic variance		Environmental variance		Measurement variance
V_P	=	V_G	+	V_E	+	V_M

$$h^2 = V_G / V_P$$

Heritability

Figure 82-2 Heritability concept. The phenotypic variance of a particular trait can be partitioned between the contributions of the genetic variance, the environmental variance, and the measurement variance. This is usually empirically determined. Heritability is defined by the proportion of the phenotypic variance that is accounted for by the genetic variance. One can estimate the heritability from correlation of a quantitative trait between relatives.

Genetic **association studies** are more powerful in identifying common gene variants (>5% in the population) that confer increased risk of disease, but they fail if the disease-causing gene variants are relatively rare. Detection of the modest effect of each variant and interactions with environmental factors requires well-powered studies that often include thousands of subjects. A number of parallel approaches for analyzing the aggregate effects of rare variants in genes have also been developed. Such rare variant association methods also seem to require large sample sizes because the gene effects have also proven to be relatively weak.

Linkage mapping and association studies require markers along the DNA that can be ascertained, or **genotyped,** with large-scale, high-throughput laboratory techniques. Markers that are typically used are in the forms of microsatellites and **single-nucleotide polymorphisms** (SNPs; Fig. 82-3). Although humans all have the same genetic material, each person's genome is slightly different. A sample of the same region of genome from 50 people will reveal that approximately 1 in every 200 bases varies from the more common form. Although most SNPs lack any obvious function, a few alter the amino acid sequence of the protein or affect regulation of gene expression. Some of these functional alterations directly affect susceptibility to disease. A complex clinical **phenotype** can be defined by the presence or absence of a disease as a **dichotomous trait**, or by selection of a clinically meaningful variable such as serum glucose in type 2 diabetes, which is a continuous or **quantitative trait**.

Although it might not be possible to define subgroups of patients in advance based on common disease mechanisms, the more uniform the phenotype, the more likely that a genetic study will be successful. **Locus heterogeneity** refers to the situation in which a trait results from the independent action of more than 1 gene. **Allelic heterogeneity** indicates that more than 1 variant in a particular gene can contribute to disease risk. The development of a trait or disease from a nongenetic mechanism results in a **phenocopy**. These 3 factors often contribute to the difficulty in identifying individual disease susceptibility genes because they reduce the effective size of the study population.

A person bearing any variant or **allele** (inherited unit, DNA segment, or chromosome) in a gene has a certain probability of being affected with a specific gene variant-associated disease. This is called the

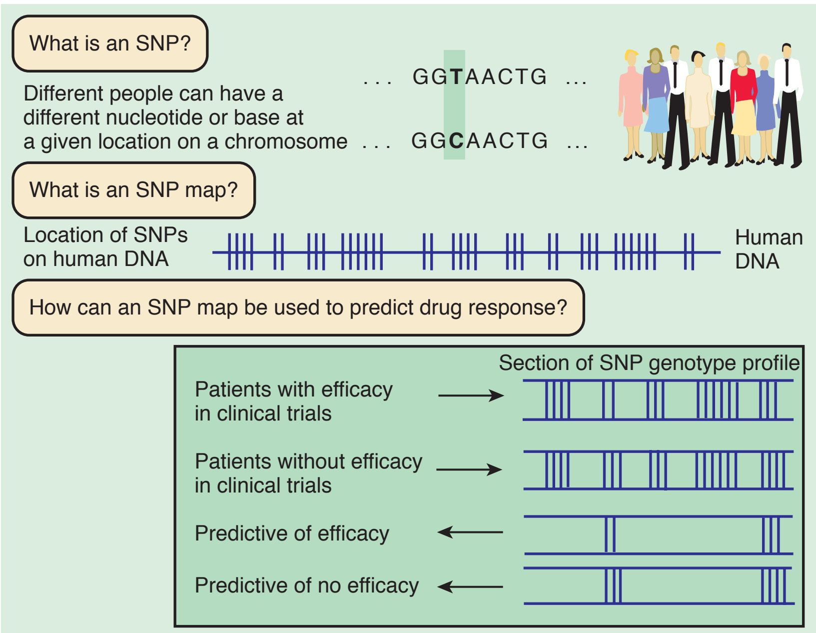

Figure 82-3 Different combinations of SNPs are found in different individuals. The locations of these SNPs can be pinpointed on maps of human genes. Subsequently, they can be used to create profiles that are associated with difference in response to a drug, such as efficacy and nonefficacy. *(Adapted from Roses A: Pharmacogenetics and the practice of medicine,* Nature *405:857-865, 2000. Copyright 2000. Reprinted by permission of Macmillan Publishers Ltd.)*

penetrance. Some diseases manifest signs only later in life (age-related penetrance), which could lead to misclassifying children who actually have the disease-producing gene as unaffected. Single-gene disorders are typically caused by mutations with relatively high penetrance, but some common variants have very low penetrance because their overall contribution to the disease is small. Many such common variants can contribute to disease risk for a complex trait. For example, normal human height is influenced by more than 400 genes.

Ideally, important environmental exposures should be measured and accounted for in a population because there may be a dependent interaction between the environmental factor and specific genetic variant. An example is the likely requirement for a viral infection preceding onset of type 1 diabetes. Although **gene X environment interactions** are strongly suspected to play an important role in common diseases, it is difficult to identify and measure them. Very large studies with uniform collection of information about environmental exposures are rare. New methods, such as genome-wide analysis of DNA methylation, may show evidence of environmental effects—so-called **developmental programming**. This information might be used to discover and validate gene-environment interactions.

LINKAGE MAPPING

Linkage studies were used in the past to isolate genes that cause rare genetic syndromes; modified methods have been used to identify chromosomal regions linked to more common diseases. Linkage studies involve tagging segments of a person's genome with markers that allow identification of segments that have been inherited through the family along with disease. The markers are typically **microsatellites** or **SNPs** that define and help to distinguish which type of an allele any person carries. The type of an allele is referred to as a **genotype.** Linkage analyses of common diseases have shown inconsistent results. Factors such as heterogeneity, pleiotropy, variable expressivity, and reduced penetrance, in addition to variability in environmental exposures, weaken the power of linkage studies in complex traits.

GENETIC ASSOCIATION

For multifactorial common diseases, association analyses may be used to identify causally important genes. There are two types of association study: **direct association,** in which the causal variant itself is tested to see whether its presence correlates with disease, and **indirect association,** in which markers that are physically close to the biologically important variant are used as proxies. The correlation of markers with other genetic variants in a small region of the genome is called **linkage disequilibrium**. Indirect association is enabled by the construction of a detailed genetic map in 3 reference populations (Europeans, Asians, West Africans) through the International HapMap Project. SNPs that tag most of the genome have been identified and can be genotyped at low cost using specially designed microarrays.

Three basic study designs are used for association testing: a case-control design, in which the frequency of an allele in the affected group is compared with the unaffected group; a family-based control design, in which parents or siblings of an affected individual are used as the controls; and a cohort design, in which large numbers of subjects are ascertained and then followed for the onset of any number of diseases. The cohort analysis is very expensive and there are few true cohort studies.

Family-based control study designs are somewhat attractive for pediatric diseases because it is usually possible to enroll parents. These studies solve a major problem in testing for association because the parents are perfectly matched for genetic background. When parents are collected, the statistical test used for these studies is called the **transmission disequilibrium test** (TDT). TDT compares the transmitted genotype with the inferred nontransmitted genotype. The success of all association analysis depends on the design of a well-powered study, with enough subjects, and an accurately measured trait to avoid phenotypical misclassification. In large, population-based studies, confounding by ethnicity or **population stratification** could distort results. Some genetic variants are more common in people from a particular ethnic group, which could cause an apparent association of a variant with a disease, when the disease rate happens to be higher in that group. This association would not be a true association between an allele and a disease, because the association would be confounded by genetic background. The family-based tests using the TDT are immune to population stratification. However, TDT and related study designs are inherently less efficient than case-control studies. Newer methods for measuring subtle mismatching between cases and controls using many thousands of markers routinely genotyped in genome-wide association studies allow this effect to be accounted for.

Association studies should be a powerful tool to find genetic variation that confers risk to an individual; the effect of any one genetic variant will be a very small contribution to the complex disease pathway. Genetic variants have been found that implicate a novel gene in a process, motivating more in-depth research into systems that will affect disease outcome. Associations such as the *ApoE4* variant with an increased risk of Alzheimer disease are noted by many studies. Many published association results are not reproducible; insufficient power and stratification might account for the inconsistencies. As of early 2014, more than 6000 disease associations for more than 600 medically important traits have been discovered and replicated in large studies.

New low-cost methods for sequencing the complete exomes and genomes of individuals will soon allow a more comprehensive evaluation of the full range of genetic variants involved in common diseases. The goal of the $1000 genome once seemed distant but may be achieved very soon. Rare genetic variants, including small insertions or deletions, could turn out to be extremely important in explaining the impact of genetic factors in important pediatric diseases such as autism, cardiovascular malformations, and other birth defects. Common traits such as obesity, diabetes, and autoimmune diseases might also be affected by rare variants. In common severe disorders like intellectual disability and complex heart malformations, de novo mutations (i.e., mutations not present in either parent) are likely to play an important role.

Chapter 83

Genetic Approaches to Rare and Undiagnosed Diseases

William A. Gahl, David R. Adams, Thomas C. Markello, Neal F. Boerkoel, and Cynthia J. Tifft

Rare and novel disorders often present in childhood and represent a diagnostic challenge that can be addressed using advanced genetic techniques.

SCOPE OF GENETIC DISEASE

An estimated 7000 rare disorders are recognized, and the existence of approximately 23,000 human genes suggests that many more genetic diseases will be discovered in the future. These genetic diseases comprise a set of maladies amenable to a variety of diagnostic approaches. Knowledge about the human genome creates a new opportunity to diagnose extremely rare disorders and discover new diseases. One

approach was taken by the National Institutes of Health (NIH) Undiagnosed Diseases Program (UDP).

Potential reasons patients may remain undiagnosed despite intensive prior investigation include:

- The genetic mutation had not previously been associated with the disease phenotype
- There is allelic heterogeneity (same gene but different mutation producing a different phenotype)
- There is locus heterogeneity (different genes producing similar phenotype)
- Presentation of monosymptomology or unusual features of a polysymptomatic or rare disease

The 3,000 patient applications to the UDP have involved collaboration between the referring healthcare team and the NIH group. Prior investigations are recounted in a summary letter from the referring clinician and documented with medical records that include photos, videos, imaging and histologic slides of biopsy material. Specialty consultants review the records and the UDP directors determine the next steps. The patients who are accepted come to the Clinical Center for a week-long inpatient admission. Approximately half of the patients with undiagnosed diseases have neurological disease; cardiovascular, rheumatology, immunology, and pulmonary problems are also frequent. Approximately 40% of accepted patients are children, among whom unknown multiple congenital anomalies and neurologic disorders are common.

CLINICAL EVALUATION

The term undiagnosed refers to patients who remain without a definitive diagnosis after an extensive workup. This occurs in part because every individual has a unique genetic and environmental background, and diseases express themselves in an unlimited number of ways. Undiagnosed conditions include those that have never been seen by the diagnostician, unusual presentations of otherwise recognizable conditions, and combinations of conditions that obfuscate each other's identities. A thorough clinical investigation allows the clinician to broaden the differential diagnosis through research, consultation, clinical testing and consideration of atypical presentations of previously known diseases. Extensive phenotyping, imaging, and other tests provide better documentation of the presentation and make the case available for association with future newly discovered diseases, genetic variants, and patient cohorts.

A complete history anchors the data, and includes prenatal and neonatal findings, developmental milestones, growth pattern, onset and progression of symptoms and signs, precipitating influences, response to medications, and a pedigree to determine which family members are affected. Pertinent physical findings include dysmorphisms, organomegaly, neurologic impairment, bone involvement, and dermatologic findings. Because many rare and novel disorders are multisystemic, consultants play a critical role in every diagnostic evaluation. Typical studies performed to address possible diagnoses are listed in Table 83-1. The evaluation of a pediatric neurology case involves even more extensive studies (Table 83-2).

An inpatient admission allows for close interaction among experts in different fields, informs the workup of complex cases, and often leads to a focus on the discovery of a new disease. In that situation, other family members need to be evaluated to definitively ascertain whether they are affected with the disorder under consideration.

AVAILABLE COMMERCIAL LABORATORY GENETIC STUDIES

Once phenotyping is complete, a differential list of genetic disorders can be compiled. Laboratory molecular testing is available for an increasingly large spectrum of molecular disorders. In many cases, several related diseases are included in a panel of molecular tests. Examples include X-linked cognitive impairment, hereditary spastic paraplegia, spastic paraplegia and gait, spinocerebellar ataxias, dystonias, and mitochondrial disorders. Some of these individual tests and panels are expensive, and added together they may exceed the cost of exome sequencing.

Table 83-1 Initial Studies to Generate New Diagnostic Hypotheses

TEST(S)	RELATED DISORDERS/ DISORDER GROUPS
Electrolytes, lactate, pyruvate	Energy metabolism defects, including mitochondrial disorders
Plasma amino acids	Renal disorders, amino acid disorders
Urine organic acids	Renal disorders, organic acid disorders, energy metabolism disorders, vitamin deficiencies
Aldolase, creatine phosphokinase	Muscle disorders
Carnitine (free, total, acyl, panel)	Fatty acid oxidation disorders, carnitine metabolism disorders
Cerebrospinal fluid (CSF) analysis	Neurotransmitter disorders, inborn errors of metabolism, select disorders that may present only in the CSF
Brain MRI/magnetic resonance spectroscopy	Structural clues to disorders affecting central nervous system
Mass spectrometry to detect *N*- and *O*-linked proteoglycan abnormalities	Congenital disorders of glycosylation
Lysosomal enzyme testing	Lysosomal storage diseases
White cell and skin electron microscopy	Lysosomal storage diseases; neuronal lipofuscinoses
Pathologic evaluation of affected tissues with special stains, DNA hybridization	Any
Echo-/electrocardiogram	Cardiac defects
Nerve conduction velocity/ electromyogram	Neurologic defects
Fibroblast cell line	Any
Single-nucleotide polymorphism/exome/ genome/karyotype	Any
Erythrocyte sedimentation rate, C-reactive protein	Inflammatory disorders

SINGLE-NUCLEOTIDE POLYMORPHISM ARRAYS

There are 2 technologies that are cost-effective for medical uses and can examine the entire genome with resolution at the level of a single base pair. These are single-nucleotide polymorphism (SNP) arrays (microarrays or chips) and next-generation sequencing. The human genome's 3.2 billion bases include many that are polymorphic. Polymorphisms are bases that are not the usual one at a defined position and yet occur with a frequency of >1% within a given population. For any 2 individuals who are not closely related, there are approximately 2.5×10^6 SNPs that vary between them (and between each individual and the canonical human reference), or about 1 polymorphism for every 1,000 bases in the genome on average. Within a single ethnic population there is about 1 common SNP per 3,000-7,000 bases, where common means a greater than 10% chance that any 1 patient will be polymorphic (heterozygous) at that position. A few hundred thousand to a few million of these common SNPs can be included on a DNA hybridization array and examined simultaneously in a single laboratory test. This technique produces genome-wide results that reveal copy number variations; mosaicism is also revealed, as are regions of

identity by descent. These results are very useful in complementing the next-generation sequencing results. One example of this is the use of the SNP deletion regions to denote where to look for a point mutation in the next-generation sequence of the child (to detect the compound heterozygous recessive pairing of a deletion with a point mutation).

EXOME SEQUENCING

Technical advances have allowed for massive DNA sequencing at a reasonable price, making it feasible to determine the sequence of the coding regions of almost all of the human genes. Because this involves 1.7% of the 3.2 billion bases in the human genome, **exome sequences** comprise approximately 60,000,000 bases. These satisfactorily cover 80-85% of the known genes, and are determined by sequencing short "reads" (DNA fragments) and aligning them to a composite reference sequence of the human genome. In part because of SNP interference with hybridization, ambiguities in alignment, and chemistry error rates, the average exome has about 20,000 bases (0.03%) that differ from the "reference" sequence and from any other single, unrelated human sequence of the same ethnic group. Most of these variants are inconsequential polymorphisms. The problem is that each of the 20,000 variants of unknown significance is a **potential** disease-causing variant, yet only 1 is ***the*** disease-causing mutation for a monogenic disorder (with perhaps 2 or 3 additional loci modifying severity). The task of the clinician is to reduce the credible variants from 20,000 to a manageable number, such as 5.

This process involves using "filters," or programs that eliminate false-positive variants without eliminating the true variants. The single best filter uses the exome sequencing (ES) of nuclear family members (i.e., parents and siblings), but only if their true affected or unaffected status is certain. If, for example, an unaffected sibling's gene has 2 variants on opposite alleles that are the same as those of the affected proband, then those variants can be eliminated as causing the proband's disease. This emphasizes the importance of collecting family DNA and obtaining a very careful evaluation of family members. In general, having the proband, both parents and a sibling provides sufficient power to reduce the candidate variants to a reasonable number for all mendelian inheritance models, assuming complete penetrance.

As an example, if autosomal recessive inheritance is postulated, then the ES analysis should require mutations on both alleles of the proband, with 1 of the 2 mutations present in 1 parent and the other

mutation present in the other parent. Affected sibs must have both mutations, and unaffected sibs must have either 1 or none. Software programs have succeeded using a homozygous recessive model, and for significantly deleterious variants, using a compound heterozygous recessive model.

Base changes that result in amino acid changes (missense mutations) are evaluated by programs that gauge the pathogenicity of the change. This involves estimates of how tightly the base is conserved over evolution, whether the amino acid changes charge, size, or conformation, and, sometimes, where in the protein the amino acid change resides. Analyzing how changes in the genetic code influence protein function remains an inexact science, but approximations have been used with some success. Software programs, including PolyPhen-2, SIFT, and MutationTaster, rate the pathogenicity of amino acid changes. In addition, evolutionary consistency of a base can be evidence of deleteriousness of a change in that base, even if it is not involved in an amino acid change (promoter binding domains, methylation sites). Finally, some filters compare variants to databases that list changes considered to be benign (database of single-nucleotide polymorphisms), known to cause diseases other than those under investigation, or simply found frequently in many random genomes (1000 Genomes). These databases can be very helpful, but they are not entirely reliable because their entries have not been curated in all cases to a medically useful level of confidence.

The analysis of exome sequences is advancing rapidly, based upon the development of new filters and larger, better, and more informative databases. However, several key points need to be considered when employing genome-scale sequencing for clinical diagnostics.

Positive predictive value gives the likelihood that a positive test is a true positive. This is higher in a population in which a disease is frequent and lower in a population where the disease is rare. A person being tested with ES will show no clinical signs or symptoms of most of the genetic diseases for which the ES tests. Therefore, many apparently positive findings will be false positives. This manifests as the frequent occurrence of DNA variations in genes that are associated with phenotypes that do not match the person being tested. Such variants are difficult to interpret.

Individual versus family studies are relevant, as family data allow for variants to be substantially filtered. This advantage must be weighed against the financial costs of studying families versus individuals. Furthermore, family studies are useless if an affected person is called unaffected or *vice versa*. *Therefore, phenotyping family members is critical*. For later-onset conditions, younger siblings may not be suitable for inclusion in an exome study unless their affected status can be determined unambiguously.

Data revisiting policies must be addressed. Genome-scale sequencing generates data for many genes beside those involved in the current diagnostic effort. The sequencing data are of potential use in the future care of the patient. Even though some mutated genes are not reported because they are not currently associated with any medical condition, future advances may implicate such a gene in a human disease. The person ordering the exome study should be aware of the data reuse policy of the testing facility. In the current testing environment, time-limited data reuse and/or reuse fees are increasingly common.

Early discussion with a genetic specialist is critical. Genetic counseling should be sought before an exome study is sent rather than after the results become available. Proper consent for exome studies is an involved process, including information about disease risk factors, unrelated medical conditions, carrier states and cancer susceptibility. Consented individuals should be given the opportunity to consider which types of results they would like to have returned.

Anticipating findings that are difficult to use clinically is an important part of counseling. The problem of variants of unknown significance is well known for any type of genetic testing. Genome-scale sequencing amplifies this problem to include a wide variety of results that are difficult to use for medical decision making. Depending on the breadth of analysis and the resulting clinical report, different numbers of such findings will be returned to the ordering physician. Discussing such variants with families can be difficult; counseling families about the likelihood of receiving this type of result before testing is performed can help the family to cope when the report is returned (see Chapter 77).

When used as a gene panel, ES rules *in* but does not rule *out*. An exome study is a cost-effective way to test many genes at one time. However, there can be variation in coverage of any given exon among exome datasets. Therefore, even though exome studies are a powerful tool for variant discovery, they are not always sufficient to exclude variants in a panel of genes. With careful analysis involving laboratory validation on many similarly processed individuals, the exome coverage of any given gene can be assessed. However, commercial/clinical testing facilities may be unwilling to perform such an analysis when a large set of genes needs to be considered. Therefore, there is still a role for the use of a gene panel when the index of suspicion is high for a disorder caused by 1 of a large group of genes. Cerebellar ataxia and hereditary spastic paraparesis are examples.

Providing information to the testing facility improves the chances of a diagnosis. ES interpretation will benefit substantially from the incorporation of accurate and detailed clinical information about the presenting phenotype. The more clinical information that is provided to the testing lab, the more specific and useful the clinical report will be.

GENE FUNCTION STUDIES

Despite filtering for frequency and predicted deleteriousness, a variant identified by genomic sequencing cannot be interpreted as the cause of an individual's disease unless it has been previously demonstrated to cause a disease with a similar phenotype. To prove causality, medical genetics relies upon association (the recurrence of mutations within a gene among individuals with a similar phenotype). For rare diseases, there may be too few affected patients to demonstrate a statistically-significant association. In this setting, other evidence will be required to connect a specific genetic variant with an isolated phenotype. One approach is to accumulate additional diagnostic data about the patient that can be used to prioritize genetic variants (phenotype ontologies, metabolomics, glycomics, proteomics, and lipidomics). A second approach is to develop models that recapitulate the disease in question, such as mice, zebrafish, fruit flies, yeast, and cultured cells. Third, the variant in question can be linked to a biologic process or pathway that is known to cause a similar phenotype when disturbed. Finally, standardized and correlated phenotypic and genomic data are deposited into a database to identify other individuals with a similar phenotype and mutations in the same gene.

Physicians may apply their past biases to a group of variants that could be disease causing, but this is often misleading. A standardized computational approach would be preferable. For example, the Human Phenotype Ontology will standardize the description of a disease and, because the descriptors have been mapped to other human diseases and to mutant model organisms, will identify possible candidate genes and genetic networks for causing the disease. Similarly, untargeted laboratory screening tests provide an unbiased survey of patient cellular biology and physiology and a more informed prioritization of variants causing the patient's disease.

The ultimate proof of causality is to ameliorate the disease process by correcting the genetic defect, and this can sometimes be demonstrated in a model system that recapitulates the human disease. If model systems fail to identify the genetic cause of an individual's disease, one must search for other patients with a similar phenotype and mutations in the same gene. This can be accomplished using public databases that are interpreted using strict statistical and biologic standards.

PEDIATRIC ISSUES

During its first 4 yr, the UDP at NIH received 500 pediatric applications. In >10% of cases, more than 1 family member, usually a sibling, was similarly affected. There were 2 peaks in the age distribution of the children: 1 at 4-5 yr, reflecting patients with congenital disorders, and 1 at 16-18 yr representing disorders with symptom onset at early school age. The majority of applicants had been on a diagnostic odyssey for more than 5 yr. Of the 200 pediatric cases accepted, 175 were

evaluated to date and 25% received a diagnosis. Of the diagnoses, half were obtained using conventional diagnostic methods, including clinical suspicion with molecular confirmation, biochemical testing with molecular confirmation, or radiographic interpretation. In the remainder of cases the diagnosis was arrived at using SNP analysis and next-generation sequencing; all of these were rare diseases.

Pediatric medical records require attention to what has and what has not been completed previously. The electronic medical record is an important tool for medical practice, but *copy forward* functions can perpetuate errors, such as reports of normal testing when in fact the test was recommended or ordered but cancelled. Repetitive copying also fosters sloppiness in critical thinking, failure to take an adequate history, and missing the nuances of symptom progression. *A history and physical examination should be performed anew and all prior testing results confirmed via copies of original laboratory reports.*

Prolonged and painful procedures should be performed under sedation, but the risks associated with sedation must be weighed against the value of the information and samples to be obtained (see Table 83-2).

CONSIDERATIONS FOR FAMILIES OF UNDIAGNOSED CHILDREN

When a child comes to a genetics clinic for evaluation the parents want to know:

- What does my child have? (diagnosis)
- Why did it happen? (etiology/inheritance)
- What will happen in the future? (natural history)
- Is there a treatment? (therapy)
- Could the same thing happen to other family members? (recurrence risk)

The answers to all of these questions require an accurate diagnosis. The lack of a diagnosis also makes both the family and the physician uncomfortable, raises suspicion among relatives and acquaintances, and creates feelings of guilt about not having worked hard enough to find a diagnosis. As a consequence, families consult more and more specialists, and are often frustrated with the lack of coordination among providers. It is helpful for the family to save copies of every test and every visit from each institution and compile them in a binder for travel among institutions. A 2-3 page narrative summarizing the child's history, medications, list of healthcare providers with contact information, main medical issues, level of functioning on well days and sick days, and interventions that worked in the past, can be invaluable in an emergency room setting. An electronic copy is easily updated. Parents can always be the best advocates for their child, particularly an undiagnosed child.

Recommendations to parents of an undiagnosed child are similar to those that apply to any child with chronic illness:

- Keep copies of all records, electronic and otherwise, and organize them routinely, especially copies of original reports from "send-out" labs.
- Carry an updated emergency letter.
- Establish a medical home even if you obtain many second opinions.
- Find a physiatrist (rehabilitation medicine physician) to coordinate rehabilitative care.
- Be aggressive with the school system about services using, a legal advocate if necessary.
- Explore parent support groups for unknown disorders (Syndromes Without a Name, National Organization for Rare Disorders).
- Periodically check with providers (especially geneticists) for new diagnoses reported in the medical literature.
- Carve out time for yourselves as caregivers by engaging extended family members or respite care services.
- Work at supporting and being attentive to well children in the family.
- For the very sick dying child, consider an autopsy as a final attempt to establish a diagnosis especially when there is a possibility of future pregnancies.

THE DIAGNOSTIC SPECTRUM

The extent of determining the diagnosis varies considerably, from that of recognizing a clinical entity, to a largely molecular diagnosis, or to one in which the entire pathogenesis is known. In addition to known disorders, SNP and ES analyses may also identify variants in genes that are candidates for causing a new disease.

One example of a diagnosis involves 2 brothers whose parents were first cousins. The brothers had an early-onset spastic ataxia-neuropathy syndrome, with lower-extremity spasticity, peripheral neuropathy, ptosis, oculomotor apraxia, dystonia, cerebellar atrophy, and progressive myoclonic epilepsy. A homozygous missense mutation (c.1847G>A; p.Y616C) in *AFG3L2*, which encodes a subunit of a mitochondrial protease, was identified by ES. The AFG3L2 protein can bind to another AFG3L2 molecule or to paraplegin. UDP collaborators in Germany used a yeast model system to demonstrate that the patients' mutation affects the specific amino acid involved in the formation of both of these complexes. As a result, the brothers exhibited the signs and symptoms of a known AFG3L2 defect, autosomal dominant spinocerebellar ataxia type 28 (SCA28), and a known paraplegin defect, hereditary spastic paraplegia type 7 (SPG7). Other features of a mitochondrial disorder (oculomotor apraxia, extrapyramidal dysfunction, myoclonic epilepsy) were also present. The 2 brothers represent the first such cases in the world, and expand the phenotype of AFG3L2 disease.

A second example involves 2 siblings ages 5 and 10 yr with hypotonia, developmental delays, facial dysmorphisms, hearing loss, nystagmus, seizures, and atrophy on brain MRI. In this case, the leading clue was biochemical in nature, and genetic analysis confirmed the diagnosis. Urine thin-layer chromatography for oligosaccharides identified a strong band determined by mass spectrometry to consist of a tetrasaccharide containing 3 glucoses and one mannose. This suggested a defect of glucosidase I, the first enzyme involved in endoplasmic reticulum trimming of *N*-linked glycoproteins from a high-mannose to a complex form. Mutation analysis confirmed compound heterozygous mutations in the glucosidase I gene, establishing the diagnosis of congenital disorder of glycosylation IIb; the 2 siblings were the second and third patients in the world with this disorder.

The genetic analysis of rare and undiagnosed diseases has also yielded a variety of unique phenotypes that very likely represent new diseases. When variants in multiple genes are candidates for causing such a disorder, functional studies are required to demonstrate causality. This was successfully accomplished for a new disorder of vascular calcification identified and elucidated through the UDP at the NIH and found to be caused by a genetic deficiency of CD73, an enzyme on the surface of vascular cells that converts adenosine monophosphate to adenosine and inorganic phosphate.

Metabolic Disorders

PART XI

Chapter 84
An Approach to Inborn Errors of Metabolism

Iraj Rezvani and Geoffrey A. Rezvani

Many childhood conditions are caused by single-gene mutations that encode specific proteins. These mutations can result in the alteration of primary protein structure or the amount of protein synthesized. The function of a protein, whether it is an enzyme, receptor, transport vehicle, membrane component, or structural element, may be compromised or abolished. These hereditary biochemical disorders are termed **inborn errors of metabolism** or **inherited metabolic disorders.**

Most mutations are clinically inconsequential and represent polymorphic differences that set individuals apart *(genetic polymorphism).* Some mutations produce disease states that range from very mild to lethal. Severe forms of these disorders usually become clinically apparent in the newborn period or shortly thereafter.

COMMON CHARACTERISTICS OF GENETIC DISORDERS OF METABOLISM

Although the manifestations of genetic metabolic disorders are quite variable, the following features are shared among most of these conditions:

1. The affected infant is normal at birth and becomes symptomatic later on in life. This differentiates these infants from those who appear sick at birth as a result of birth trauma, intrauterine insults, chromosomal abnormalities, or other genetic diseases.
2. The nature of the mutation that causes the dysfunction of the gene usually varies from family to family. This results in variation in severity of the phenotype in different families. An exception to this is found when a specific mutation has been preserved in an ethnic group primarily from inbreeding (the founder effect). An example is maple syrup urine disease in Old Order Mennonites in the United States (mainly in Lancaster County, PA), in whom all the affected infants have the same mutation and hence the same phenotype (see Chapter 85.6).
3. Mutations causing severe malfunction of the gene or its product result in clinical manifestations shortly after birth. In general, the earlier the appearance of clinical symptoms, the more severe the disease.
4. The majority of conditions are inherited as autosomal recessive traits. Therefore, a history of consanguinity in the parents or of an unexplained death of a family member in the neonatal period may raise the question of an inherited metabolic disease in the sick infant.
5. Most genetic metabolic conditions can be controlled successfully by some form of therapy, and a few can be potentially cured by the use of bone marrow or liver transplants. These patients can have a normal life if diagnosed and treated early, before irreversible damage to organs, especially to the brain, occurs. This underlines the importance of early diagnosis, which can be achieved through mass screening of all newborn infants.

MASS SCREENING OF NEWBORN INFANTS

Common characteristics of genetic metabolic conditions and the significance of early diagnosis make a strong argument for screening all newborn infants for the presence of these conditions. During the past half-century, methods have been developed to screen all infants inexpensively with accurate and fast-yielding results. Tandem mass spectrometry is the latest technical advance in the field. This method requires a few drops of blood to be placed on a filter paper and mailed to a central laboratory for assay. A large number of genetic conditions can be identified by this method when complemented by a few equally efficient assays for other specific disorders (Tables 84-1 and 84-2). Severe forms of some of these diseases may cause clinical manifestations before the results of the newborn screening become available. It should also be noted that these methods may identify mild forms of inherited metabolic conditions, some of which may never cause clinical manifestations in the lifetime of the individual. Potential psychosocial implications of such findings can be drastic and deserve serious consideration. An example of this is 3-methylcrotonyl-coenzyme A carboxylase deficiency, which has been identified with unexpectedly high frequency in screening programs using tandem mass spectrometry. The majority of these children have remained asymptomatic (see Chapter 85.6).

CLINICAL MANIFESTATIONS OF GENETIC METABOLIC DISEASES

Physicians and other healthcare providers who care for children should familiarize themselves with early manifestations of genetic metabolic disorders, because (1) severe forms of some of these conditions may cause symptoms before the results of screening studies become available, and (2) the current screening methods, although quite extensive, identify a small number of all inherited metabolic conditions. In the newborn period, the clinical findings are usually nonspecific and similar to those seen in infants with sepsis. A genetic disorder of metabolism should be considered in the differential diagnosis of a severely ill newborn infant, and special studies should be undertaken if the index of suspicion is high (Fig. 84-1).

Signs and symptoms such as lethargy, poor feeding, convulsions, and vomiting may develop as early as a few hours after birth. Occasionally, vomiting may be severe enough to suggest the diagnosis of pyloric stenosis, which is usually not present, although it may occur simultaneously in such infants. Lethargy, poor feeding, convulsions, and coma also may be seen in infants with hypoglycemia (see Chapters 92 and 107) or hypocalcemia (see Chapters 51 and 571). Measurements of blood concentrations of glucose and calcium and response to intravenous injection of glucose or calcium usually establish these diagnoses. Some of these disorders have a high incidence in specific population groups. Tyrosinemia type 1 is more common among French-Canadians of Quebec than in the general population. Therefore, knowledge of the ethnic background of the patient may be helpful in diagnosis. *Physical examination* usually reveals nonspecific findings; most signs are related to the central nervous system. Hepatomegaly is a common finding in a variety of inborn errors of metabolism. Occasionally, a peculiar odor may offer an invaluable aid to the diagnosis (Table 84-3). A physician caring for a sick infant should smell the patient and the patient's excretions; for example, patients with maple syrup urine disease have the unmistakable odor of maple syrup in their urine and on their bodies.

Occasionally, the onset of a genetic metabolic condition may occur months or years after birth. These children usually have mutations that render the gene partially nonfunctional. *Clinical manifestations,* such as intellectual disability, motor deficits, developmental regression, convulsions, myopathy, recurrent emesis, and cardiomyopathy, in a child beyond the neonatal period should raise the possibility of an inherited

Table 84-1 Disorders Recommended By the American College of Medical Genetics Task Force for Inclusion in Newborn Screening ("Primary Disorders")*

DISORDERS OF ORGANIC ACID METABOLISM
Isovaleric acidemia
Glutaric aciduria type I
3-Hydroxy-3-methylglutaric aciduria
Multiple carboxylase deficiency
Methylmalonic acidemia, mutase deficiency form
3-Methylcrotonyl-CoA carboxylase deficiency
Methylmalonic acidemia, cblA and cblB forms
Propionic acidemia
β-Ketothiolase deficiency
DISORDERS OF FATTY ACID METABOLISM
Medium-chain acyl-CoA dehydrogenase deficiency
Very-long-chain acyl-CoA dehydrogenase deficiency
Long-chain 3-hydroxy acyl-CoA dehydrogenase deficiency
Trifunctional protein deficiency
Carnitine uptake defect
DISORDERS OF AMINO ACID METABOLISM
Phenylketonuria
Maple syrup urine disease
Homocystinuria
Citrullinemia
Argininosuccinic acidemia
Tyrosinemia type I
HEMOGLOBINOPATHIES
Sickle cell anemia (hemoglobin S)
Hemoglobin S-β-thalassemia
Hemoglobin SC disease
OTHER DISORDERS
Congenital hypothyroidism
Biotinidase deficiency
Congenital adrenal hyperplasia
Galactosemia
Hearing deficiency
Cystic fibrosis

*At this time, there is state-to-state variation in newborn screening; a list of the disorders that are screened for by each state is available at http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/nbsdisorders.pdf.

cblA, Cobalamin A defect; cblB, cobalamin B defect; CoA, coenzyme A.

Table 84-2 Secondary Conditions Recommended By American College of Medical Genetics* Task Force for Inclusion in Newborn Screening

ORGANIC ACID METABOLISM DISORDERS
Methylmalonic acidemia, cblC and cblD forms
2-Methyl-3-hydroxybutyric aciduria
Isobutyryl-CoA dehydrogenase deficiency
2-Methylbutyryl-CoA dehydrogenase deficiency
3-Methylglutaconic aciduria
Malonic acidemia
FATTY ACID OXIDATION DISORDERS
Medium-/short-chain 3-OH acyl-CoA dehydrogenase deficiency
Short-chain acyl-CoA dehydrogenase deficiency
Medium-chain ketoacyl-CoA thiolase deficiency
Glutaric acidemia type 2
Carnitine palmitoyltransferase I deficiency
Carnitine palmitoyltransferase II deficiency
Carnitine acylcarnitine translocase deficiency
Dienoyl-CoA reductase deficiency
AMINO ACID METABOLISM DISORDERS
Hyperphenylalaninemia, benign (not phenylketonuria)
Tyrosinemia type II
Tyrosinemia type III
Defects of biopterin cofactor biosynthesis
Defects of biopterin cofactor regeneration
Argininemia
Hypermethioninemia
Citrullinemia type II
HEMOGLOBINOPATHICS
Hemoglobin variants (including hemoglobin E)
OTHERS
Galactose epimerase deficiency
Galactokinase deficiency

*The American College of Medical Genetics task force recommended reporting 25 disorders ("secondary targets") in addition to the primary disorders that can be detected through screening but that do not meet the criteria for primary disorders.

cblC, Cobalamin C defect; cblD, cobalamin D defect; CoA, coenzyme A.

Table 84-3 Inborn Errors of Amino Acid Metabolism Associated with Peculiar Odor

INBORN ERROR OF METABOLISM	URINE ODOR
Glutaric acidemia (type II)	Sweaty feet, acrid
Hawkinsinuria	Swimming pool
3-Hydroxy-3-methylglutaric aciduria	Cat urine
Isovaleric acidemia	Sweaty feet, acrid
Maple syrup urine disease	Maple syrup
Hypermethioninemia	Boiled cabbage
Multiple carboxylase deficiency	Tomcat urine
Oasthouse urine disease	Hops-like
Phenylketonuria	Mousey or musty
Trimethylaminuria	Rotting fish
Tyrosinemia	Boiled cabbage, rancid butter

metabolic disease. There may be an episodic or intermittent pattern, with episodes of acute clinical manifestations separated by periods of seemingly disease-free states. The episodes are usually triggered by stress or a nonspecific catabolic insult such as an infection. The child may die during one of these acute attacks. A genetic disorder of metabolism should be considered in any child with 1 or more of the following manifestations: unexplained intellectual disability, developmental delay or regression, motor deficits or adventitious movements (e.g., dystonia, choreoathetosis), convulsions, unusual odor (particularly during an acute illness); intermittent episodes of unexplained vomiting, acidosis, mental deterioration, psychotic behavior or coma; hepatomegaly; renal stones; muscle weakness; or cardiomyopathy. For example, urea cycle defects may present with confusion, behavioral disturbances, catatonia, hallucinations, psychosis, or depression. Catatonia may also be seen in disorders of folate metabolism, porphyria, Wilson disease, and some storage diseases. Severe seizures may be noted in molybdenum cofactor deficiency, biotinidase deficiency, neuronal ceroid lipofuscinosis, nonketolic hyperglycinemia, or creatine deficiency.

Diagnosis usually requires a variety of specific *laboratory studies.* Measurements of serum concentrations of ammonia, bicarbonate, and pH are often very helpful initially in differentiating major causes of genetic metabolic disorders (see Fig. 84-1). Elevation of blood ammonia is usually caused by defects of urea cycle enzymes. Infants with elevated blood ammonia levels from urea cycle defects commonly have normal serum pH and bicarbonate values; without measurement of blood ammonia, they may remain undiagnosed and succumb to their disease. Elevation of serum ammonia is also observed in some infants with certain organic acidemias. These infants are severely acidotic because of accumulation of organic acids in body fluids.

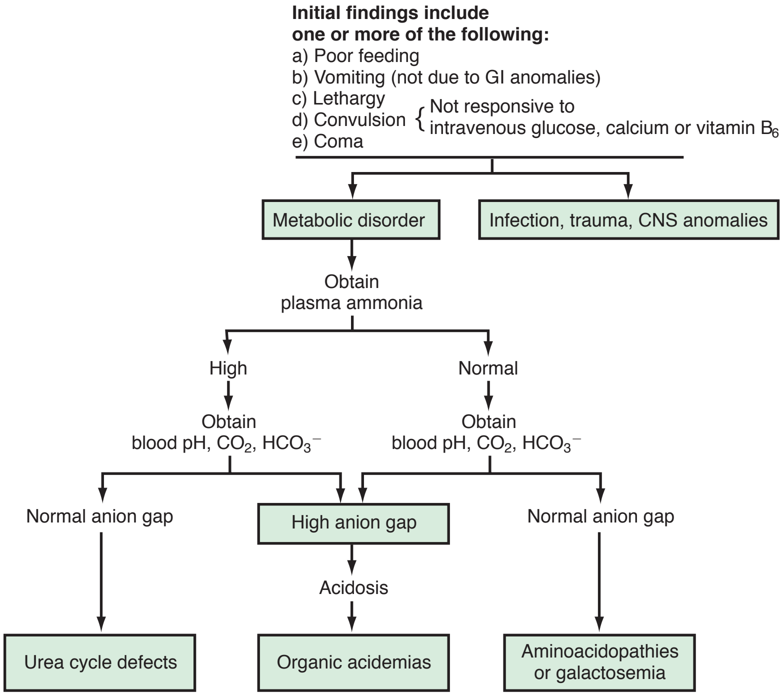

Figure 84-1 **Initial clinical approach to a full term newborn infant with a suspected genetic metabolic disorder.** This schema is a guide to the elucidation of some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases.

When blood ammonia, pH, and bicarbonate values are normal, other aminoacidopathies (such as hyperglycinemia) or galactosemia should be considered; galactosemic infants may also manifest cataracts, hepatomegaly, ascites, and jaundice.

TREATMENT

The majority of patients with genetic disorders of metabolism respond to 1 or all of the following treatments:

1. Special diets play an important role in the treatment of affected children. Dietary changes should be tailored to the pathophysiology of the condition and vary greatly among disorders.
2. Peritoneal dialysis or hemodialysis for expeditious removal of accumulated noxious compounds. This is a very effective modality for treatment of the acute phase of the condition.
3. Administration of the deficient metabolite.
4. Administration of the cofactor or coenzyme to maximize the residual enzyme activity.
5. Activation of alternate pathways to reduce the noxious compounds accumulated because of the genetic mutation.
6. Administration of the deficient enzyme.
7. Bone marrow transplantation.
8. Liver transplantation.

The bone marrow and liver transplantation modalities have the potential to cure the metabolic abnormalities. Replacement of the mutant gene with a normal one (gene therapy) is still in the experimental phase.

Treatment of genetic disorders of metabolism is complex and requires medical and technical expertise. The therapeutic regimen often needs to be tailored to the individual patient because of large phenotypic variations in the severity of the disease, even within a single family. Providing education and support for the family is the key to successful long-term therapy. Even in patients with hopeless prognoses every effort should be made to establish correct diagnoses premortem as the autopsy results are often noncontributory to the diagnosis. Effective treatment is best achieved by a team of specialists (physician metabolic genetics specialist, nutritionist, geneticist, neurologist, and psychologist) in a major medical center.

Chapter 85

Defects in Metabolism of Amino Acids

85.1 Phenylalanine

Iraj Rezvani and Can H. Ficicioglu

Phenylalanine is an essential amino acid. Dietary phenylalanine not utilized for protein synthesis is normally degraded by way of the tyrosine pathway (Fig. 85-1). Deficiency of the enzyme phenylalanine hydroxylase (PAH) or of its cofactor tetrahydrobiopterin (BH_4) causes accumulation of phenylalanine in body fluids and in the brain.

Hyperphenylalaninemia depends on the degree of enzyme deficiency and may vary from very high plasma concentrations (>20 mg/dL or >1,200 µmole/L, **classic phenylketonuria**) to mildly elevated levels (2-10 mg/dL or 120-600 µmole/L, **mild hyperphenylalaninemia**). In affected infants with plasma concentrations >20 mg/dL, excess phenylalanine is metabolized to phenylketones (phenylpyruvate and phenylacetate; see Fig. 85-1) that are excreted in the urine, giving rise to the term *phenylketonuria* (PKU). These metabolites have no role in pathogenesis of central nervous system (CNS) damage in patients with PKU; their presence in the body fluids simply signifies the severity of the condition. The term **hyperphenylalaninemia** implies lower plasma levels (<20 mg/dL) of phenylalanine. The brain is the main organ affected by hyperphenylalaninemia. The CNS damage in affected patients is caused by the elevated concentration of phenylalanine in brain tissue. The high blood levels of phenylalanine in PKU saturate the transport system across the blood–brain barrier causing inhibition of the cerebral uptake of other large neutral amino acids such as tyrosine and tryptophan. The exact mechanism of damage caused by elevated levels of intracerebral phenylalanine remains elusive. There have been a few adults with classic PKU and normal intelligence who have

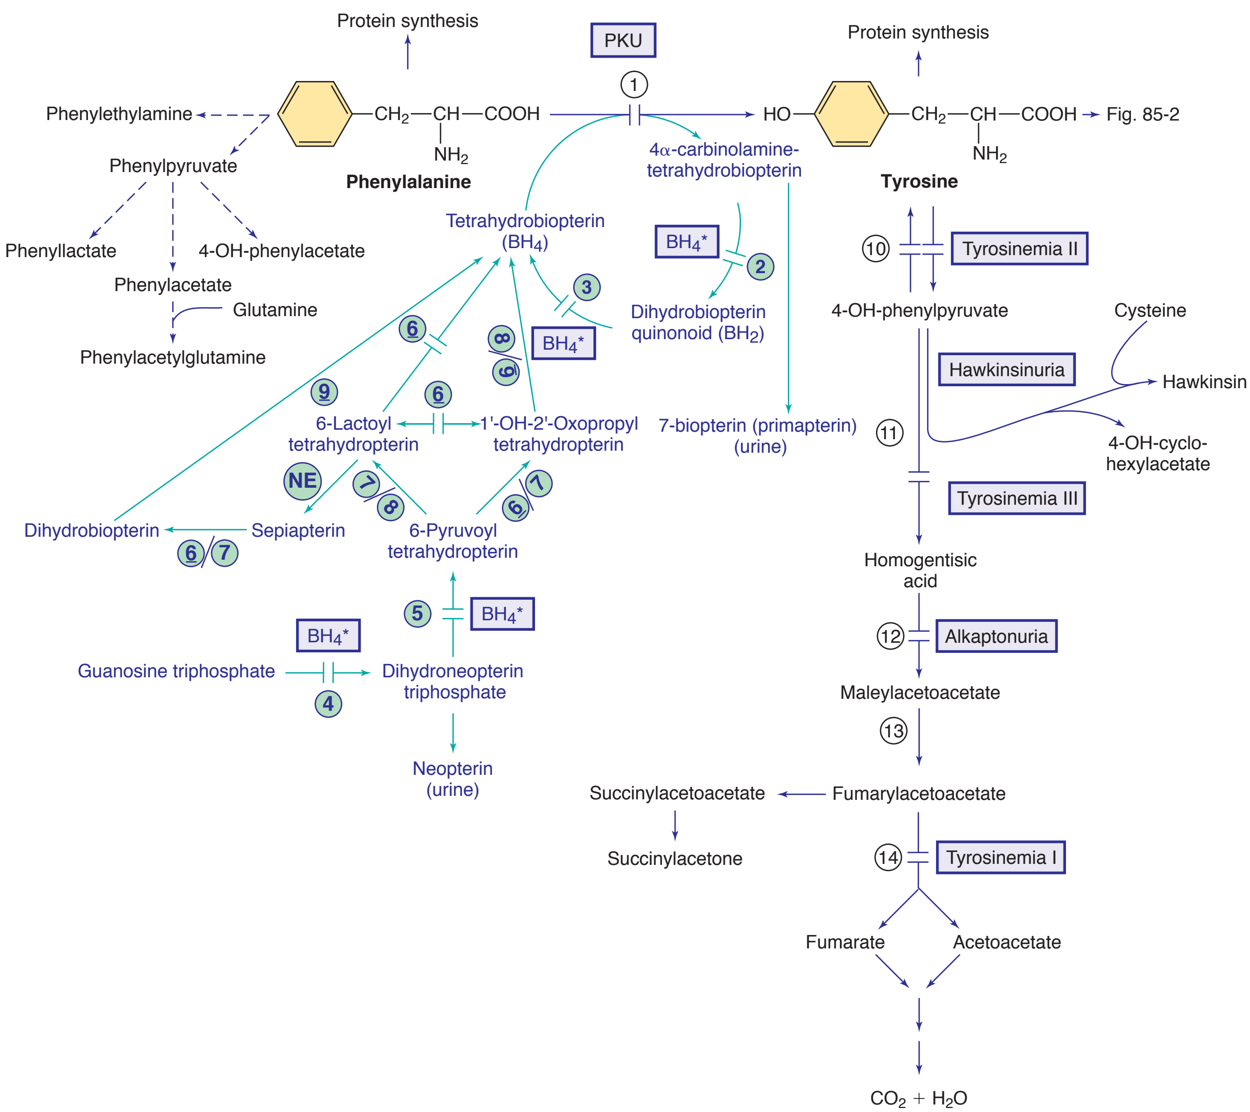

Figure 85-1 Pathways of phenylalanine and tyrosine metabolism. Enzyme defects causing genetic conditions are depicted as horizontal bars crossing the reaction arrow(s). Pathways for synthesis of cofactor BH_4 are shown in purple. PKU* refers to defects of BH_4 metabolism that affect the phenylalanine, tyrosine, and tryptophan hydroxylases (see Figs. 85-2 and 85-5). **Enzymes:** *(1)* Phenylalanine hydroxylase, *(2)* pterin-carbinolamine dehydratase, *(3)* dihydrobiopterin reductase, *(4)* guanosine triphosphate (GTP) cyclohydrolase, *(5)* 6-pyruvoyltetrahydropterin synthase, *(6)* sepiapterin reductase, *(7)* carbonyl reductase, *(8)* aldolase reductase, *(9)* dihydrofolate reductase, *(10)* tyrosine aminotransferase, *(11)* 4-hydroxyphenylpyruvate dioxygenase, *(12)* homogentisic acid dioxygenase, *(13)* maleylacetoacetate isomerase, *(14)* fumarylacetoacetate hydrolase, *(NE)* nonenzymatic.

never been treated with a phenylalanine-restricted diet. Phenylalanine content of the brain in these individuals was found to be close to that of normal subjects when studied by magnetic resonance spectroscopy (MRS).

CLASSIC PHENYLKETONURIA

Severe hyperphenylalaninemia (plasma phenylalanine levels >20 mg/dL), if untreated, invariably results in the development of signs and symptoms of classic PKU, except in rare unpredictable cases (see above).

Clinical Manifestations

The affected infant is normal at birth. Profound intellectual disability develops gradually if the infant remains untreated. Cognitive delay may not be evident for the first few months. In untreated patients, 50-70% will have an IQ below 35, and 88-90% will have an IQ below 65. Only 2-5% of untreated patients will have normal intelligence. Many patients require institutional care if the condition remains untreated. Vomiting, sometimes severe enough to be misdiagnosed as pyloric stenosis, may be an early symptom. Older untreated children become hyperactive with autistic behaviors, including purposeless hand movements, rhythmic rocking, and athetosis.

The infants are lighter in their complexion than unaffected siblings. Some may have a seborrheic or eczematoid rash, which is usually mild and disappears as the child grows older. These children have an unpleasant odor of phenylacetic acid, which has been described as musty or mousey. Neurologic signs include seizures (approximately 25%), spasticity, hyperreflexia, and tremors; more than 50% have electroencephalographic abnormalities. Microcephaly, prominent maxillae with widely spaced teeth, enamel hypoplasia, and growth retardation are other common findings in untreated children. The clinical manifestations of classic PKU are rarely seen in those countries in which neonatal screening programs for the detection of PKU are in effect.

Nonphenylketonuria Hyperphenylalaninemias (Milder Forms of Hyperphenylalaninemia)

In any screening program for PKU, a group of infants is identified in whom initial plasma concentrations of phenylalanine are above normal (i.e., >2 mg/dL or 120 µmole/L) but <20 mg/dL (1,200 µmole/L). These infants do not excrete phenylketones. Patients with non-PKU

hyperphenylalaninemia may still require dietary therapy, depending on their untreated plasma phenylalanine level. Attempts have been made to classify these patients in different subgroups depending on the degree of hyperphenylalaninemia, but such a practice has little clinical or therapeutic advantage. The possibility of deficiency of BH_4 should be investigated in all infants with the milder forms of hyperphenylalaninemia (see below).

Diagnosis

Because of the gradual and nonspecific nature of early clinical symptoms such as vomiting, developmental delay, or eczematoid rash, hyperphenylalaninemia is usually diagnosed through newborn screening in all developed countries. In infants with positive screening results, diagnosis should be confirmed by quantitative measurement of plasma phenylalanine concentration. Identification and measurement of phenylketones in the urine has no place in any screening program. In countries and places where such programs are not in effect, identification of phenylketones in the urine by ferric chloride may offer a simple test for diagnosis of infants with developmental and neurologic abnormalities. Once the diagnosis of hyperphenylalaninemia is established, additional studies for BH_4 metabolism should be performed to rule out BH_4 deficiency as the cause of hyperphenylalaninemia (see below).

Neonatal Screening for Hyperphenylalaninemia

Effective and relatively inexpensive methods for mass screening of newborn infants have been developed and are used in the United States and several other countries. A few drops of blood, which are placed on a filter paper and mailed to a central laboratory, are used for assay. The bacterial inhibition assay of Guthrie, which was the first method used for this purpose, has been replaced by more precise and quantitative methods (fluorometric and tandem mass spectrometry). The method of choice is tandem mass spectrometry, which identifies all forms of hyperphenylalaninemia with a low false-positive rate and excellent accuracy and precision. The addition of the phenylalanine : tyrosine molar ratio has further reduced the number of false-positive results. Diagnosis must be confirmed by measurement of plasma phenylalanine concentration. Blood phenylalanine in affected infants with PKU may rise to diagnostic levels as early as 4 hr after birth, even in the absence of protein feeding. It is recommended that the blood for screening be obtained in the first 24-48 hr of life after feeding protein to reduce the possibility of false-negative results, especially in the milder forms of the condition.

Treatment

The mainstay of treatment of PKU is a low–phenylalanine diet. The general consensus is to start diet treatment immediately in patients with blood phenylalanine levels above 10 mg/dL (600 µmole/L). Most physicians also advocate phenylalanine-restricted diet in patients with mild hyperphenylalaninemia whose levels are persistently above 6 mg/dL (360 µmole/L). It is generally accepted that infants with persistent (more than a few days) plasma levels of phenylalanine ≥6 mg/dL (360 µmole/L) should be treated with a phenylalanine-restricted diet similar to that for classic PKU. The goal of therapy is to reduce phenylalanine levels in the plasma and brain. Formulas free of or low in phenylalanine are commercially available. The diet should be started as soon as the diagnosis is established. Because phenylalanine is not synthesized endogenously, small amounts of phenylalanine should be added to the diet to prevent *phenylalanine deficiency*. Dietary deficiency of this amino acid is manifested by lethargy, failure to thrive, anorexia, anemia, rashes, diarrhea, and even death; moreover, tyrosine becomes an essential amino acid in this disorder and its adequate intake must be ensured. Special food items low in phenylalanine are commercially available for dietary treatment of affected children and adults.

There is no firm consensus concerning optimal level of blood phenylalanine in affected patients either across different countries or among treatment centers in the United States. In 2001, the National Institutes of Health Consensus Development Panel recommended that plasma phenylalanine levels be maintained between 2 and 6 mg/dL in neonates through 12 yr of age and between 2 and 15 mg/dL in older individuals. Given that brain development continues in adolescence and even in adulthood, maintenance of lower plasma phenylalanine levels (2-10 mg/dL) has been strongly encouraged even after 12 yr of age. The duration of diet therapy is also controversial. Discontinuation of therapy, even in adulthood, may cause deterioration of IQ and cognitive performance. The current recommendation from the 2001 National Institutes of Health Consensus Development Panel is that all patients be kept on a phenylalanine-restricted diet for life. Lifelong adherence to a low phenylalanine diet is extremely difficult. Patients, who maintain good control as children but discontinue the phenylalanine-restricted diet as teenagers or adults, may experience significant difficulties with executive function concentration, emotional liability, and depression. Executive dysfunction may also occur in early treated children in spite of diet treatment.

Given the difficulty of maintaining a strict low-phenylalanine diet, there are continuing attempts to find other modalities for treatment of these patients. Administration of large neutral amino acids (LNAAs) is another approach to diet therapy. LNAAs (tyrosine, tryptophan, arginine, leucine, isoleucine, valine, methionine, histidine, lysine, threonine and phenylalanine) share the same transporter protein (LNAA type 1, LAT-1) for transit through the intestinal cell membrane and blood–brain barrier. Binding of LNAA to the transporter protein is a competitive process. The rationale for use of LNAA is that these molecules compete with phenylalanine for transport across the blood–brain barrier; therefore, large concentrations of other LNAAs in the intestinal lumen and in the blood reduce the uptake of phenylalanine into bloodstream and the brain. Clinical trials to establish the efficacy of this treatment are lacking at this time. Oral administration of BH_4, the cofactor for PAH, may result in reduction of plasma levels of phenylalanine in some patients with PAH deficiency. Plasma levels of phenylalanine in these patients may decrease enough to allow for considerable modification of their dietary restriction. In very rare cases, the diet may be discontinued because the phenylalanine levels remain under 6 mg/dL. The response to BH_4 cannot be predicted consistently on the basis of genotype, especially in compound heterozygous patients. Sapropterin dihydrochloride (Kuvan), a synthetic form of BH_4, which acts as a cofactor in patients with residual PAH activity, is approved by the FDA to reduce phenylalanine levels in PKU. At a dose of 10 mg/kg/day, it reduces phenylalanine levels in up to 40% of patients. Preliminary trials with recombinant phenylalanine ammonia lyase have been encouraging and demonstrated reduced blood levels of phenylalanine during treatment.

Low mineral bone density and osteopenia have been reported in affected individuals of all ages. Although inadequate intake of natural proteins seems to be the major culprit, the exact pathogenesis of this sequela remains unclear.

Long-term care of patients with PKU is best achieved by a team of experienced professionals (metabolic specialist, nutritionist, and psychologist) in a regional treatment center.

Pregnancy in Women with Hyperphenylalaninemia (Maternal Phenylketonuria)

Pregnant women with hyperphenylalaninemia who are not on a phenylalanine-restricted diet have a very high risk of having offspring with intellectual disability, microcephaly, growth retardation, congenital malformations, and congenital heart disease. These complications are directly correlated with elevated maternal blood phenylalanine levels during pregnancy. Prospective mothers who have been treated for hyperphenylalaninemia should be maintained on a phenylalanine-restricted diet before and during pregnancy; the best observed outcomes occur when strict control of maternal blood phenylalanine concentration is instituted before pregnancy or by 8 wk of gestation at the latest. The currently recommended phenylalanine concentrations are between 2 and 6 mg/dL (120-360 µmol/L) throughout the pregnancy. All women with hyperphenylalaninemia who are of childbearing age should be counseled properly as to the risk of the just described congenital anomalies in their offspring.

HYPERPHENYLALANINEMIA CAUSED BY DEFICIENCY OF THE COFACTOR TETRAHYDROBIOPTERIN

In 1-3% of infants with hyperphenylalaninemia, the defect resides in 1 of the enzymes necessary for production or recycling of the cofactor BH_4 (see Fig. 85-1). If these infants are misdiagnosed as having PKU, they may deteriorate neurologically despite adequate control of plasma phenylalanine. BH_4 is synthesized from guanosine triphosphate (GTP) through several enzymatic reactions (see Fig. 85-1). In addition to acting as a cofactor for PAH, BH_4 is also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are involved in the biosynthesis of dopamine (Fig. 85-2) and serotonin (see Fig. 85-5), respectively. Therefore, patients with hyperphenylalaninemia as a result of BH_4 deficiency also manifest neurologic findings related to deficiencies of the neurotransmitters dopamine and serotonin. Four enzyme deficiencies leading to defective BH_4 formation cause hyperphenylalaninemia with concomitant deficiencies of dopamine and serotonin. These include autosomal recessive GTP cyclohydrolase deficiency, pterin-carbinolamine dehydratase deficiency, dihydropteridine reductase deficiency, and 6-pyruvoyltetrahydropterin synthase deficiency. More than half of the reported patients have had a deficiency of 6-pyruvoyltetrahydropterin synthase. Autosomal dominant forms of GTP deficiency and sepiapterin reductase deficiency result in deficiencies of neurotransmitters without hyperphenylalaninemia (see Chapter 85.11 and Fig. 85-1).

Clinical Manifestations

Infants with cofactor deficiency are identified during screening programs for PKU because of evidence of hyperphenylalaninemia. Plasma phenylalanine levels may be as high as those in classic PKU or in the range of milder forms of hyperphenylalaninemia. However, the clinical manifestations of the neurotransmitter disorders differ greatly from those of PKU. Neurologic symptoms of the neurotransmitter disorders often manifest in the first few months of life and include extrapyramidal signs (choreoathetotic or dystonic limb movements, axial and truncal hypotonia, hypokinesia), feeding difficulties, and autonomic abnormalities. Intellectual disability, seizures, hypersalivation, and swallowing difficulties are also seen. The symptoms are usually progressive and often have a marked diurnal fluctuation. Prognosis and outcome strongly depend on the age at which the diagnosis is made and treatment is introduced, but also on the specific nature of the mutation and resulting enzyme defect.

Diagnosis

Despite the low incidence of BH_4 defects, all newborns with hyperphenylalaninemia detected through newborn screening should be screened for BH_4 defects.

BH_4 deficiency and the responsible enzyme defect may be diagnosed by the following studies:

1. Measurement of neopterin (oxidative product of dihydroneopterin triphosphate) and biopterin (oxidative product of dihydrobiopterin and BH_4) in body fluids, especially urine (see Fig. 85-1). In patients with GTP cyclohydrolase deficiency, urinary excretion of both neopterin and biopterin is very low. In patients with 6-pyruvoyltetrahydropterin synthase deficiency, there is a marked elevation of neopterin excretion and a concomitant decrease in biopterin excretion. In patients with dihydropteridine reductase deficiency, neopterin is normal, but biopterin is very high. Excretion of biopterin increases in this enzyme deficiency because the quinonoid dihydrobiopterin cannot be recycled back to BH_4. Patients with pterin-carbinolamine dehydratase deficiency excrete 7-biopterin (an unusual isomer of biopterin) in their urine. In addition, examination of cerebrospinal fluid (CSF) reveals decreased levels of dopamine, serotonin, and their metabolites in all patients with BH_4 deficiency (see Chapter 85.11).
2. BH_4 loading test. An oral dose of BH_4 (20 mg/kg) normalizes plasma phenylalanine and phenylalanine : tyrosine ratio in patients with BH_4 deficiency within 4-8 hr. The blood phenylalanine should be elevated (>400 µmole/L) to enable interpretation of the results. This may be achieved by discontinuing diet therapy for 2 days before the test or by administering a loading dose of phenylalanine (100 mg/kg) 3 hr before the test. In BH_4-responsive PKU caused by PAH deficiency, blood phenylalanine levels may decrease during the BH_4 loading test, but increase later even with BH_4 supplementation. Patients who demonstrate phenylalanine levels within normal range over at least a week without a phenylalanine-restricted diet can be continued on BH_4 supplementation as the sole treatment for the hyperphenylalaninemia. However, it is imperative that plasma

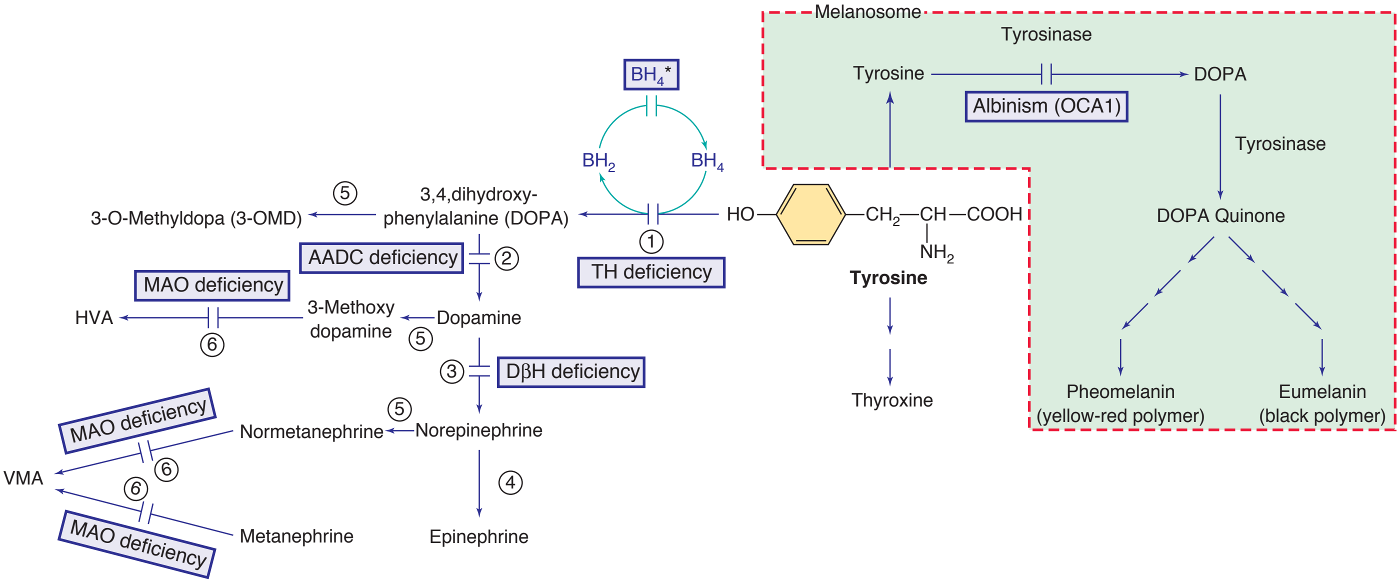

Figure 85-2 Other pathways involving tyrosine metabolism. PKU* indicates hyperphenylalaninemia caused by tetrahydrobiopterin (BH_4) deficiency (see Fig. 85-1). HVA, homovanillic acid; VMA, vanillylmandelic acid. **Enzymes:** *(1)* Tyrosine hydroxylase (TH), *(2)* aromatic L-amino acid decarboxylase (AADC), *(3)* dopamine β-hydroxylase (DβH), *(4)* phenylethanolamine-*N*-methyltransferase (PNMT), *(5)* catechol *O*-methyltransferase (COMT), *(6)* monoamine oxidase (MAO).

phenylalanine levels be monitored prospectively to ensure that phenylalanine levels remain within the normal range.
3. Enzyme assay. The activity of dihydropteridine reductase can be measured in the dry blood spots on the filter paper used for screening purposes. 6-Pyruvoyltetrahydropterin synthase activity can be measured in the liver, kidneys, and erythrocytes. Carbinolamine dehydratase activity can be measured in the liver and kidneys. GTP cyclohydrolase activity can be measured in the liver and in cytokine (interferon-γ) stimulated mononuclear cells or fibroblasts (the enzyme activity is normally very low in unstimulated cells).
4. Genetic test. Mutation analysis and deletion/duplication studies are clinically available for all these enzyme defects and help to confirm the diagnosis.

Treatment

The goals of therapy are to correct hyperphenylalaninemia and to restore neurotransmitter deficiencies in the CNS. The control of hyperphenylalaninemia is important in patients with cofactor deficiency, because high levels of phenylalanine cause intellectual disability and also interfere with the transport of neurotransmitter precursors (tyrosine, tryptophan) into the brain. Plasma phenylalanine should be maintained as close to normal as possible (<6 mg/dL). This can be achieved by oral supplementation of BH_4 (5-20 mg/kg/day). Sapropterin dihydrochloride (Kuvan), a synthetic form of BH_4, is commercially available, although it is expensive.

Lifelong supplementation with **neurotransmitter precursors** such as L-dopa and 5-hydroxytryptophan, along with carbidopa to inhibit degradation of L-dopa before it enters the CNS, is necessary in most of these patients even when treatment with BH_4 normalizes plasma levels of phenylalanine. BH_4 does not readily enter the brain to restore neurotransmitter production. To minimize untoward side effects (especially L-dopa–induced dyskinesia), the treatment should be started with low doses of L-dopa/carbidopa and 5-hydroxytryptophan, and should be adjusted based on response to therapy and clinical improvement for each individual patient. Supplementation with folinic acid is also recommended in patients with dihydropteridine reductase deficiency. Unfortunately, attempting to normalize neurotransmitter levels using neurotransmitter precursors usually does not fully resolve the neurologic symptoms as a result of the inability to attain normal levels of BH_4 in the brain. Patients often demonstrate intellectual disability, fluctuating abnormalities of tone, eye movement abnormalities, poor balance and coordination, decreased ability to ambulate, and seizures in spite of supplementation with neurotransmitter precursors.

Hyperprolactinemia occurs in patients with BH_4 deficiency and may be the result of hypothalamic dopamine deficiency. Measurement of serum prolactin levels may be a convenient method for monitoring adequacy of neurotransmitter replacement in affected patients.

Some drugs, such as trimethoprim sulfamethoxazole, methotrexate, and other antileukemic agents, are known to inhibit dihydropteridine reductase enzyme activity and should be used with great caution in patients with BH_4 deficiency.

Genetics and Prevalence

All defects causing hyperphenylalaninemia are inherited as autosomal recessive traits. The prevalence of PKU in the United States is estimated at 1 in 14,000 to 1 in 20,000 live births. The prevalence of non-PKU hyperphenylalaninemia is estimated at 1 in 50,000 live births. The condition is more common in whites and Native Americans and less prevalent in African-Americans, Hispanics, and Asians.

The gene for PAH is located on chromosome 12q23.2 and many disease-causing mutations have been identified in different families. The majority of patients are compound heterozygotes for 2 different mutant alleles. The gene for 6-pyruvoyl tetrahydropterin synthase *(PTS)*, the most common cause of BH_4 deficiency, resides on chromosome 11q23.1, the gene for dihydropteridine reductase *(QDPR)* is located on chromosome 4p15.2, and those of carbinolamine dehydratase *(PCBD1)* and GTP cyclohydrolase *(GCH1)* are on 10q22.1 and 14q22.2, respectively. Many disease-causing mutations of these genes have been identified. Prenatal diagnosis is possible using specific genetic probes in cells obtained from biopsy of the chorionic villi.

TETRAHYDROBIOPTERIN DEFECTS WITHOUT HYPERPHENYLALANINEMIA

See Chapter 85.11.

85.2 Tyrosine

Grant A. Mitchell and Iraj Rezvani

Tyrosine is derived from ingested proteins or is synthesized endogenously from phenylalanine. It is used for protein synthesis and is a precursor of dopamine, norepinephrine, epinephrine, melanin, and thyroxine. Excess tyrosine is metabolized to carbon dioxide and water (see Fig. 85-1). Hereditary causes of hypertyrosinemia include deficiencies of tyrosine aminotransferase, 4-hydroxyphenylpyruvate dioxygenase (4-HPPD), and fumarylacetoacetate hydrolase. *Acquired hypertyrosinemia* may occur in severe hepatocellular dysfunction (liver failure), scurvy (vitamin C is the cofactor for 4-HPPD), and hyperthyroidism. Hypertyrosinemia is common in blood samples obtained soon after eating and in premature infants.

TYROSINEMIA TYPE I (TYROSINOSIS, HEREDITARY TYROSINEMIA, HEPATORENAL TYROSINEMIA)

This severe disease of the liver, kidney, and peripheral nerves is caused by a deficiency of the enzyme fumarylacetoacetate hydrolase. Organ damage is believed to result from accumulation of metabolites of tyrosine degradation, especially fumarylacetoacetate and succinylacetone.

Clinical Manifestations and Natural History

Untreated, the affected infant appears normal at birth and typically presents between 2 and 6 mo of age but rarely may become symptomatic in the 1st mo or appear healthy beyond the 1st yr of life. The earlier the presentation, the poorer the prognosis. The 1 yr mortality of untreated children, which is approximately 60% in infants who develop symptoms before 2 mo of age, decreases to 4% in infants who become symptomatic after 6 mo of age.

An acute **hepatic crisis** commonly heralds the onset of the disease and is usually precipitated by an intercurrent illness that produces a catabolic state. Fever, irritability, vomiting, hemorrhage, hepatomegaly, jaundice, elevated levels of serum transaminases, and hypoglycemia are common. An odor resembling boiled cabbage may be present, resulting from increased methionine metabolites. Most hepatic crises resolve spontaneously, but may progress to liver failure and death. Between the crises, varying degrees of failure to thrive, hepatomegaly, and coagulation abnormalities often persist. Cirrhosis and eventually hepatocellular carcinoma occur with increasing age. Carcinoma is unusual before 2 yr of age.

Episodes of acute **peripheral neuropathy** resembling acute porphyria occur in approximately 40% of affected children. These crises, often triggered by a minor infection, are characterized by severe pain, often in the legs, associated with extensor hypertonia of the neck and trunk, vomiting, paralytic ileus, and, occasionally, self-induced injuries of the tongue or buccal mucosa. Marked weakness and paralysis occur in about 30% of episodes, which may lead to respiratory failure requiring mechanical ventilation. Crises typically last 1-7 days but recuperation from paralytic crises can require weeks to months.

Renal involvement is manifested as a Fanconi-like syndrome with hyperphosphaturia, hypophosphatemia, normal anion gap metabolic acidosis, and vitamin D–resistant rickets. Nephromegaly and nephrocalcinosis may be present on ultrasound examination. Glomerular failure may occur in adolescents and older patients.

Hypertrophic cardiomyopathy and hyperinsulinism are seen in some infants.

Laboratory Findings

The presence of elevated levels of succinylacetone in serum and urine is diagnostic for tyrosinemia type I (see Fig. 85-1). In untreated patients, the blood level of α-fetoprotein is increased, often markedly, and liver-synthesized coagulation factors are decreased in most patients; serum levels of transaminases are often increased, with marked increases being possible during acute hepatic episodes. Serum concentration of bilirubin is usually normal but can be increased with liver failure. Increased levels of α-fetoprotein are present in the cord blood of affected infants, indicating intrauterine liver damage. Plasma tyrosine levels are usually elevated at diagnosis but this is a nonspecific finding and is dependent on dietary intake. Plasma levels of other amino acids, particularly methionine, may also be elevated in patients with liver damage. Hyperphosphaturia, hypophosphatemia, and generalized aminoaciduria may occur. The urinary level of 5-aminolevulinic acid is elevated because of inhibition of 5-aminolevulinic hydratase by succinylacetone.

Diagnosis is usually established by demonstration of elevated levels of succinylacetone in urine or blood. Neonatal screening for hypertyrosinemia detects only a minority of patients with tyrosinemia type I. Succinylacetone, which is now assayed by some neonatal screening programs, has higher sensitivity and specificity than tyrosine and is the preferred metabolite for screening. Tyrosinemia type I should be differentiated from other causes of hepatitis and hepatic failure in infants, including galactosemia, hereditary fructose intolerance, neonatal iron storage disease, giant cell hepatitis, and citrullinemia type II (see Chapter 85.12).

Treatment and Outcome

A diet low in phenylalanine and tyrosine can slow but does not halt the progression of the condition. The **treatment of choice** is nitisinone, which inhibits tyrosine degradation at 4-HPPD (see Fig. 85-1). This treatment prevents acute hepatic and neurologic crises. Although nitisinone stops or greatly slows disease progression, some pretreatment liver damage is not reversible. Therefore, patients must be followed for development of cirrhosis or **hepatocellular carcinoma**. On imaging, the presence of even a single liver nodule usually indicates underlying cirrhosis. Most liver nodules in tyrosinemic patients are benign but current imaging techniques do not accurately distinguish all malignant nodules. Liver transplantation is an effective therapy for tyrosinemia type I and alleviates the risk of hepatocellular carcinoma. The impact of nitisinone treatment on the need for liver transplantation is still under study but the greatest effect is in patients treated early, such as children detected by neonatal screening, prior to the development of clinical symptoms. In early-treated patients, nitisinone has greatly reduced the need for liver transplantation. At any age, nitisinone treatment eliminates the occurrence of acute episodes of liver failure and neurologic crises although they are at risk for impaired cognitive function. Because nitisinone treatment causes an increase in plasma tyrosine level, a diet restricted in tyrosine and phenylalanine is prescribed. Rarely, nitisinone-treated patients develop corneal crystals, presumably of tyrosine, which are reversible by strict dietary compliance. This finding, combined with observations of developmental delay in some patients with tyrosinemia type II who chronically have elevated tyrosine levels, suggest that a diet low in phenylalanine and tyrosine should be continued in patients treated with nitisinone. The dietary treatment of patients with tyrosine and phenylalanine restriction necessitates surveillance to ensure adequate intakes of other nutrients and amino acids.

Genetics and Prevalence

Tyrosinemia type I is inherited as an autosomal recessive trait. The gene for fumarylacetoacetate hydrolase (*FAH*) maps to chromosome 15q 25.1 and; numerous disease-causing mutations of the gene have been reported. DNA analysis is useful for molecular prenatal diagnosis if the familial mutations are known and for carrier testing in groups at risk for specific mutations such as French-Canadians from the Saguenay-Lac Saint-Jean region of Quebec. The prevalence of the condition is estimated to be 1 in 1,846 live births in the Saguenay-Lac Saint-Jean region and approximately 1 in 100,000 live births worldwide. But tyrosinemia type I is panethnic; lack of French-Canadian or Scandinavian ancestry does not exclude the diagnosis. Prenatal diagnosis is typically performed by measurement of succinylacetone in amniotic fluid, or if the familial mutations are known, by DNA analysis of amniocytes or of chorionic villi.

TYROSINEMIA TYPE II (RICHNER-HANHART SYNDROME, OCULOCUTANEOUS TYROSINEMIA)

This rare autosomal recessive disorder is caused by deficiency of tyrosine aminotransferase and results in palmar and plantar hyperkeratosis, herpetiform corneal ulcers, and intellectual disability (see Fig. 85-1). **Ocular manifestations,** which may occur as early as 6 mo of age, include excessive tearing, redness, pain, and photophobia. Corneal lesions are presumed to be because of tyrosine deposition. In contrast to herpetic ulcers, corneal lesions in tyrosinemia type II stain poorly with fluorescein and often are bilateral. **Skin lesions**, which may develop later in life, include painful, nonpruritic hyperkeratotic plaques on the soles, palms, and fingertips. Intellectual disability, which occurs in approximately 50% of patients, is usually mild to moderate.

The principal **laboratory finding** in untreated patients is marked hypertyrosinemia (20-50 mg/dL; 1,100-2,750 µmole/L). Surprisingly, 4-hydroxyphenylpyruvic acid and its metabolites are also elevated in urine despite being downstream from the metabolic block (see Fig. 85-1). This is hypothesized to occur via the action of other transaminases in the presence of high tyrosine concentrations, producing 4-hydroxyphenylpyruvic acid in cellular compartments like the mitochondrion in which it cannot be further degraded. In contrast to tyrosinemia type I, liver and kidney function are normal, as are serum concentrations of other amino acids and succinylacetone. Tyrosinemia type II is caused by *TAT* gene mutations, causing deficiency of cytosolic tyrosine aminotransferase activity in liver.

Diagnosis of type II tyrosinemia is established by assay of plasma tyrosine concentration in patients with suggestive findings. Molecular diagnosis is possible. Assay of liver tyrosine aminotransferase activity requires a liver biopsy and is rarely indicated.

Treatment with a diet low in tyrosine and phenylalanine improves the biochemical abnormalities and can normalize the skin and eye. The claim that intellectual disability may be prevented by early diet therapy is reasonable and is consistent with some case reports. The gene for tyrosine aminotransferase (*TAT)* maps to chromosome 16q22.2 and several disease-causing mutations have been identified. About half of reported cases are of Italian descent.

TYROSINEMIA TYPE III (PRIMARY DEFICIENCY OF 4-HYDROXYPHENYLPYRUVATE DIOXYGENASE [4-HPPD])

Only a few cases have been reported; most were detected by amino acid chromatography performed for various neurologic findings. Age at presentation has been from 1-17 mo. Developmental delay, seizures, intermittent ataxia, and self-destructive behavior are reported; a causal link to 4-HPPD deficiency is not formally established. Liver and renal abnormalities are absent. Asymptomatic infants with 4-HPPD deficiency have been identified by neonatal screening for hypertyrosinemia.

The **diagnosis** is suspected in children with sustained moderate increases in plasma levels of tyrosine (typically 350-700 µmole/L on a normal diet) and the presence of 4-hydroxyphenylpyruvic acid and its metabolites 4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids in urine. Diagnosis may be refined by demonstrating the presence of mutations in the gene (*HPD*) for 4-HPPD on chromosome 12q24.31, or rarely, by demonstrating a low activity of 4-HPPD enzyme; the latter requires a liver biopsy and is not usually indicated.

Given the possible association with neurologic abnormalities, dietary reduction of plasma tyrosine levels is prudent. It is also logical

to attempt a trial of vitamin C, the cofactor for 4-HPPD. The condition is inherited as an autosomal recessive trait.

HAWKINSINURIA

Certain missense mutations in the gene for 4-HPPD result in an abnormal enzyme activity. The mutant enzyme, incapable of normally oxidizing 4-hydroxyphenylpyruvate to homogentisic acid, forms an intermediate that reacts with cysteine to form the unusual organic acid hawkinsin ([2-L-cystein-*S*-yl-1,4-dihydroxycyclohex-5-en-1-yl]acetic acid, named after the first affected family, Fig. 85.1); secondary glutathione deficiency may occur. Hawkinsinuria is inherited as an autosomal dominant trait and a few specific causal missense mutations have been identified. The same mutation, a substitution of threonine for the normal alanine codon at position 33 of the 4-HPPD gene, has been identified in unrelated patients with hawkinsinuria. The condition is, perhaps, more prevalent than once realized.

Individuals with this disorder are symptomatic only during infancy. The symptoms usually appear in the first few months of life; commonly after weaning from breastfeeding and with the introduction of a high-protein diet. Severe metabolic acidosis, ketosis, failure to thrive, mild hepatomegaly, and an unusual odor (described as like that of a swimming pool) are reported manifestations of this disorder. Mental development is usually normal.

Symptomatic infants and asymptomatic affected children and adults excrete hawkinsin, 4-hydroxyphenylpyruvic acid, and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids), 4-hydroxycyclohexylacetic acid and 5-oxoproline (owing to secondary glutathione deficiency) in their urine. The plasma tyrosine level, which is moderately elevated in the symptomatic infants, may become normal in the asymptomatic affected individuals. **Treatment** consists of a low-protein diet during infancy. Breastfeeding is encouraged. A trial with large doses of vitamin C (up to 1,000 mg/24 hr) is also recommended. The mutant enzyme is susceptible to inhibition by nitisinone; clinical studies showing the efficacy of this agent in symptomatic infants are lacking at this time, and the indications for its use are not known.

TRANSIENT TYROSINEMIA OF THE NEWBORN

In a small number of newborn infants, plasma tyrosine may be as high as 60 mg/dL (3,300 µmole/L) during the 1st 2 wk of life. Most affected infants are premature and are receiving high-protein diets. Transient tyrosinemia is felt to result from delayed maturation of 4-HPPD (see Fig. 85-1). Lethargy, poor feeding, and decreased motor activity are noted in some patients. Most are asymptomatic and are identified by a high blood phenylalanine or tyrosine level on routine screening. Laboratory findings include marked elevation of plasma tyrosine with a moderate increase in plasma phenylalanine. The finding of hypertyrosinemia differentiates this condition from PKU. 4-Hydroxyphenylpyruvic acid and its metabolites (see above) are present in the urine. Hypertyrosinemia usually resolves spontaneously in the 1st mo of life. It can be corrected promptly by reducing dietary protein to below 2 g/kg/24 hr and by administering vitamin C (200-400 mg/24 hr). Mild intellectual deficits have been reported in some infants who had this condition, but the causal relationship to hypertyrosinemia is not conclusively established.

ALKAPTONURIA

This rare (with an incidence of approximately 1 in 250,000 live births) autosomal recessive disorder is caused by a deficiency of homogentisic acid oxidase (homogentisate 1,2-dioxigenase). In alkaptonuria, large amounts of homogentisic acid are formed (see Fig. 85-1), which are excreted in urine or deposited in tissues.

The main **clinical manifestations** of alkaptonuria consist of ochronosis and arthritis in adulthood. The only sign in children is a blackening of the urine on standing, caused by oxidation and polymerization of homogentisic acid. A history of gray- or black-stained diapers should suggest the diagnosis. This sign may never be noted; hence, diagnosis is often delayed until adulthood. *Ochronosis,* which is seen clinically as dark spots on the sclera or ear cartilage, results from the accumulation of the black polymer of homogentisic acid. *Arthritis* is another result of this deposition and can be disabling with advancing age. It involves the large joints (spine, hip, and knee) and is usually more severe in males. Like rheumatoid arthritis, the alkaptonuric arthritis has acute exacerbations, but the radiologic findings are typical of osteoarthritis, with characteristic narrowing of the joint spaces and calcification of the intervertebral discs. High incidence of heart disease (mitral and aortic valvulitis, calcification of the heart valves, and myocardial infarction) has been noted.

The **diagnosis** is confirmed by finding massive excretion of homogentisic acid on urine organic acid testing. Tyrosine levels are normal. The enzyme is expressed only in the liver and kidneys.

Treatment of the arthritis is symptomatic. Nitisinone efficiently reduces homogentisic acid production in alkaptonuria. If presymptomatic individuals are detected, treatment with nitisinone, combined with a phenylalanine- and tyrosine-restricted diet, seems reasonable, although no experience is available regarding long-term efficacy.

The gene for homogentisic acid oxidase *(HGD)* maps to chromosome 3q13.3. Several disease-causing mutations have been identified. Alkaptonuria is commonest in the Dominican Republic and Slovakia.

TYROSINE HYDROXYLASE DEFICIENCY

See Chapter 85.11.

ALBINISM (See also Chapters 622 and 653)

Albinism is caused by deficiency of melanin, the main pigment of the skin and eye (Table 85-1). Melanin is synthesized by melanocytes from tyrosine in a membrane-bound intracellular organelle, the melanosome. Melanocytes originate from the embryonic neural crest and migrate to the skin, eyes (choroid and iris), hair follicles, and inner ear. The melanin in the eye is confined to the iris stromal and retinal pigment epithelia, whereas in skin and hair follicles, it is secreted into the epidermis and hair shaft. Albinism can be caused by deficiencies of melanin synthesis, by some hereditary defects of melanosomes, or by disorders of melanocyte migration. Neither the biosynthetic pathway of melanin nor many facets of melanocyte cell biology are completely elucidated (see Fig. 85-2). The end products are 2 pigments: *pheomelanin,* which is a yellow-red pigment, and *eumelanin,* a brown-black pigment.

Table 85-1 Classification of Major Causes of Albinism

TYPE	GENE	CHROMOSOME
OCULOCUTANEOUS ALBINISM (OCA)		
OCA1 (tyrosinase deficient)	*TYR*	11q14-q21
OCA1A (severe deficiency)	*TYR*	11q14-q21
OCA1B (mild deficiency)*	*TYR*	11q14-q21
OCA2 (tyrosinase positive)†	*OCA2*	15q12-q13
OCA3 (Rufous, red OCA)	*TYRP1*‡	9p23
OCA4	*SLC45A2*	5p13.3
Hermansky-Pudlak syndrome	*HPS1-9*	Different chromosomes
Chédiak-Higashi syndrome	*LYST*	1q42.1
OCULAR ALBINISM (OA)		
OA1 (Nettleship-Falls type)	*OA*	Xp22.3
LOCALIZED ALBINISM		
Piebaldism	*KIT*	4q12
Waardenburg syndrome (WS1-WS4)	See text	See text

*This includes Amish, minimal pigment, yellow albinism, and platinum and temperature-sensitive variants.
†Includes brown OCA.
‡Tyrosinase-related protein 1.

Clinically, primary albinism can be generalized or localized. Primary generalized albinism can be either ocular or oculocutaneous. Some syndromes feature albinism in association with platelet, immunological, or neurological dysfunction.

In generalized oculocutaneous albinism, hypopigmentation can be either complete or partial. Individuals with complete albinism do not develop either generalized (tanning) or localized (pigmented nevi) skin pigmentation.

The diagnosis of albinism is usually evident, but for some white children whose families are particularly light-skinned, normal variation may be a diagnostic consideration. Unlike patients with albinism, normal fair-skinned children progressively develop pigmentation with age, do not exhibit the eye manifestations of albinism, and have pigmentary development similar to other family members. The clinical diagnosis of oculocutaneous albinism, as opposed to other types of cutaneous hypopigmentation, requires the presence of characteristic eye findings.

The ocular manifestations of albinism include hypopigmentation of iris and retina with foveal hypoplasia along with, reduced visual acuity, refractive errors, nystagmus, alternating strabismus, and a red reflex (diffuse reddish hue of the iris produced during ophthalmoscopic or slit-lamp examination of the eye). There is also an abnormality in routing of the optic fibers at the chiasm. Unlike normally in pigmented individuals, in patients with albinism the majority of the nerve fibers from the temporal side of the retina cross to the contralateral hemisphere of the brain. This results in lack of biocular (stereoscopic) vision and depth perception, and in repeated switching of vision from eye to eye, causing alternating strabismus. This abnormality also causes a characteristic pattern of visual-evoked potentials. These findings are highly specific for albinism and can be used to formally establish the clinical diagnosis. Regular ophthalmologic follow-up is recommended for patients with oculocutaneous albinism; correction of refractive errors can maximize visual function. Normally the alternating strabismus does not result in amblyopia and does not require surgery.

Patients with albinism should be counseled to avoid UV radiation by wearing protective long-sleeved clothing and by using sunscreens with a sun protection factor rating above 30. All forms of oculocutaneous albinism are autosomal recessive traits.

Melanin is also present in the cochlea. Albino individuals may be more susceptible to ototoxic agents such as gentamicin.

Many clinical forms of albinism have been identified. Some of the seemingly distinct clinical forms are caused by different mutations of the same gene. Several genes located on different chromosomes are involved in melanogenesis (see Table 85-1). Attempts to differentiate types of albinism based on the mode of inheritance, tyrosinase activity, or the extent of hypopigmentation have failed to yield a comprehensive classification. The following classification is based on the distribution of albinism in the body and the type of mutated gene.

Mutation detection is clinically available for most albinism genes (see Table 85-1). Molecular diagnosis is of little use therapeutically in isolated albinism but can be helpful for precise genetic counseling of families.

Oculocutaneous (Generalized) Albinism

Lack of pigment is generalized, affecting skin, hair, and eyes. At least 4 genetically distinct forms of oculocutaneous albinism (OCA) have been identified: OCA_1, OCA_2, OCA_3, and OCA_4. The lack of pigment is complete in patients with OCA_1 A; the other types may not be clinically distinguishable from one another. All affected individuals have ocular manifestations of albinism (see above). All forms are inherited as autosomal recessive traits.

OCA_1 (Tyrosinase-Deficient Albinism)

The defect in these patients resides in the tyrosinase gene, *TYR*, located on chromosome 11q14.3. Many mutant alleles have been identified. Most affected individuals are genetic compounds, heterozygous for 2 different mutant alleles. A clinical clue to the diagnosis of OCA_1 is complete lack of pigment at birth. The condition can be subdivided to OCA_1 A and OCA_1 B, based on enzyme activity and difference in clinical manifestations as a function of age.

OCA_1 A (Tyrosinase-Negative OCA)

In these individuals, who have the most severe form of OCA, both *TYR* alleles have mutations that completely inactivate tyrosinase. Clinically, lack of pigment in the skin (milky white), hair (white hair), and eyes (red gray irides) is evident at birth and remains unchanged throughout life. They do not tan and do not develop pigmented nevi or freckles.

OCA_1 B

These patients have *TYR* gene mutations that preserve some residual activity. Clinically they completely lack pigment at birth, but with age become light blond with light blue or hazel eyes. They develop pigmented nevi and freckles and they may tan. OCA_1 B patients, depending on the degree of pigmentation, were once subdivided into different groups and thought to be genetically distinct.

OCA_2 (Tyrosinase-Positive OCA)

This is the most common form of generalized OCA, particularly in African blacks. Clinically, the phenotype is highly variable; most patients demonstrate some pigmentation of the skin and eyes at birth and continue to accumulate pigment throughout their lives. The hair is yellow at birth and may darken with age. They have pigmented nevi and freckles and some may tan. They may be clinically indistinguishable from OCA_1 B. Individuals with OCA_2, however, have normal tyrosinase activity in hair bulbs. The defect is in the *OCA_2* gene which is homologous to the *p* (pink-eyed dilution) gene in the mouse. This gene produces the P protein, a melanosome membrane protein. Patients with forms of Prader-Willi and Angelman syndromes caused by microdeletion of chromosome 15q12 that includes the *OCA_2* gene have mild pigmentary deficiency (see Chapter 81.8).

OCA_3 (Rufous Albinism)

This form has been identified only in Africans, African-Americans, and natives of New Guinea. Patients have reddish hair and reddish brown skin as adults. The skin color is peculiar to this form. In the young, the coloration may resemble that of OCA_2. Patients with OCA_3 can make pheomelanin but not eumelanin. The mutation is in the tyrosinase-related protein 1 (*TYRP1*) gene (located on chromosome 9p23), the function of which is not well-understood.

OCA_4

Similar manifestations to OCA_2 (both in the skin and the eyes) have been observed in patients (mostly from Japan) with mutations in the *SLC45A2* (previously called *MATP*) gene located on chromosome 5p13.2.

Ocular Albinism

Ocular albinism (OA) is limited to the eye. All the eye findings of albinism (see above) are present. Most cases are X-linked (OA_1).

Ocular Albinism 1 (Nettleship-Falls Type)

Only the hemizygous male has the complete manifestation. Segments of abnormal retinal pigmentation may be present in heterozygous females. An X-linked OA with late-onset sensorineural deafness has also been reported. The diagnosis of ocular albinism 1 (OA_1) is evident in males with the features of albinism in the eye, normal skin pigmentation, and a positive family history suggestive of an X-linked recessive transmission. Mild hypopigmentation of the skin (compared to unaffected siblings) may be present. It is a nonprogressive disorder and the eye findings, in fact, often improve with age. In patients who are the first of their families to be affected, electron microscopic demonstration of characteristic mega melanosomes in skin biopsies or hair root specimens is useful, as is mutation analysis of the *OA_1* gene on chromosome Xp22.2.

Syndromic Forms of Generalized Albinism

Hermansky-Pudlak Syndrome

This group of autosomal recessive disorders is caused by mutations of 1 of 9 different genes located on different chromosomes, *HPS1* to *HPS9*. Hermansky-Pudlak syndrome is suspected in patients with albinism and a bleeding diathesis. Disease subtype can be established with molecular studies.

The *HPS* genes are necessary for normal structure and function of lysosome-derived organelles, including melanosomes and platelet dense bodies. Patients have a tyrosinase-positive OCA of variable severity associated with platelet dysfunction (owing to the absence of platelet dense bodies). A ceroid-like material accumulates in tissues. Hermansky-Pudlak syndrome is most prevalent in 2 regions of Puerto Rico (type 1 in the northwest and type 3 in the central regions as a result of different founder effects). The cutaneous and ocular symptoms of albinism are present. Patients can develop epistaxis, postsurgical bleeding, or abundant menses. Bleeding time is prolonged but platelet count is normal. Major complications are progressive pulmonary fibrosis in young adults and Crohn-like inflammatory bowel disease in adolescents and young adults. Kidney failure and cardiomyopathy are reported. Neutropenia is described in HPS type 2. Treatment is symptomatic.

Chédiak-Higashi Syndrome

Patients with this rare autosomal recessive condition (see Chapter 130) have OCA of variable severity and susceptibility to infection. Bacterial infections of skin and upper respiratory tract are common. Giant peroxidase-positive lysosomal granules can be seen in granulocytes in a blood smear. Patients have a reduced number of melanosomes, which are abnormally large (macromelanosomes). The bleeding tendency is typically mild. The major, life-threatening complication is macrophage activation with hemophagocytic lymphohistiocytosis, manifested by fever, lymphadenopathy, hepatosplenomegaly, cytopenias, and elevated plasma ferritin level. Patients surviving childhood may develop cerebellar atrophy, peripheral neuropathy, and cognitive delay. Mutations in the *LYST* gene on chromosome 1q are the only known cause of this syndrome.

Hypopigmentation is a feature of other syndromes, some with abnormalities of lysosomal biogenesis or melanosome biology, such as *Griscelli syndrome* (silver-gray hair, pigmentary dilution of skin, and melanosomal clumping in hair shafts and the center of melanocytes, with intellectual disability or macrophage activation with hemophagocytosis in different subtypes), *Vici syndrome* (combined immunodeficiency, intellectual disability, agenesis of the corpus callosum, cataracts, and cleft lip and palate), and MAPBP interacting protein deficiency (short stature, recurrent infections, neutropenia).

Localized Albinism

Localized albinism refers to localized patches of hypopigmentation of skin and hair, which may be evident at birth or develop with time. These conditions are caused by abnormal migration of melanocytes during embryonic development.

Piebaldism

Piebaldism is an autosomal dominant inherited condition in which the individual is usually born with a white forelock. The underlying skin is depigmented and devoid of melanocytes. In addition, there are usually white macules on the face, trunk, and extremities. Mutations in the *KIT* gene have been shown in affected patients.

Waardenburg Syndrome

In this syndrome, a white forelock is associated with lateral displacement of inner canthi of the eyes, broad nasal bridge, heterochromia of irides, and sensorineural deafness. This condition is inherited as an autosomal dominant trait. Four major types of this syndrome have been identified. Patients with type 1 (WS1, the most common form) have all the above clinical findings including lateral displacement of inner canthi. The condition is caused by mutation (>90%) or deletion of the *PAX3* gene. Patients with type 2 (WS2) have all the clinical findings of WS1 except the lateral displacement of inner canthi. Genetically, this is a heterogeneous condition caused by mutations in different genes located on different chromosomes. Patients with type 3 (WS3) have all the findings seen in individuals with WS1 plus hypoplasia and contractures of the upper limbs. It is caused by heterozygous or homozygous mutations of *PAX3* gene. Type 4 (WS4), associated with Hirschsprung disease, is heterogeneous; mutations in different genes (*EDN3, EDNRB,* or *SOX10*) have been identified in different patients.

Other causes of localized hypopigmentation are discussed in other chapters (e.g., hypomelanosis of Ito, see Chapters 81 and 653; and vitiligo, see Chapter 653).

Bibliography is available at Expert Consult.

85.3 Methionine

Iraj Rezvani and David S. Rosenblatt

The usual pathway for catabolism of methionine, an essential amino acid, produces *S*-adenosylmethionine, which serves as a methyl group donor for methylation of a variety of compounds in the body, and cysteine, which is formed through a series of reactions collectively called trans-sulfuration (Fig. 85-3).

HOMOCYSTINURIA (HOMOCYSTINEMIA)

Normally, most homocysteine, an intermediate compound of methionine degradation, is remethylated to methionine. This methionine-sparing reaction is catalyzed by the enzyme methionine synthase, which requires a metabolite of folic acid (5-methyltetrahydrofolate) as a methyl donor and a metabolite of vitamin B_{12} (methylcobalamin), as well as *S*-adenosylcobalamin, as cofactors (see Fig. 85-3). Only approximately 20% of total homocysteine (and its dimer homocystine) is in free form in the plasma of normal individuals. The rest is bound to proteins as mixed disulfides. Three major forms of homocystinemia and homocystinuria have been identified.

Homocystinuria Caused by Cystathionine β-Synthase Deficiency (Classic Homocystinuria)

This is the most common inborn error of methionine metabolism. Approximately 40% of affected patients respond to high doses of vitamin B_6 and usually have milder clinical manifestations than those who are unresponsive to vitamin B_6 therapy. These patients possess some residual enzyme activity.

Infants with this disorder are normal at birth. **Clinical manifestations** during infancy are nonspecific and may include failure to thrive and developmental delay. The diagnosis is usually made after 3 yr of age, when subluxation of the ocular lens **(ectopia lentis)** occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive **intellectual disability** is common. Normal intelligence has been reported. In an international survey of more than 600 patients, IQ scores ranged from 10-135. Higher IQ scores are seen in vitamin B_6–responsive patients. **Psychiatric and behavioral disorders** have been observed in more than 50% of affected patients. Convulsions occur in approximately 20% of patients. Affected individuals with homocystinuria manifest **skeletal abnormalities** resembling those of Marfan syndrome (see Chapter 702); they are usually tall and thin, with elongated limbs and arachnodactyly. Scoliosis, pectus excavatum or carinatum, genu valgum, pes cavus, high-arched palate, and crowding of the teeth are commonly seen. These children usually have fair complexions, blue eyes, and a peculiar malar flush. Generalized osteoporosis, especially of the spine, is the main roentgenographic finding. **Thromboembolic episodes** involving both large and small vessels, especially those of the brain, are common and may occur at any age. Optic atrophy, paralysis, cor pulmonale, and severe hypertension (from renal infarcts) are among the serious consequences of thromboembolism, which is caused by

changes in the vascular walls and increased platelet adhesiveness secondary to elevated homocystine levels. The risk of thromboembolism increases after surgical procedures. Spontaneous pneumothorax and acute pancreatitis are rare complications.

Elevations of both methionine and homocystine (or homocysteine) in body fluids are the diagnostic **laboratory findings**. Freshly voided urine should be tested for homocystine because this compound is unstable and may disappear as the urine is stored. Cystine is low or absent in plasma. The diagnosis may be established by assay of the enzyme in liver biopsy specimens, cultured fibroblasts, or phytohemagglutinin-stimulated lymphocytes or by DNA analysis.

Treatment with high doses of vitamin B_6 (200-1,000 mg/24 hr) causes dramatic improvement in most patients who are responsive to this therapy. The degree of response to vitamin B_6 treatment may be different in different families. Some patients may not respond because of folate depletion; a patient should not be considered unresponsive to vitamin B_6 until folic acid (1-5 mg/24 hr) has been added to the treatment regimen. Restriction of methionine intake in conjunction with cysteine supplementation is recommended for patients who are unresponsive to vitamin B_6. The need for dietary restriction and its extent remains controversial in patients with vitamin B_6–responsive form. In some patients with this form, addition of betaine may obviate the need for any dietary restriction. Betaine (trimethylglycine, 6-9 g/24 hr for adults or 200-250 mg/kg/day for children) lowers homocysteine levels in body fluids by remethylating homocysteine to methionine (see Fig. 85-3); this may result in further elevation of plasma methionine levels. This treatment has produced clinical improvement (preventing vascular events) in patients who are unresponsive to vitamin B_6 therapy. Cerebral edema has occurred in a patient with vitamin B_6–nonresponsive homocystinuria and dietary noncompliance during betaine therapy. Administration of large doses of vitamin C (1 g/day) has improved endothelial function; long-term clinical efficacy is not known.

More than 100 pregnancies in women with the classic form of homocystinuria have been reported with favorable outcomes for both mothers and infants. The majority of infants were full-term and normal. Postpartum thromboembolic events occurred in a few mothers. All but 1 of the 38 affected male patients has had normal offspring.

The screening of newborn infants for classic homocystinuria has been performed worldwide and a prevalence of 1 in 200,000 to 1 in 350,000 live births has been estimated. The condition seems more common in New South Wales, Australia (1 in 60,000 live births), and Ireland. Early treatment of patients identified by the screening process has produced favorable results. The mean IQ of 16 patients with vitamin B_6–unresponsive form treated in early infancy was 94 ± 4. Dislocation of the lens seemed to be prevented in some patients.

Homocystinuria is inherited as an autosomal recessive trait. The gene for cystathionine β-synthase *(CBS)* is located on chromosome 21q22.3. Prenatal diagnosis is feasible by performing an enzyme assay of cultured amniotic cells or chorionic villi or by DNA analysis. Many disease-causing mutations (>150) have been identified in different families. The majority of affected patients are compound heterozygotes for 2 different alleles. Heterozygous carriers are usually asymptomatic; thromboembolic events and coronary heart disease are more common in these individuals than in the normal population.

Homocystinuria Caused by Defects in Methylcobalamin Formation

Methylcobalamin is the cofactor for the enzyme methionine synthase, which catalyzes remethylation of homocysteine to methionine. There are at least 7 distinct defects in the intracellular metabolism of cobalamin that may interfere with the formation of methylcobalamin. To better understand the metabolism of cobalamin, see methylmalonic acidemia (Fig. 85-4; see Chapter 85.6 and Fig. 85-3). The 7 defects are designated as *cbl*C, *cbl*D (including *cbl*D variant 1), *cbl*E *(methionine synthase reductase)*, *cbl*G *(methionine synthase)*, and *cbl*F, *cbl*J, and *cbl*X. Patients with *cbl*C, *cbl*D (not including those with *cbl*D variant 1 or variant 2), *cbl*F, *cblJ*, and *cblX* defects have methylmalonic acidemia in addition to homocystinuria, because formation of both adenosylcobalamin and methylcobalamin is impaired (See Chapter 85.6 for further information about these defects.).

Patients with *cbl*E, *cbl*G, and *cbl*D variant 1 defects are unable to form methylcobalamin and develop homocystinuria without methylmalonic acidemia (see Fig. 85-4); fewer than 40 patients are known with each of these diseases.

The **clinical manifestations** are similar in patients with all of these defects. Vomiting, poor feeding, failure to thrive, lethargy, hypotonia, seizures, and developmental delay may occur in the first few months of life. One patient with the *cbl*G defect was not symptomatic (except for mild developmental delay) until she was 21 yr old when she developed difficulty in walking and numbness of the hands. **Laboratory findings** include megaloblastic anemia, homocystinuria, and hypomethioninemia. The presence of megaloblastic anemia differentiates these defects from homocystinuria due to methylenetetrahydrofolate reductase deficiency (see below). The absence of hypermethioninemia differentiates both of these conditions from cystathionine β-synthase deficiency (see above). Renal artery thrombosis, hemolytic uremic syndrome, pulmonary hypertension and optic nerve atrophy have been reported in some patients with these defects.

Diagnosis is established by complementation studies performed in cultured fibroblasts. Prenatal diagnosis has been accomplished by studies in amniotic cell cultures. These conditions (*cbl*E, *cbl*G, and *cbl*D variant 1) are inherited as autosomal recessive traits. The gene for *cbl*E is *MTRR*, encoding methionine synthase reductase (located on chromosome 5p15.3-p15.2) and the gene for *cbl*G is *MTR*, encoding methionine synthase (located on chromosome 1q43); *cbl*D variant 1 is caused by mutations affecting the C-terminal of the *MMADHC* gene (located on chromosome 2q23.2). Several disease-causing mutations, including a common missense mutation (P1173L) in the *MTR* gene, have been described.

Treatment with vitamin B_{12} in the form of hydroxycobalamin (1-2 mg/24 hr) is used to correct the clinical and biochemical findings. Results vary among both diseases and sibships.

Defects causing both homocystinuria and methylmalonic acidemias are discussed in Chapter 85.6.

Homocystinuria Caused by Deficiency of Methylenetetrahydrofolate Reductase

This enzyme reduces 5,10-methylenetetrahydrofolate to form 5-methyltetrahydrofolate, which provides the methyl group needed for remethylation of homocysteine to methionine (see Fig. 85-3).

The severity of the enzyme defect and the clinical manifestations varies considerably in different families. **Clinical findings** vary from apnea, seizure, microcephaly, coma, and death to developmental delay, ataxia, and motor abnormalities or even psychiatric manifestations. Premature vascular disease or peripheral neuropathy has been reported as the only manifestation of this enzyme deficiency in some patients. Adults with severe enzyme deficiency may even be completely asymptomatic. Exposure to the anesthetic nitrous oxide (which inhibits methionine synthase) in patients with methylenetetrahydrofolate reductase (MTHFR) deficiency may result in neurologic deterioration and death.

Laboratory findings include moderate homocystinemia and homocystinuria. The methionine concentration is low or low normal. This finding differentiates this condition from classic homocystinuria caused by cystathionine β-synthase deficiency. Absence of megaloblastic anemia distinguishes this condition from homocystinuria caused by methylcobalamin formation (see above). Thromboembolism of vessels has also been observed in these patients. Diagnosis may be confirmed by the enzyme assay in cultured fibroblasts or leukocytes or by finding causal mutation in the *MTHR* gene.

A number of polymorphisms have been described in the *MTHR* gene. Two of these (677C → T and 1298A → C) may affect levels of plasma total homocysteine and have been studied as possible risk factors for a wide variety of medical conditions, ranging from birth defects to vascular disease and even cancer, Alzheimer disease, and death from leukemia. To date, the best data support a role for 677C → T polymorphism as a risk factor for neural tube defects. Although a clinical test for this polymorphism is widely available, its predictive value in any given individual has yet to be determined.

Treatment of severe MTHFR deficiency with a combination of folic acid, vitamin B_6, vitamin B_{12}, methionine supplementation, and betaine has been tried. Of these, early treatment with betaine seems to have the most beneficial effect.

The condition is inherited as an autosomal recessive trait; the gene for the enzyme has been located on chromosome 1p36.3 and many disease-causing mutations have been reported in the *MTHFR* gene. Prenatal diagnosis can be offered by measuring MTHFR enzyme activity in cultured chorionic villus cells or amniocytes, by linkage analysis in informative families, or by DNA analysis of the mutation.

HYPERMETHIONINEMIA

Primary (Genetic) Hypermethioninemia

Elevation of plasma level of methionine occurs in the following genetic conditions:

1. **Classic homocystinuria (see above).**
2. **Hepatic methionine adenosyltransferase (MAT I/MAT III) deficiency:** This enzyme, which has 2 isoforms, MAT I (tetrameric) and MAT III (dimeric), is encoded by a single gene *(MAT 1A)* and is involved in the first step of methionine catabolism (see Fig. 85-3). Another structurally similar enzyme, MAT II, is encoded by a different gene (*MAT 2A* on chromosome 2p11.2) and is expressed predominately in nonhepatic tissues (kidney, brain, lymphocytes). Deficiency of MAT I/MAT III causes hypermethioninemia without homocystinuria. The majority of these patients have been diagnosed in the neonatal period through screening for homocystinuria. Most affected individuals have residual enzyme activity and remain asymptomatic throughout life despite persistent hypermethioninemia. Some complain of an unusual offensive odor to their breath (boiled cabbage). A few patients with complete enzyme deficiency have had neurologic abnormalities related to demyelination (intellectual disability, dystonia, dyspraxia).

   Laboratory studies reveal markedly elevated levels of plasma methionine with a low level of *S*-adenosylmethionine and normal concentrations of *S*-adenosylhomocysteine and homocysteine. These findings differentiate this condition from other causes of hypermethioninemia.

   No uniformly accepted therapeutic regimen has yet emerged. Diets low in methionine result in lowering of plasma methionine, but the advisability of such diets has been questioned since lowering of the plasma methionine level causes further lowering of *S*-adenosylmethionine in the body.

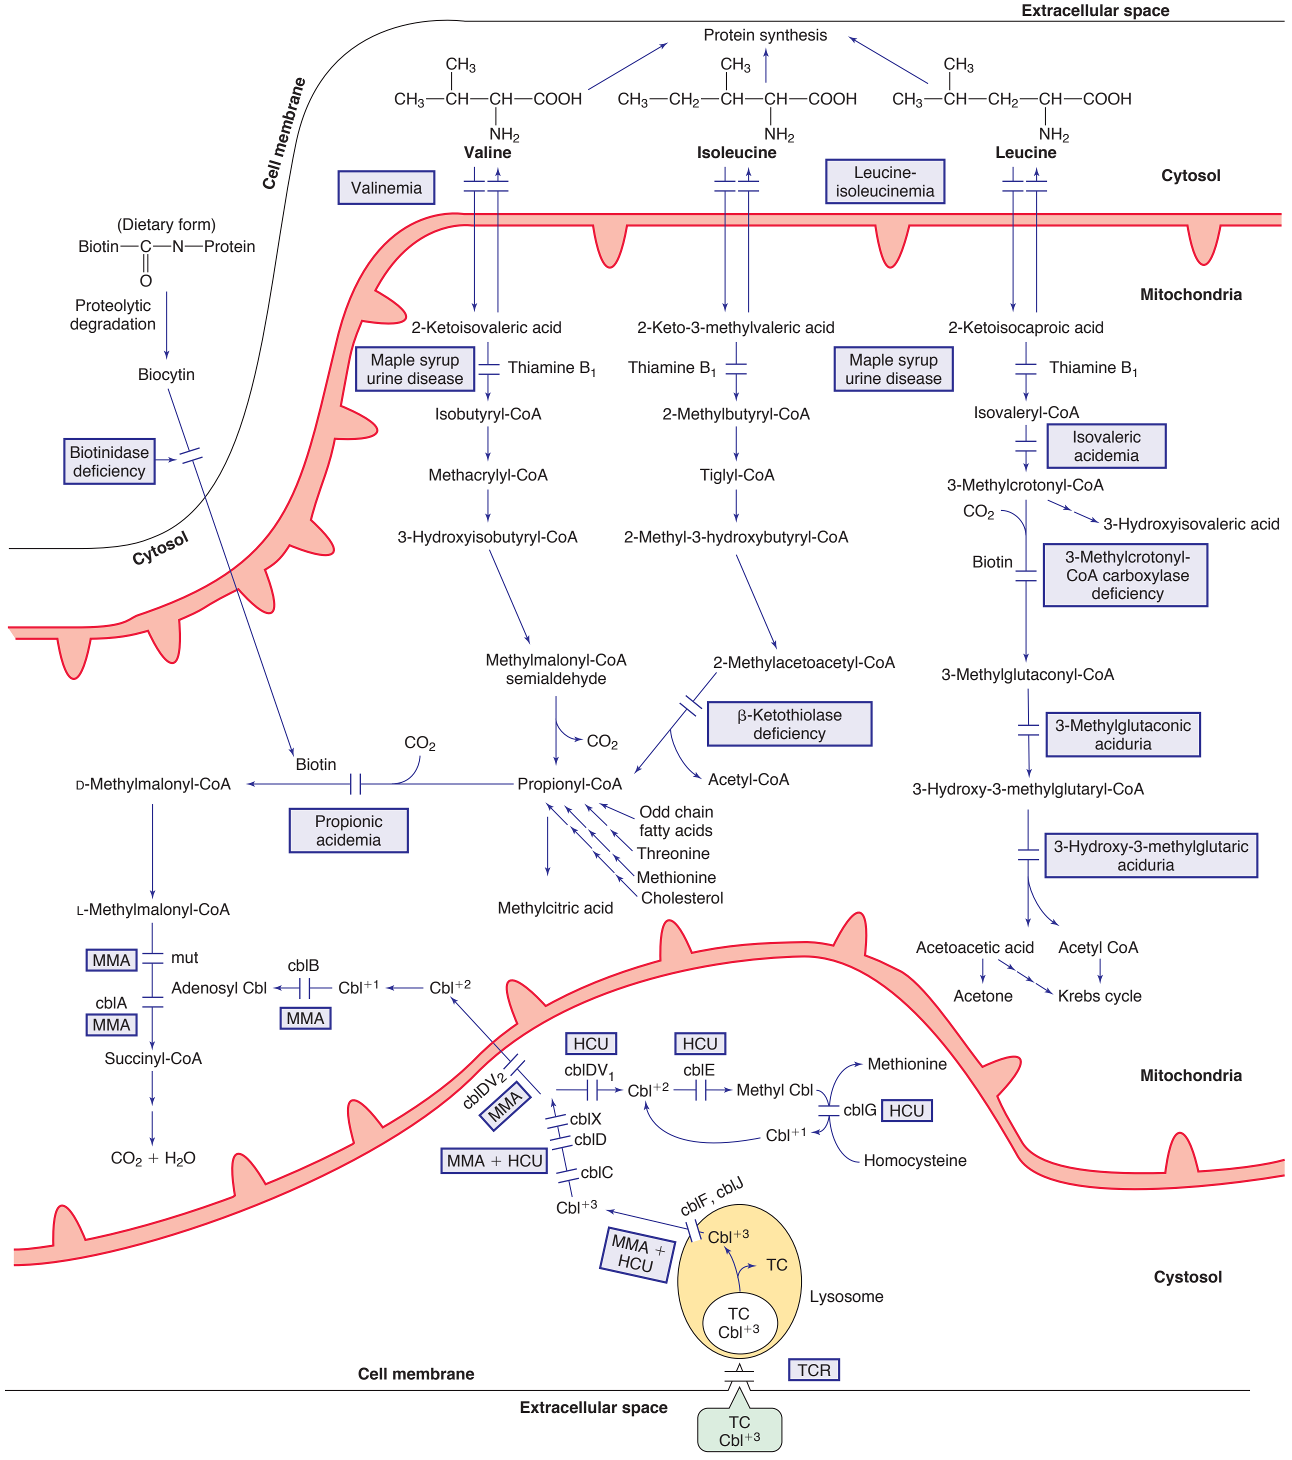

Figure 85-4 Pathways in the metabolism of the branched-chain amino acids, biotin, and vitamin B_{12} (cobalamin). Adenosyl Cbl, adenosylcobalamin; Cbl, cobalamin; cbl, defect in metabolism of cobalamin; cblDV1, cblD variant 1; cblDV2, cblD variant 2; HCU, homocystinuria; Methyl Cbl, methylcobalamin; MMA, methylmalonic acidemia; MUT, mutase; OHCbl, hydroxycobalamin; TC, transcobalamin; TCR, transcobalamin receptor. See text for the name of the enzymes.

Supplementation with *S*-adenosylmethionine in conjunction with a low methionine diet seems prudent, but no large clinical experience is yet available. Normal pregnancies producing normal offspring have been reported in mothers with MAT (MAT IA) deficiency. The condition is inherited as an autosomal recessive trait. The gene for hepatic MAT is on chromosome 10q22 and several disease-causing mutations have been identified.

3. **Glycine *N*-methyltransferase deficiency:** Although there are many methyltransferases present in the body, glycine *N*-methyltransferase is the critical one for catabolism of *S*-adenosylmethionine to *S*-adenosylhomocysteine (see Fig. 85-3). Three patients with deficiency of this enzyme have been reported to date. Clinically, patients were asymptomatic except for mild hepatomegaly and elevated serum levels of transaminases. Other laboratory findings included hypermethioninemia and very high

levels of serum *S*-adenosylmethionine. No specific treatment has yet been identified. The condition seems to be inherited as an autosomal recessive trait; the gene for the enzyme *(GNMT)* is on chromosome 6p21.1.

4. **Adenosylhomocysteine hydrolase deficiency:** Deficiency of this enzyme (see Fig. 85-3) has been reported in 6 patients from 5 different families. Psychomotor retardation and severe hypotonia were common clinical findings in affected individuals. Laboratory studies included elevated levels of serum creatine kinase, hypoalbuminemia (causing fetal hydrops in 1 family), hypoprothrombinemia and markedly elevated levels of serum *S*-adenosylhomocysteine with moderate elevations of plasma methionine and *S*-adenosylmethionine. Marked elevation in *S*-adenosylhomocysteine has been thought to cause inhibition of methyltransferases, including those involved in synthesis of creatine (see Fig. 85-10) and choline, resulting in their deficiencies. MRI of the brain showed delayed myelination of the white matter. Treatment with a low methionine diet in conjunction with creatine and phosphatidylcholine shows encouraging results in some patients.
5. **Tyrosinemia type I** (see Chapter 85.2).
6. **Citrin deficiency** (see Chapter 85.12).

Acquired (Nongenetic) Hypermethioninemia

Hypermethioninemia occurs in premature and some full-term infants receiving high-protein diets, in whom it may represent delayed maturation of the enzyme MAT. Lowering the protein intake usually resolves the abnormality. It is also commonly found in patients with various forms of liver disease.

CYSTATHIONINEMIA (CYSTATHIONINURIA)

Secondary cystathioninuria occurs in patients with vitamin B_6 or B_{12} deficiency, liver disease (particularly damage caused by galactosemia), thyrotoxicosis, hepatoblastoma, neuroblastoma, ganglioblastoma, or defects in remethylation of homocysteine.

Cystathionase deficiency results in massive cystathioninuria and mild to moderate cystathioninemia; cystathionine is not normally detectable in blood. Deficiency of this enzyme is inherited as an autosomal recessive trait and its prevalence is estimated to be about 1 in 14,000 live births. Affected subjects with a wide variety of clinical manifestations have been reported. Lack of a consistent clinical picture and the presence of cystathioninuria in a number of individuals free of clinical findings suggest that cystathionase deficiency may be of no clinical significance. A majority of reported cases are responsive to oral administration of large doses of vitamin B_6 (≥100 mg/24 hr). When cystathioninuria is discovered in a patient, vitamin B_6 treatment seems indicated, but its beneficial effect has not been established. The gene encoding for cystathionase (*CTH*) is located on chromosome16 1p31.1

Bibliography is available at Expert Consult.

85.4 Cysteine/Cystine

Iraj Rezvani

Cysteine is a sulfur-containing nonessential amino acid that is synthesized from methionine (see Fig. 85-3). In the presence of oxygen, 2 molecules of cysteine are oxidized to form cystine. The most common genetic disorders of cysteine/cystine metabolism are cystinuria (see Chapter 547) and cystinosis (see Chapter 529.3).

Sulfite Oxidase Deficiency (Molybdenum Cofactor Deficiency)

At the last step in cysteine metabolism, sulfite is oxidized to sulfate by sulfite oxidase, and the sulfate is excreted in the urine (see Fig. 85-3). This enzyme requires a molybdenum-pterin complex named molybdenum cofactor. This cofactor is also necessary for the function of 2 other enzymes in humans: xanthine dehydrogenase (which oxidizes xanthine and hypoxanthine to uric acid) and aldehyde oxidase (involved in oxidizing a number of natural compounds and drugs). Three enzymes, encoded by 3 different genes (*MOCS1*, *MOCS2,* and *GPHN*) are involved in the synthesis of the cofactor. The genes for these enzymes are mapped to chromosomes 6p21.2, 5q11.2, and 14q23.3, respectively. Deficiency of any of the 3 enzymes causes cofactor deficiency with identical phenotype. Most patients, who were originally diagnosed as having sulfite oxidase deficiency, have been proven to have molybdenum cofactor deficiency. Both conditions are inherited as autosomal recessive traits. The gene for sulfite oxidase (*SUOX*) is on chromosome 12q13.2.

The enzyme and or the cofactor deficiencies produce identical **clinical manifestations**. Refusal to feed, vomiting, severe intractable seizures (tonic, clonic, myoclonic), cortical atrophy with subcortical multicystic lesions, and severe developmental delay may develop within a few weeks after birth. Bilateral dislocation of ocular lenses is a common finding in patients who survive the neonatal period. The intractable seizures seen in this condition are, in large part, a consequence of secondary vitamin B_6 dependency. The accumulation of sulfites in body fluids in this condition causes the inhibition of antiquitin enzyme which is necessary for conversion of α-aminoadipic semialdehyde to α-aminoadipic acid; the resultant accumulation of α-aminoadipic semialdehyde and its cyclic form P6C causes the inactivation of pyridoxal-5-phosphate (active form of vitamin B_6) and, hence, the vitamin B_6–dependent epilepsy (see also Chapter 85.14).

These children excrete large amounts of sulfite, thiosulfate, *S*-sulfocysteine, xanthine, and hypoxanthine in their urine. Urinary and serum levels of uric acid and urinary concentration of sulfate are diminished. Fresh urine should be used for screening purposes and for quantitative measurements of sulfite, because oxidation of sulfite to sulfate at room temperature may produce false-negative results. Increased concentrations of α-aminoadipic semialdehyde and its cyclic form, P6C, and pipecolic acid are present in the CSF, plasma, and urine.

Diagnosis is confirmed by measurement of sulfite oxidase and molybdenum cofactor in fibroblasts and liver biopsies, respectively or by DNA studies. Prenatal diagnosis is possible by performing an assay of sulfite oxidase activity in cultured amniotic cells, in samples of chorionic villi or by DNA studies.

No effective **treatment** is available; large doses of vitamin B_6 (5-100 mg/kg) result in dramatic alleviation of seizures but do not seem to alter the devastating neurologic outcome. Most children die in the 1st 2 yr of life. One patient had an initial response to cyclic pyranopterin monophosphate (cPMP). The prevalence of these deficiencies in the general population is not known.

85.5 Tryptophan

Iraj Rezvani

Tryptophan is an essential amino acid and a precursor for nicotinic acid (niacin) and serotonin (Fig. 85-5). The genetic disorders of metabolism of serotonin, one of the major neurotransmitters, are discussed in Chapter 85.11.

HARTNUP DISORDER

In this autosomal recessive disorder, named after the first affected family, there is a defect in the transport of monoamino-monocarboxylic amino acids (neutral amino acids), including tryptophan, by the intestinal mucosa and renal tubules. The transporter protein for these amino acids (B0AT1) is encoded by the *SLC6A19* gene located on chromosome 5p15.33. Two chemically close transcription factors, angiotensin-converting enzyme (ACE2) in the intestine and renal tubules, and collectrin in the renal tubules, are required for expression of B0AT1 transporter protein by the *SLC6A19* gene. The mutated gene in patients with Hartnup disorder, unable to interact with the above

transcription factors, results in deficiency of B0AT1 protein either in the intestine or in the renal tubules or in both. This explains the absence of renal or intestinal transport defect seen in some affected families. Decreased intestinal absorption of tryptophan in conjunction with its increased renal loss is believed to cause reduced availability of tryptophan for niacin synthesis in affected individuals. Most children with Hartnup defect remain asymptomatic. The major clinical manifestation in the rare symptomatic patient is cutaneous photosensitivity. The skin becomes rough and red after moderate exposure to the sun, and with greater exposure, a pellagra-like rash may develop. The rash may be pruritic, and a chronic eczema may develop. The skin changes have been reported in affected infants as young as 10 days of age. Some patients may have intermittent ataxia manifested as an unsteady, wide-based gait. The ataxia may last a few days and usually recovers spontaneously. Mental development is usually normal. Two individuals in the original kindred were cognitively impaired. Episodic psychiatric manifestations such as irritability, emotional instability, depression, and suicidal tendencies, have been observed; these changes are usually associated with bouts of ataxia. Short stature and atrophic glossitis are seen in some patients.

Most children diagnosed with Hartnup disorder by neonatal screening have remained asymptomatic. This indicates that other factors are also involved in pathogenesis of the clinical condition.

The main **laboratory finding** is aminoaciduria, which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine). Urinary excretion of proline, hydroxyproline, and arginine remains normal. This finding differentiates Hartnup disorder from other causes of generalized aminoaciduria, such as Fanconi syndrome. Plasma concentrations of neutral amino acids are usually normal. This seemingly unexpected finding occurs because these amino acids are absorbed as dipeptides and the transport system for small peptides is intact in Hartnup disorder. The indole derivatives (especially indican) may be found in large amounts in some patients, owing to bacterial breakdown of unabsorbed tryptophan in the intestines.

Diagnosis is established by the striking intermittent nature of symptoms and the previously described urinary findings.

Treatment with nicotinic acid or nicotinamide (50-300 mg/24 hr) and a high-protein diet results in a favorable response in symptomatic patients. Because of the intermittent nature of the clinical manifestations, the efficacy of these treatments is difficult to evaluate. The prevalence of the disorder is estimated to be 1 in 20,000 to 1 in 30,000 live births. Normal outcome both for mother and fetus is reported in affected pregnant women.

Bibliography is available at Expert Consult.

85.6 Valine, Leucine, Isoleucine, and Related Organic Acidemias

Iraj Rezvani and David S. Rosenblatt

The early steps in the degradation of these 3 essential amino acids, the **branched-chain amino acids**, are similar (see Fig. 85-4). The intermediate metabolites are all organic acids, and deficiency of any of the degradative enzymes, except for the transaminases, causes acidosis; in such instances, the organic acids proximal to the enzymatic block accumulate in body fluids and are excreted in the urine. These disorders commonly cause metabolic acidosis, which usually occurs in the first few days of life. Although most of the clinical findings are nonspecific, some manifestations may provide important clues to the nature of the enzyme deficiency. Figure 85-6 presents an approach to infants suspected of having an organic acidemia. Definitive diagnosis is usually established by identifying and measuring specific organic acids in body fluids (blood, urine), by the enzyme assay, and by identification of the mutant gene.

Organic acidemias are not limited to defects in the catabolic pathways of branched-chain amino acids. Disorders causing accumulation of other organic acids include those derived from lysine (see Chapter 85.14), those associated with lactic acid (see Chapter 87), and dicarboxylic acidemias associated with defective fatty acid degradation (see Chapter 86.1).

MAPLE SYRUP URINE DISEASE

Decarboxylation of leucine, isoleucine, and valine is accomplished by a complex enzyme system (branched-chain α-ketoacid dehydrogenase [BCKDH]) using thiamine (vitamin B_1) pyrophosphate as a coenzyme. This mitochondrial enzyme consists of 4 subunits: $E_{1\alpha}$, $E_{1\beta}$, E_2, and E_3. The E_3 subunit is shared with 2 other dehydrogenases in the body, namely pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Deficiency of any of these subunits causes maple syrup urine disease (MSUD) (see Fig. 85-4), named after the sweet odor of maple syrup found in body fluids, especially urine. Clinical conditions caused by defects in $E_{1\alpha}$, $E_{1\beta}$, E_2 and E_3 are designated as MSUD type IA, type IB, type 2, and type 3 respectively. This classification, however, is not very helpful clinically because the severity of clinical manifestations does not correlate with or correspond specifically to any single type. An affected infant with type 1A defect can have clinical manifestations ranging from relatively mild to very severe. A more useful classification, based on clinical findings and response to thiamine administration, has identified 5 phenotypes of MSUD as follows:

Classic Maple Syrup Urine Disease

This form has the most severe clinical manifestations. Affected infants who are normal at birth develop poor feeding and vomiting in the 1st wk of life; lethargy and coma may ensue within a few days. Physical examination reveals hypertonicity and muscular rigidity with severe opisthotonos. Periods of hypertonicity may alternate with bouts of flaccidity manifested as repetitive movements of the extremities (boxing and bicycling). Neurologic findings are often mistakenly thought to be caused by generalized sepsis and meningitis. Cerebral edema may be present; convulsions occur in most infants, and hypoglycemia is common. In contrast to most hypoglycemic states, correction of the blood glucose concentration does not improve the clinical condition. Aside from the serum glucose, routine laboratory findings are usually unremarkable, except for varying degrees of metabolic acidosis. Death usually occurs in untreated patients in the first few weeks or months of life.

Diagnosis is often suspected because of the peculiar odor of maple syrup found in urine, sweat, and cerumen (see Fig. 85-6). It is usually confirmed by amino acid analysis showing marked elevations in plasma levels of leucine, isoleucine, valine, and alloisoleucine (a stereoisomer of isoleucine not normally found in blood) and depression of alanine. Leucine levels are usually higher than those of the other 3 amino acids. Urine contains high levels of leucine, isoleucine, and valine and their respective ketoacids. These ketoacids may be detected qualitatively by adding a few drops of 2,4-dinitrophenylhydrazine reagent (0.1% in 0.1N HCl) to the urine; a yellow precipitate of 2,4-dinitrophenylhydrazone, is formed in a positive test. Neuroimaging during the acute state may show cerebral edema, which is most prominent in the cerebellum, dorsal brainstem, cerebral peduncle, and internal capsule. After recovery from the acute state and with advancing age, hypomyelination and cerebral atrophy may be seen in neuroimaging of the brain. The enzyme activity can be measured in leukocytes and cultured fibroblasts.

Treatment of the acute state is aimed at hydration and rapid removal of the branched-chain amino acids and their metabolites from the tissues and body fluids. Because renal clearance of these compounds is poor, hydration alone may not produce a rapid improvement. Peritoneal dialysis or, preferably, hemodialysis is the most effective mode of therapy in critically ill infants and should be instituted promptly; significant decreases in plasma levels of leucine, isoleucine, and valine are usually seen within 24 hr of institution of treatment. Sufficient calories and nutrients should be provided intravenously or orally as soon as possible so as to reverse the patient's catabolic state. Cerebral edema, if present, may need to be treated with mannitol, diuretics (e.g., furosemide), or hypertonic saline.

Treatment after recovery from the acute state requires a diet low in branched-chain amino acids. Synthetic formulas devoid of leucine, isoleucine, and valine are available commercially. Because these amino acids cannot be synthesized endogenously, small amounts of them should be added to the diet; the amount should be titrated carefully by performing frequent analyses of the plasma amino acids. A clinical condition resembling **acrodermatitis enteropathica** (see Chapter 671) occurs in affected infants whose plasma isoleucine concentration becomes very low; addition of isoleucine to the diet causes a rapid and complete recovery. Patients with MSUD should remain on the diet for the rest of their lives. Liver transplantation has been performed in a number of patients with classic MSUD with promising results. These children have been able to tolerate a normal diet.

The long-term prognosis of affected children remains guarded. Severe ketoacidosis, cerebral edema, and death may occur during any stressful situation such as infection or surgery, especially in mid-childhood. Cognitive and other neurologic deficits are common sequelae.

Intermediate (Mild) Maple Syrup Urine Disease

In this form, affected children develop milder disease after the neonatal period. **Clinical manifestations** are insidious and limited to the CNS. Patients have mild to moderate intellectual disability (usually after 5 mo of age) with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the branched-chain amino acids and their ketoacid derivatives in the urine. Plasma concentrations of leucine, isoleucine, and valine are moderately increased whereas those of lactate and pyruvate are normal. These children are commonly diagnosed during an intercurrent illness when signs and symptoms of classic MSUD may occur. The dehydrogenase activity is 3-40% of normal. Because patients with thiamine-responsive MSUD usually have manifestations similar to those seen in the mild form, a trial of thiamine therapy is recommended. Diet therapy, similar to that of classic MSUD, is needed.

Intermittent Maple Syrup Urine Disease

In this form of MSUD, seemingly normal children develop vomiting, odor of maple syrup, ataxia, lethargy, and coma during any stress or catabolic state such as infection or surgery. During these attacks, laboratory findings are indistinguishable from those of the classic form, and death may occur. **Treatment** of the acute attack of intermittent

MSUD is similar to that of the classic form. After recovery, although a normal diet is tolerated, a diet low in branched-chain amino acids is recommended. Activity of the dehydrogenase in patients with the intermittent form is higher than in the classic form and may reach 40% of the normal activity.

Thiamine-Responsive Maple Syrup Urine Disease

Some children with mild or intermediate forms of MSUD who are treated with high doses of thiamine have dramatic clinical and biochemical improvement. Although some respond to treatment with thiamine at 10 mg/24 hr, others may require as much as 200 mg/24 hr for at least 3 wk before a favorable response is observed. These patients also require diets deficient in branched-chain amino acids. The enzymatic activity in these patients is 30-40% of normal.

Maple Syrup Urine Disease Caused by a Deficiency of E_3 Subunit (Maple Syrup Urine Disease Type 3)

This is a very rare disorder. Patients develop lactic acidosis in addition to signs and symptoms similar to those of intermediate MSUD because the E_3 subunit is also a component of pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Progressive neurologic impairment manifested by hypotonia and developmental delay occurs after 2 mo of age. Abnormal movements progress to ataxia. Death may occur in early childhood.

Laboratory findings include persistent lactic acidosis with high levels of plasma lactate, pyruvate, and alanine. Plasma concentrations of branched-chain amino acids are moderately increased. Patients excrete large amounts of lactate, pyruvate, α-glutarate, and the 3 branched-chain ketoacids in their urine.

No effective **treatment** is available. Dietary restrictions of branched-chain amino acids and treatment with high doses of thiamine, biotin, and lipoic acid have been ineffective.

Genetics and Prevalence of Maple Syrup Urine Disease

All forms of MSUD are inherited as an autosomal recessive trait. The gene for each subunit resides on different chromosomes. The gene for $E_{1\alpha}$ (*BCKDHA*) is on chromosome 19q13.1-q13.2; that for $E_{1\beta}$ (*BCKDHB*) is on chromosome 6q14.1; the gene for E_2 (*DBT*) is on chromosome 1p21.2; and that for E_3 (*DLD*) is on chromosome 7q31.1. Many different disease-causing mutations (>160) have been identified in patients with different forms of MSUD. A given clinical phenotype is caused by a variety of genotypes; as an example, patients from different pedigrees with the classic form of MSUD have been shown to have mutations in genes for $E_{1\alpha}$, $E_{1\beta}$, or E_2 subunits. The exception is the thiamine-responsive MSUD that is shown to be caused by mutations in the E_2 gene in all reported cases to date. Most patients are compound heterozygotes inheriting 2 different mutant alleles. Mutations in genes for $E_{1\alpha}$ (45%) and $E_{1\beta}$ (35%) account for approximately 80% of cases.

The prevalence is estimated at 1 in 185,000 live births. The classic form of MSUD is more prevalent in the Old Order Mennonites in the United States, with estimated prevalence of 1 in 380 live births. Affected patients in this population are homozygous for a specific mutation (c.1312T>A) in the $E_{1\alpha}$ subunit gene.

Early detection of MSUD is feasible by mass screening of newborn infants. In most cases (especially those with classic form of MSUD), however, the infant may be quite sick by the time the results of the screening becomes available (see Chapter 84). Prenatal diagnosis has been accomplished by enzyme assay of the cultured amniocytes, cultured chorionic villus tissue, or direct assay of samples of the chorionic villi and by identification of the mutant gene.

Several successful pregnancies have occurred in women with different forms of MSUD. No ill effects have been observed in the offspring of these patients. Episodes of metabolic decompensation have occurred in the mothers during pregnancy and the postpartum period.

ISOVALERIC ACIDEMIA

This condition is caused by the deficiency of the enzyme isovaleryl CoA dehydrogenase (see Fig. 85-4). Clinically, two forms of the condition are recognized in symptomatic patients: the acute form and the chronic intermittent form.

Clinical manifestations in the *acute form* include vomiting and severe acidosis in the first 2 wk of life. Lethargy, convulsions, and coma may ensue, and death may occur if proper therapy is not initiated. The vomiting may be severe enough to suggest pyloric stenosis. The characteristic odor of "sweaty feet" may be present (in body sweat and cerumen, but not in the urine; see Fig. 85-6). Infants who survive this acute episode will go on to have the chronic intermittent form later in life. In the *chronic intermittent form of the disease,* the first clinical manifestations (vomiting, lethargy, acidosis or coma) may not appear until the child is a few months or a few years old. In both forms, acute episodes of metabolic decompensations may occur during a catabolic state such as an infection. Acute episodes may be mistaken for diabetic ketoacidosis. With worldwide application of newborn screening technology (see Chapter 84) it is now becoming clear that the clinical spectrum in affected patients can range from completely asymptomatic to the acute form. Older siblings of symptomatic newborn infants have been reported with identical genotype and biochemical abnormalities but without any clinical manifestations.

Laboratory findings during the acute attacks include ketoacidosis, neutropenia, thrombocytopenia, and occasionally pancytopenia. Hypocalcemia, hyperglycemia, and moderate to severe hyperammonemia may be present in some patients. Increases in plasma ammonia may suggest a defect in the urea cycle (see Chapter 85.12). In urea cycle defects, the infant is not acidotic (see Fig. 85-6).

Diagnosis is established by demonstrating marked elevations of isovaleric acid and its metabolites (isovalerylglycine, 3-hydroxyisovaleric acid) in body fluids, especially urine. The main compound in plasma is isovalerylcarnitine, which can be measured even in a few drops of dried blood on a filter paper. Diagnosis can be confirmed by measurement of the enzyme activity in cultured skin fibroblasts or by the identification of the mutant gene.

Treatment of the acute attack is aimed at hydration, reversal of the catabolic state (by providing adequate calories orally or intravenously), correction of metabolic acidosis (by infusing sodium bicarbonate), and removal of the excess isovaleric acid. Because isovalerylglycine has a high urinary clearance, administration of glycine (250 mg/kg/24 hr) is recommended to enhance formation of isovalerylglycine. L-Carnitine (100 mg/kg/24 hr orally) also increases removal of isovaleric acid by forming isovalerylcarnitine, which is excreted in the urine. In patients with significant hyperammonemia (blood ammonia >200 µM), measures that reduce blood ammonia should be employed (see Chapter 85.12). Exchange transfusion and peritoneal dialysis may be needed if the previously described measures fail to induce significant clinical and biochemical improvement. After recovery from the acute attack, the patient should receive a low-protein diet (1.0-1.5 g/kg/24 hr) and should be given glycine and carnitine supplements. Pancreatitis (acute or recurrent forms) has been reported in survivors. Normal development can be achieved with early and proper treatment.

Prenatal diagnosis may be accomplished by measuring isovalerylglycine in amniotic fluid, by enzyme assay in cultured amniocytes, or by identification of the mutant gene. Successful pregnancy with favorable outcomes both for the mother and the infant has been reported. Mass screening of newborn infants for detection of this condition is in use in the United States and other countries (see Chapter 84). Isovaleric acidemia is inherited as an autosomal recessive trait. The gene (*IVD*) has been mapped to chromosome 15q15.1 and many disease-causing mutations have been identified. The prevalence of the condition is estimated from 1 in 62,500 (in parts of Germany) to 1 in 250,000 live births (in the United States).

MULTIPLE CARBOXYLASE DEFICIENCIES (DEFECTS IN UTILIZATION OF BIOTIN)

Biotin is a water-soluble vitamin that is a cofactor for all 4 carboxylase enzymes in humans: pyruvate carboxylase, acetyl CoA carboxylase,

propionyl CoA carboxylase, and 3-methylcrotonyl CoA carboxylase. The latter 2 are involved in the metabolic pathways of leucine, isoleucine, and valine (see Fig. 85-4).

Dietary biotin is bound to proteins; free biotin is generated in the intestine by the action of digestive enzymes, by intestinal bacteria, and perhaps by biotinidase. The latter enzyme, which is found in serum and most tissues in the body, is also essential for the recycling of biotin in the body by releasing it from the apoenzymes (carboxylases; see Fig. 85-4). Free biotin must form a covalent peptide bond with the apoprotein of the 4 carboxylases to form the activated enzyme (holocarboxylase). This binding is catalyzed by holocarboxylase synthetase. Deficiencies in this enzyme activity or in biotinidase result in malfunction of all the carboxylases and in organic acidemia.

Holocarboxylase Synthetase Deficiency (Multiple Carboxylase Deficiency Neonatal or Early Form)

Infants with this rare autosomal recessive disorder become symptomatic in the first few weeks of life. Symptoms may appear as early as a few hours after birth to 21 mo of age. **Clinically,** the affected infants who seem normal at birth develop breathing difficulties (tachypnea and apnea) shortly after birth. Feeding problems, vomiting, and hypotonia are also commonly present. If the condition remains untreated, generalized erythematous rash with exfoliation and alopecia (partial or total), failure to thrive, irritability, seizures, lethargy, and even coma may occur. Developmental delay is common. Immune deficiency manifests with susceptibility to infection. The urine may have a peculiar odor, which has been described as similar to tomcat urine. The rash, when present, differentiates this condition from other organic acidemias (see Fig. 85-6).

Laboratory findings include metabolic acidosis, ketosis, hyperammonemia, and the presence of a variety of organic acids (lactic acid, propionic acid, 3-methylcrotonic acid, 3-methylcrotonylglycine, tiglylglycine, methylcitrate, and 3-hydroxyisovaleric acid) in body fluids. Diagnosis is confirmed by the enzyme assay in lymphocytes or cultured fibroblasts or by identification of the mutant gene. Most mutations cause the enzyme to have an increased K_m (Michaelis-Menten dissociation constant) for biotin; the enzyme activity in such patients can be restored by the administration of large doses of biotin.

Treatment with biotin (10 mg/day orally) usually results in an improvement in clinical manifestations and may normalize the biochemical abnormalities. Early diagnosis and treatment are critical to prevent irreversible neurologic damage. In some patients, however, complete resolution may not be achieved even with large doses (up to 80 mg/day) of biotin.

The gene for holocarboxylase synthetase (*HLCS*) is located on chromosome 21q22.1 and many disease-causing mutations have been identified in different families. Prenatal diagnosis has been accomplished by assaying enzyme activity in cultured amniotic cells and by measurement of intermediate metabolites (3-hydroxyisovalerate and methylcitrate) in amniotic fluid or by DNA analysis. Pregnant mothers who had previous offspring with holocarboxylase synthetase deficiency have been treated with biotin late in pregnancy. Affected infants were normal at birth, but the efficacy of the treatment as related to the outcome remains unclear.

Biotinidase Deficiency (Multiple Carboxylase Deficiency—Juvenile or Late Form)

The absence of biotinidase results in biotin deficiency. Infants with this deficiency may develop **clinical manifestations** similar to those seen in infants with holocarboxylase synthetase deficiency but, unlike the latter, symptoms may appear later when the child is several months or years old; symptoms may develop as early as 1 wk of age. Therefore, the term "late form" does not apply to all cases and can be misleading. The delay is presumably because of the presence of sufficient free biotin derived from the mother or the diet. Clinical manifestations are mostly confined to skin and the nervous system. Atopic or seborrheic dermatitis, candidiasis, alopecia, ataxia, seizures (usually myoclonic type), hypotonia, developmental delay, optic atrophy, sensorineural hearing loss, and immunodeficiency (from T-cell abnormalities) may occur. A small number of children with intractable seborrheic dermatitis and partial (15-30% activity) deficiency of the enzyme, in whom the dermatitis resolved with biotin therapy, have been reported; these children were otherwise asymptomatic. Asymptomatic children and adults with this enzyme deficiency have been identified in screening programs. Most of these individuals have been shown to have partial deficiency of the enzyme activity. With the advent of mass screening of newborn infants and early identification and treatment of the affected patients, the clinical disease is predicted to become extinct.

Laboratory findings and the pattern of organic acids in body fluids resemble those associated with holocarboxylase synthetase deficiency (see above). Diagnosis can be established by measurement of the enzyme activity in the serum or by the identification of the mutant gene.

Treatment with free biotin (5-20 mg/24 hr) results in a dramatic clinical and biochemical response. Treatment with biotin is also suggested for individuals with partial biotinidase deficiency.

The prevalence of this autosomal recessive trait is estimated at 1 in 60,000 live births. The gene for biotinidase (*BTD*) is located on chromosome 3p25.1 and many disease-causing mutations (approximately 150) have been identified in different families. Prenatal diagnosis is possible by the measurement of the enzyme activity in the amniotic cells or by identification of the mutant gene.

Multiple Carboxylase Deficiency Because of Dietary Biotin Deficiency

Acquired deficiency of biotin may occur in infants receiving total parenteral nutrition without added biotin, in patients receiving prolonged anticonvulsant drugs (phenytoin, primidone, carbamazepine) or in children with short bowel syndrome or chronic diarrhea who are receiving formulas low in biotin. Excessive ingestion of raw eggs may also cause biotin deficiency because the protein avidin in egg white binds biotin and makes it unavailable for absorption. Infants with biotin deficiency may develop dermatitis, alopecia, and candidal skin infections.

ISOLATED 3-METHYLCROTONYL COENZYME A (CoA) CARBOXYLASE DEFICIENCY

This enzyme is 1 of 4 carboxylase enzymes in the body that require biotin as a cofactor (see Fig. 85-4). An isolated deficiency of this enzyme must be differentiated from disorders of biotin metabolism (multiple carboxylase deficiency), which causes diminished activity of all 4 carboxylases (see above). 3-Methylcrotonyl CoA carboxylase is a heteromeric enzyme consisting of α (biotin containing) and β subunits.

Clinical manifestations are highly variable, ranging from fatal neonatal onset (seizures, hypotonia, acidosis) to completely asymptomatic adults (including mothers of affected newborn infants). In the severe form of the condition, the affected infant who has been seemingly normal develops an acute episode of vomiting, hypotonia, lethargy, and convulsions after a minor infection. The onset is usually between 3 wk and 3 yr of age. Death may occur during the acute episode.

Laboratory findings during acute episodes include mild to moderate acidosis, ketosis, severe hypoglycemia, hyperammonemia, and elevated serum levels of liver transaminases. Large amounts of 3-hydroxyisovaleric acid and 3-methylcrotonylglycine are found in the urine. Urinary excretion of 3-methylcrotonic acid is not usually increased in this condition because the accumulated 3-methylcrotonyl CoA is converted to 3-hydroxyisovaleric acid. Severe secondary carnitine deficiency is common. The condition should be differentiated biochemically from multiple carboxylase deficiency (see above) in which lactic acid and metabolites of propionic acid are present in body fluids in addition to 3-hydroxyisovaleric acid. Diagnosis may be confirmed by measurement of the enzyme activity in cultured fibroblasts or by DNA analysis. Documentation of normal activities of other carboxylases is necessary for definitive diagnosis.

Treatment of acute episodes is similar to that of isovaleric acidemia (see above). Hydration and measures to correct metabolic acidosis and hypoglycemia (by infusing sodium bicarbonate and glucose) should be instituted promptly. Administration of L-carnitine and glycine is also recommended. These patients are unresponsive to biotin therapy. Patients who, in earlier reports, were found to be biotin-responsive were most probably suffering from multiple carboxylase deficiency as a result of biotinidase deficiency (see above). Long-term treatment includes a diet restricted in leucine in conjunction with the oral administration of L-carnitine (75-100 mg/kg/24 hr) and the prevention of catabolic states. Normal growth and development are expected in these patients.

The condition is inherited as an autosomal recessive trait. The gene for α subunit (*MCC1*) is located on chromosome 3q27.1 and that for the β subunit (*MCC2*) is mapped to chromosome 5q13.2. Mutation in either of these genes may result in the deficiency of the enzyme activity. Similar phenotype may be caused by different genotype. Several disease-causing mutations in either gene have been identified in different families. Newborn screening programs using tandem mass spectrometry have identified an unexpectedly high number of infants with 3-methylcrotonyl CoA carboxylase deficiency (1 : 50,000). Only a small number (<10%) of the affected infants become symptomatic; none of the symptoms reported so far could be clearly attributed to the degree of enzyme deficiency. These findings have questioned the advisability of including this condition in the routine newborn screening programs because the psychologic and financial burdens may outweigh the potential benefits.

3-METHYLGLUTACONIC ACIDURIA

Six inherited conditions are known to be associated with excessive excretion of 3-methylglutaconic acid in the urine. Deficiency of the enzyme 3-methylglutaconyl CoA hydratase (see Fig. 85-4) has been documented in only 1 condition (type I). In the other 5 conditions, the enzyme activity is normal despite a modest 3-methylglutaconic aciduria. The reason for increased urinary excretion of 3-methyglutaconic acid in these conditions is not completely understood; although these conditions are caused by mutations in different genes, the gene products are all critical for normal mitochondrial function. Only 3-methyglutaconic acidurias—types I, II, and III—are discussed here because the clinical pictures of types IV and V (dilated cardiomyopathy with ataxia) are not well delineated.

3-Methylglutaconic Aciduria Type I (3-Methylglutaconyl Coenzyme A Hydratase Deficiency)

See Figure 85-4.

Two main clinical forms of the condition have been described. In the childhood form, nonspecific neurodevelopmental findings such as speech delay or regression, choreoathetoid movements, optic atrophy, and mild psychomotor delay may be present. Metabolic acidosis may occur during a catabolic state. In the adulthood form, affected individuals remain asymptomatic until the 2nd or 3rd decades of life, when a clinical picture of slowly progressing leukoencephalopathy with optic atrophy, dysarthria, ataxia, spasticity, and dementia occurs. MRI of brain typically shows white matter abnormalities that may precede appearance of clinical symptoms by years. Asymptomatic affected children and adults have also been reported. Patients excrete large amounts of 3-methylglutaconic acid and moderate amounts of 3-hydroxyisovaleric and 3-methylglutaric acids in urine. Deficiency of 3-methylglutaconyl CoA hydratase has been shown in cultured fibroblasts and lymphoblasts. **Treatment** with a low leucine diet seems to be indicated even in asymptomatic affected individuals. Beneficial effects of this therapy on the clinical course of the disease remain to be determined. Administration of L-carnitine has resulted in clinical improvement in 1 patient. The condition is inherited as an autosomal recessive trait; the gene for the hydratase enzyme (*AUH*) is mapped to chromosome 9q22.3.

3-Methylglutaconic Aciduria Type II (X-Linked Cardiomyopathy, Neutropenia, Growth Retardation, and 3-Methylglutaconic Aciduria with Normal 3-Methylglutaconyl Coenzyme A Hydratase, Barth Syndrome)

This X-linked mitochondrial condition is caused by deficiency of tafazzin, a mitochondrial protein (enzyme), encoded by *TAZ* gene. This enzyme is necessary for processing of immature cardiolipin into the mature form (cardiolipin remodeling). Cardiolipin, a mitochondrial phospholipid, is critical for the integrity of inner mitochondrial membrane. **Clinical manifestations** of this condition, which usually occur in the first year of life in a male infant, include dilated cardiomyopathy (manifested as respiratory distress and heart failure), hypotonia, growth retardation, hypoglycemia, and moderate to severe cyclic neutropenia. The onset of clinical manifestations may be as late as 49 yr of age, but most affected individuals become symptomatic by adolescence. If patients survive infancy, relative improvement may occur with advancing age. Cognitive development is usually normal despite delayed motor function.

Laboratory findings include mild to moderate increases in urinary excretion of 3-methylglutaconic, 3-methylglutaric, and 2-ethylhydracrylic acids. Unlike 3-methylglutaconic aciduria type I, urinary excretion of 3-hydroxyisovaleric acid is not elevated. The activity of the enzyme 3-methylglutaconyl CoA hydratase is normal. Cyclic neutropenia is a common finding. Lactic acidosis, hypoglycemia, low serum cholesterol concentration and abnormal mitochondrial ultrastructure have been shown in some patients. Total cardiolipin and subclasses of cardiolipin are very low in skin fibroblast cultures from these patients. This finding may be useful for establishing the diagnosis.

The condition is inherited as an X-linked recessive trait. The gene (*TAZ*) has been mapped to chromosome Xq28 and several disease-causing mutations have been identified. The modest 3-methylglutaconic aciduria seen in this condition is thought to be related to the defect in mitochondrial membrane causing the leakage of this organic acid. No effective treatment is available. Older surviving patients may benefit from cardiac transplantation. There are reasons to believe that the condition is perhaps more common than realized; most affected patients remain undiagnosed or misdiagnosed as having viral cardiomyopathy.

3-Methylglutaconic Aciduria Type III (Costeff Optic Atrophy Syndrome)

Clinical manifestations in these patients include early onset optic atrophy and later development of choreoathetoid movements, spasticity, ataxia, dysarthria, and mild developmental delay. All reported patients except 1 were Iraqi Jews living in Israel. These patients excrete moderate amounts of 3-methylglutaconic and 3-methylglutaric acids. Activity of the enzyme 3-methylglutaconyl CoA hydratase is normal. The reason for the increased excretion of these organic acids remains unclear. The condition is inherited as an autosomal recessive trait. The gene for this condition (*OPA3*) is mapped to chromosome 19q13.2-q13.3. Mutation of this gene is believed to cause mitochondrial dysfunction. No effective treatment is available.

β-KETOTHIOLASE (3-OXOTHIOLASE) DEFICIENCY (MITOCHONDRIAL ACETOACETYL COENZYME A THIOLASE [T_2] DEFICIENCY)

This reversible mitochondrial enzyme is involved in final steps of catabolism of isoleucine and also in oxidation of fatty acids. It cleaves 2-methylacetoacetyl CoA to propionyl-CoA plus acetyl-CoA in isoleucine catabolic pathway (see Fig. 85-4). In the fatty acid oxidation pathway, the enzyme generates 2 moles of acetyl-CoA from 1 mole of acetoacetyl-CoA (Fig. 85-7). The same enzyme synthesizes 2-methyacetoacetate-CoA and acetoacetyl-CoA in the reverse direction (Fig. 85-7).

Clinical manifestations are quite variable, ranging from an asymptomatic course in an adult to severe episodes of acidosis starting in the

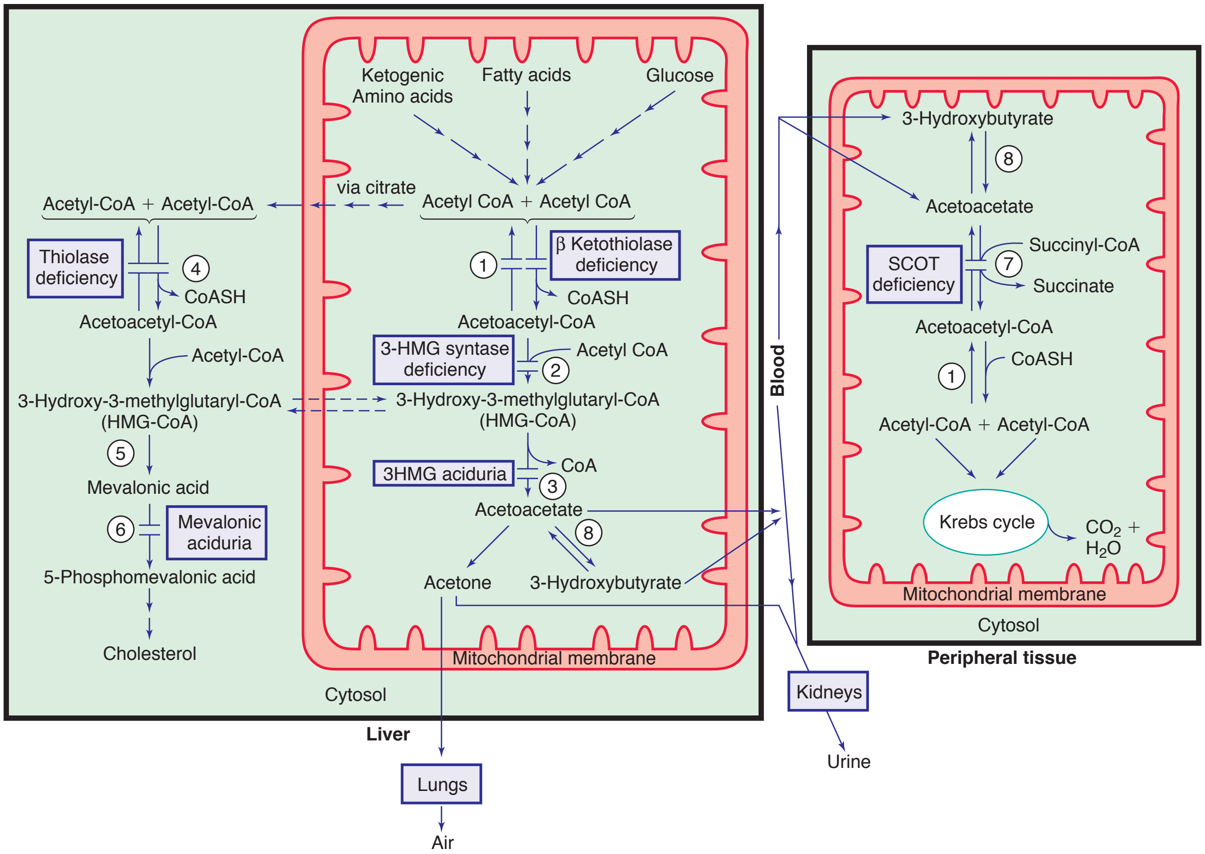

Figure 85-7 Formation (liver) and metabolism (peripheral tissues) of ketone bodies and cholesterol synthesis. **Enzymes:** *(1)* Mitochondrial acetoacetyl CoA thiolase, *(2)* HMG-CoA synthase, *(3)* HMG-CoA lyase, *(4)* cytosolic acetoacetyl CoA thiolase, *(5)* HMG-CoA reductase, *(6)* mevalonic kinase, *(7)* succinyl CoA:3-ketoacid CoA transferase (SCOT), *(8)* 3-hydroxybutyrate dehydrogenase.

1st yr of life. Typically, these children have intermittent episodes of unexplained ketosis and acidosis. These episodes usually occur after an intercurrent infection and respond quickly to intravenous fluids and bicarbonate therapy. Mild to moderate hyperammonemia may also be present during attacks. Both hypoglycemia and hyperglycemia have been reported in isolated cases. The child may be completely asymptomatic between episodes and may tolerate a normal protein diet well. Cognitive development is normal in most children. The episodes may be misdiagnosed as salicylate poisoning because of the similarity of the clinical findings and the interference of elevated blood levels of acetoacetate with the colorimetric assay for salicylate.

Laboratory findings during the acute attack include acidosis, ketosis, and hyperammonemia. The urine contains large amounts of 2-methylacetoacetate and its decarboxylated products butanone, 2-methyl-3-hydroxybutyrate, and tiglylglycine. Lower concentrations of these urinary metabolites persist during the seemingly well periods. Mass screening of newborn infants may yield false-negative results in affected infants who are well at the time of blood sampling. Mild hyperglycinemia may also be present. The clinical and biochemical findings should be differentiated from those seen with propionic and methylmalonic acidemias (see later). Diagnosis may be established by assay of the enzyme in leukocytes or cultured fibroblasts, or identification of the mutant gene.

Treatment of acute episodes includes hydration and infusion of bicarbonate to correct the acidosis; a 10% glucose solution with the appropriate electrolytes and intravenous lipids may be used to minimize the catabolic state. Restriction of protein intake (1-2 g/kg/24 hr) is recommended for long-term therapy. Oral L-carnitine (50-100 mg/kg/24 hr) is also recommended to prevent possible secondary carnitine deficiency. Long-term prognosis for achieving normal life seems very favorable. Three reported patients graduated from high school and 1 has attended college. All patients continued to have abnormal metabolites in body fluids. Successful pregnancy with normal outcomes for both mother and infant has been reported.

The pathogenesis of ketosis in this condition is not adequately explained because, in this enzyme deficiency, one expects impaired ketone formation (see Fig. 85-7). It is postulated that excess acetoacetyl CoA produced from other sources is used as a substrate for 3-hydroxy-3-methylglutaryl (HMG) CoA synthesis in the liver.

This condition is inherited as an autosomal recessive trait and may be more prevalent than has been appreciated. It is most prevalent in Tunisia. The gene (*ACAT1*) for this enzyme (T_2) is located on chromosome 11q22.3.

CYTOSOLIC ACETOACETYL COENZYME A THIOLASE DEFICIENCY

This enzyme catalyzes the cytosolic production of acetoacetyl CoA from 2 moles of acetyl CoA (see Fig. 85-7). Cytosolic acetoacetyl CoA is the precursor of hepatic cholesterol synthesis. Cytosolic acetoacetyl CoA thiolase is a completely different enzyme from mitochondrial thiolase (see above and Fig. 85-4). Clinical manifestations in patients with this very rare enzyme deficiency are similar to those in patients with mevalonic acidemia (see below). Severe progressive developmental delay, hypotonia, and choreoathetoid movements develop in the first few months of life. Laboratory findings are nonspecific; elevated levels of lactate, pyruvate, acetoacetate, and 3-hydroxybutyrate may be found in blood and urine. One patient had normal levels of acetoacetate and 3-hydroxybutyrate. Diagnosis can be established by demonstrating a deficiency in cytosolic thiolase activity in liver biopsy or in cultured fibroblasts or by DNA analysis. No effective treatment is available. The gene (*ACAT2*) for this condition is mapped to chromosome 6q25.3.

MITOCHONDRIAL 3-HYDROXY-3-METHYLGLUTARYL COENZYME A SYNTHASE DEFICIENCY

This enzyme catalyzes synthesis of 3-hydroxy-3-methylglutaryl (HMG)-CoA from acetoacetyl CoA in the mitochondria. This is a critical step in ketone body synthesis in the liver (see Fig. 85-7). A few patients with deficiency of this enzyme have been reported. All patients have had similar presentations and outcomes. Signs and symptoms of acute hypoglycemia have occurred after an acute illness (gastroenteritis). Age at presentation has ranged from 18 mo to 6 yr. All children were asymptomatic before the episodes and remained normal after the recovery (except for mild hepatomegaly with fatty infiltration). None of the patients has had a second episode, perhaps as a result of preventive measures to avoid prolonged fasting during ensuing intercurrent illnesses. Hepatomegaly was a consistent physical finding in all patients. Laboratory findings included hypoglycemia, acidosis with mild or no ketosis, elevation of liver function tests, and massive dicarboxylic aciduria. The clinical and laboratory findings may be confused with those of patients with defects in fatty acid metabolism (see Chapter 86.1). In contrast to the latter, blood concentrations of acylcarnitine conjugates are normal in patients with HMG-CoA synthase deficiency. Fasting of these patients has produced the abovementioned clinical and biochemical abnormalities.

Treatment consisted of provision of adequate calories and avoidance of prolonged periods of fasting. No dietary protein restriction was needed.

The condition is inherited as an autosomal recessive trait. The gene (*HMGCS2*) for this enzyme is located on chromosome 1p13-p12 and several disease-causing mutations have been identified. The condition should be considered in any child with fasting hypoglycemia and is perhaps more common than appreciated.

3-HYDROXY-3-METHYLGLUTARIC ACIDURIA

This condition is a result of a deficiency of HMG-CoA lyase (see Fig. 85-4). This enzyme catalyzes the conversion of HMG-CoA to acetoacetate and is a rate-limiting enzyme for ketogenesis (see Fig. 85-7). **Clinically,** more than 60% of patients become symptomatic between 3 and 11 mo of age (infantile form), whereas approximately 30% develop symptoms in the first few days of life (neonatal form). One child remained asymptomatic until 15 yr of age (childhood form). Episodes of vomiting, severe hypoglycemia, hypotonia, acidosis with mild or no ketosis, and dehydration may rapidly lead to lethargy, ataxia, and coma. These episodes often occur during a catabolic state such as fasting or an intercurrent infection. Hepatomegaly is common. These manifestations may be mistaken for Reye syndrome or medium-chain acyl-CoA dehydrogenase deficiency. Patients are usually clinically asymptomatic between the attacks; 1 patient died of acute cardiomyopathy at age 7 mo during a febrile illness. Development is usually normal, but intellectual disability and seizures with abnormalities of white matter (shown by MRI) have been observed in patients with prolonged episodes of hypoglycemia.

Laboratory findings include hypoglycemia, moderate to severe hyperammonemia, and acidosis. There is mild or no ketosis (see Fig. 85-7). Urinary excretion of 3-hydroxy-3-methylglutaric acid and other proximal intermediate metabolites of leucine catabolism (3-methylglutaconic acid and 3-hydroxyisovaleric acid) is markedly increased causing the urine to smell like cat urine. These organic acids are excreted in the urine as carnitine conjugates, resulting in secondary carnitine deficiency. Glutaric and adipic acids may also be increased in urine during acute attacks. **Diagnosis** may be confirmed by enzyme assay in cultured fibroblasts, leukocytes, or liver specimens or by identification of the mutant gene. Prenatal diagnosis is possible by the assay of the enzyme in cultured amniocytes or a chorionic villus biopsy or by DNA analysis.

Treatment of acute episodes includes hydration, infusion of glucose to control hypoglycemia, provision of adequate calories, and administration of bicarbonate to correct acidosis. Hyperammonemia should be treated promptly (see Chapter 85.12). Exchange transfusion and peritoneal dialysis may be required in patients with severe hyperammonemia. Restriction of protein and fat intake is recommended for long-term management. Oral administration of L-carnitine (50-100 mg/kg/24 hr) prevents secondary carnitine deficiency. Prolonged fasting should be avoided. One child died after routine immunization. The condition is inherited as an autosomal recessive trait. The gene (*HNGCL*) for HMG-CoA lyase resides on chromosome 1p36.11 and several disease-causing mutations have been identified in different families. The gene defect appears to be more common in the Arabic population, especially in Saudi Arabia.

SUCCINYL COENZYME A:3-KETOACID COENZYME A TRANSFERASE (SCOT) DEFICIENCY

This enzyme is necessary for the metabolism of ketone bodies (acetoacetate and 3-hydroxybutyrate) in peripheral tissues (see Fig. 85-7). A deficiency of this enzyme results in the underutilization and accumulation of ketone bodies and ketoacidosis. Only a few patients with succinyl coenzyme A:3-ketoacid coenzyme A transferase deficiency have been reported to date; the condition may not be rare because many cases are, perhaps, undiagnosed.

The **presentation** is an acute episode of unexplained severe ketoacidosis in an infant who had been growing and developing normally. About half of the patients become symptomatic in the 1st wk of life, and all become symptomatic before 2 yr of age. The acute episode is often precipitated by an intercurrent infection or a catabolic state. Death may occur during these episodes. A chronic subclinical ketosis usually persists between the attacks. Development is usually normal.

Laboratory findings during the acute episode are nonspecific and include metabolic acidosis and ketonuria with high levels of acetoacetate and 3-hydroxybutyrate in blood and urine. No other organic acids are found in the blood or in the urine. Blood glucose levels are usually normal, but hypoglycemia has been reported in 2 affected newborn infants with severe ketoacidosis. Plasma amino acids are usually normal. **Diagnosis** can be established by demonstrating a deficiency of enzyme activity in cultured fibroblasts or by DNA analysis.

Treatment of acute episodes consists of hydration, correction of acidosis, and the provision of a diet adequate in calories. Long-term treatment with a high-carbohydrate diet and avoidance of catabolic states is recommended. *This condition should be considered in any infant with unexplained bouts of ketoacidosis.* The condition is inherited as an autosomal recessive trait. The gene (*OXCT1*) for this enzyme is located on chromosome 5p13, and several disease-causing mutations have been found in different families.

MEVALONIC ACIDURIA

Mevalonic acid, an intermediate metabolite of cholesterol synthesis, is converted to 5-phosphomevalonic acid by the action of the enzyme mevalonate kinase (MVK) (see Fig. 85-7). Based on clinical manifestations and degree of enzyme deficiency, 2 forms of this condition have been recognized.

Mevalonic Aciduria, Severe Form

Clinical manifestations include intellectual disability, failure to thrive, growth retardation, hypotonia, ataxia, hepatosplenomegaly, cataracts, and facial dysmorphism (dolichocephaly, frontal bossing, low-set ears, downward slanting of the eyes, and long eyelashes). Recurrent crises, characterized by fever, vomiting, diarrhea, arthralgia, edema, lymphadenopathy, further enlargement of liver and spleen, and morbilliform rash have been observed in all patients. These episodes last 4-5 days and recur up to 25 times/yr. Death may occur during these crises.

Laboratory findings include marked elevation of mevalonic acid in urine; the concentration may be as high as 56,000 µmole/mole of creatinine (normal: <0.3). Plasma levels of mevalonic acid are also greatly increased (as high as 54 µmole/dL; normal: <0.004). This is the only abnormal organic acid found in these patients. The level of mevalonic acid tends to correlate with the severity of the condition and increases during crises. Serum cholesterol concentration is normal or mildly decreased. Serum concentration of creatine kinase is markedly increased. Sedimentation rate and serum leukotriene-4 are increased

during the crises. Serial examination of the brain by MRI reveals progressive atrophy of the cerebellum.

Diagnosis may be confirmed by assay of MVK activity in lymphocytes or in cultured fibroblasts or by DNA analysis. The enzyme activity in this form of the condition is below the detection level. No effective therapy is available. **Treatment** with high doses of prednisone (2 mg/kg/24 hr) causes improvement of the acute crises. The condition is inherited as an autosomal recessive trait. Prenatal diagnosis is possible by measurement of mevalonic acid in the amniotic fluid, by assay of the enzyme activity in cultured amniocytes or chorionic villus samples or by demonstration of the mutant gene. The gene (*MVK*) for the enzyme is on chromosome 12q24.

Periodic Fever with Hyperimmunoglobulinemia D (Mevalonic Aciduria, Mild Form)

See Chapter 163.

Some mutations of mevalonic kinase gene *(MVK)* cause mild deficiencies of the enzyme and produce the clinical picture of periodic fever with hyperimmunoglobulinemia D. These patients have periodic bouts of fever associated with abdominal pain, vomiting, diarrhea, arthralgia, arthritis, hepatosplenomegaly, lymphadenopathy, and morbilliform rash (even petechiae and purpura), which usually start before 1 yr of age. The attacks can be produced by vaccination, minor trauma, or stress; usually occur every 1-2 mo; and last 2-7 days. Patients are free of symptoms between acute attacks. The diagnostic laboratory finding is elevation of serum immunoglobulin D (IgD); IgA is also elevated in 80% of patients. During acute attacks, leukocytosis, increased C-reactive protein, and mild mevalonic aciduria may be present. High concentrations of serum IgD differentiate this condition from familial Mediterranean fever.

Treatment

See Chapter 163.

PROPIONIC ACIDEMIA (PROPIONYL COENZYME A CARBOXYLASE DEFICIENCY)

Propionic acid is an intermediate metabolite of isoleucine, valine, threonine, methionine, odd-chain fatty acids, and cholesterol catabolism. It is normally carboxylated to methylmalonic acid by the mitochondrial enzyme propionyl CoA carboxylase, which requires biotin as a cofactor (see Fig. 85-4). The enzyme is composed of 2 nonidentical subunits, α and β. Biotin is bound to the α subunit.

Clinical findings are nonspecific. In the severe form of the condition, patients develop symptoms in the first few days or weeks of life. Poor feeding, vomiting, hypotonia, lethargy, dehydration, and clinical signs of severe ketoacidosis progress rapidly to coma and death. Seizures occur in approximately 30% of affected infants. If an infant survives the first attack, similar episodes may occur during an intercurrent infection or constipation or after ingestion of a high-protein diet. Moderate to severe intellectual disability and neurologic manifestations reflective of extrapyramidal (dystonia, choreoathetosis, tremor), and pyramidal (paraplegia) dysfunction are common sequelae in the older survivors. Neuroimaging shows these abnormalities, which usually occur after an episode of metabolic decompensation, to be a result of damage to the basal ganglia, especially to the globus pallidus. This phenomenon has been referred to in the literature as **metabolic stroke**. This is the main cause of neurologic sequelae seen in the surviving affected children.

In the milder forms, the older infant may have intellectual disability without acute attacks of ketosis. Some affected children may have episodes of unexplained severe ketoacidosis separated by periods of seemingly normal health. Mass screening of newborn infants has identified milder forms of the condition; a few of these infants were completely asymptomatic at diagnosis. The severity of clinical manifestations may also be variable within a family; in 1 kindred, a brother was diagnosed at 5 yr of age whereas his 13 yr old sister, with the same level of enzyme deficiency, was asymptomatic.

Laboratory findings during the acute attack include severe metabolic acidosis with a large anion gap, ketosis, neutropenia, thrombocytopenia, and hypoglycemia. Moderate to severe hyperammonemia is common; plasma ammonia concentrations usually correlate with the severity of the disease. In contrast to other causes of hyperammonemia, plasma concentration of glutamine is within normal limits or even decreased. Presence of severe metabolic acidosis differentiates propionic academia from hyperammonemic states caused by urea cycle defects. Measurement of plasma ammonia is especially helpful in planning therapeutic strategy during episodes of exacerbation in a patient whose diagnosis has been established. Pathogenesis of hyperammonemia is not well understood. Glycine concentration is elevated in all body fluids (blood, urine, and spinal fluid) in almost all patients. This is the result of inhibition of glycine cleavage enzyme (Fig. 85-8) in the liver. Glycine elevation has also been observed in patients with methylmalonic acidemia. These disorders were collectively referred to as *ketotic hyperglycinemia* in the past before the specific enzyme deficiencies were elucidated. A decrease in plasma levels of branched-chain amino acids (leucine, isoleucine, valine) is a common finding. Mild to moderate increase in blood concentrations of lactate and lysine may also be present in these patients. Concentrations of propionic acid and methylcitric acid (presumably made by the condensation of propionyl CoA with oxaloacetic acid) are markedly elevated in the plasma and urine of infants with propionic acidemia. 3-Hydroxypropionic acid, propionylglycine, and other intermediate metabolites of isoleucine catabolism, such as tiglic acid, tiglylglycine, and 2-methyloacetoacetic acid, are also found in urine. Moderate elevations in blood levels of ammonia, glycine, and previously mentioned organic acids usually persist between the acute attacks. CT scan and MRI of the brain may reveal cerebral atrophy, demyelination, and abnormalities in the globus pallidus and basal ganglia as the evidence of a metabolic stroke in this condition (see above).

The **diagnosis** of propionic acidemia should be differentiated from multiple carboxylase deficiencies (see above and Fig. 85-6). Infants with the latter condition may have skin manifestations and excrete large amounts of lactic acid, 3-methylcrotonic acid, and 3-hydroxyisovaleric acid in addition to propionic acid. The presence of hyperammonemia may suggest a genetic defect in the urea cycle enzymes. Infants with defects in the urea cycle are usually not acidotic (see Fig. 85-1) and have elevated levels of plasma glutamine. Definitive diagnosis of propionic acidemia can be established by measuring the enzyme activity in leukocytes or cultured fibroblasts or by DNA analysis.

Treatment of acute attacks includes hydration, correction of acidosis, and amelioration of the catabolic state by provision of adequate calories through parenteral hyperalimentation. Minimal amounts of protein (0.25 g/kg/24 hr), preferably as a protein deficient in propionate precursors, should be provided in the hyperalimentation fluid very early in the course of treatment. To curtail the possible production of propionic acid by intestinal bacteria, sterilization of the intestinal tract flora by antibiotics (oral neomycin, or metronidazole) should be promptly initiated. Constipation should also be treated. Patients with propionic acidemia may develop carnitine deficiency, presumably as a result of urinary loss of propionylcarnitine formed from the accumulated organic acid. Administration of L-carnitine (50-100 mg/kg/24 hr orally or 10 mg/kg/24 hr intravenously) normalizes fatty acid oxidation and improves acidosis. In patients with concomitant hyperammonemia, measures to reduce blood ammonia should be employed (see Chapter 85.12). Very ill patients with severe acidosis and hyperammonemia require peritoneal dialysis or hemodialysis to remove ammonia and other toxic compounds rapidly and efficiently. Although no infant with true propionic acidemia has been found to be responsive to biotin, this compound should be administered (10 mg/24 hr orally) to all infants during the first attack and until the diagnosis is established.

Long-term treatment consists of a low-protein diet (1.0-1.5 g/kg/24 hr) and administration of L-carnitine (50-100 mg/kg/24 hr orally). Synthetic proteins deficient in propionate precursors (isoleucine, valine, methionine, and threonine) may be used to increase the amount of dietary protein (to 1.5-2.0 g/kg/24 hr) while causing minimal change in propionate production. Excessive supplementation with these proteins may cause a deficiency of the essential amino acids,

especially isoleucine (which may cause a condition resembling acrodermatitis enteropathica; see see Chapter 671). To avoid this problem, natural proteins should comprise most of the dietary protein (50-75%). Some patients may require chronic alkaline therapy to correct chronic acidosis. The concentration of ammonia in the blood usually normalizes between attacks, and chronic treatment of hyperammonemia is not usually needed. Catabolic states that may trigger acute attacks (infections, constipation) should be treated promptly and aggressively. Close monitoring of blood pH, amino acids, urinary content of propionate and its metabolites, and growth parameters is necessary to ensure the proper balance of the diet and the success of therapy.

Long-term prognosis is guarded. Death may occur during an acute attack. Normal psychomotor development is possible, especially in the mild forms identified through screening programs; most children identified clinically manifest some degree of permanent neurodevelopmental deficit such as tremor, dystonia, chorea, and pyramidal signs despite adequate therapy. These neurologic findings may be sequelae of a metabolic stroke occurring during an acute decompensation (see above). Cardiomyopathy with potential progression to heart failure and death may develop in older affected children despite adequate metabolic control. Acute pancreatitis has also been reported in these patients.

Prenatal diagnosis is achieved by measuring the enzyme activity in cultured amniotic cells or in samples of uncultured chorionic villi, by measurement of methylcitrate in amniotic fluid, or by identification of the mutant gene.

The condition is inherited as an autosomal recessive trait and can be identified by mass screening of newborns with a worldwide prevalence of 1:50,000 to 1:100,000 live births. It is more prevalent in Saudi Arabia (1:2,000 to 1:5,000 live births). The gene for the α subunit (*PCCA*) is located on chromosome 13q32 and that of the β subunit (*PCCB*) is mapped to the chromosome 3q21-q22. Mutations in either gene can cause the condition. Many mutations in either gene have been identified in different patients. Pregnancy with normal outcome has been reported in affected females.

METHYLMALONIC ACIDEMIA

Methylmalonic acid, a structural isomer of succinic acid, is usually derived from propionic acid as part of the catabolic pathways of isoleucine, valine, threonine, methionine, cholesterol, and odd-chain fatty acids. Two enzymes are involved in the conversion of D-methylmalonic acid to succinic acid: methylmalonyl CoA racemase, which forms the L isomer; and methylmalonyl CoA mutase, which converts the L-methylmalonic acid to succinic acid (see Fig. 85-4). The latter enzyme requires adenosylcobalamin, a metabolite of vitamin B_{12}, as a coenzyme. Deficiency of either the mutase or its coenzyme causes the accumulation of methylmalonic acid and its precursors in body fluids. A deficiency of the racemase can be associated with mild elevations of methylmalonic acid, but the clinical consequence of racemase deficiency is not known.

At least 2 forms of mutase apoenzyme deficiencies have been identified. These are designated mut^0, meaning no detectable enzyme activity, and mut^-, indicating residual, although abnormal, mutase activity. The majority of reported patients with methylmalonic acidemia have a deficiency of the mutase apoenzyme (mut^0 or mut^-). These patients are not responsive to vitamin B_{12} therapy. In the remaining patients with methylmalonic acidemia, the defect resides in the formation of adenosylcobalamin.

Defects in Metabolism of Vitamin B_{12} (Cobalamin)

Dietary vitamin B_{12} requires intrinsic factor, a glycoprotein secreted by the gastric parietal cells, for absorption in the terminal ileum. It is transported in the blood by haptocorrin and transcobalamin. The transcobalamin–cobalamin complex (TC-Cbl) is recognized by a specific receptor on the cell membrane and enters the cell by endocytosis. TC-Cbl is hydrolyzed in the lysosome, and free cobalamin is released into the cytosol (see Fig. 85-4). In the cytoplasm, cobalamin binds to the MMACHC protein (see *cbl*C later), which reduces the cobalt of the molecule from 3 valences (cob[III]alamin) to 2 (cob[II]alamin) before it enters the mitochondria, where it reacts with adenosine triphosphate and an unknown reductase to form adenosylcobalamin (coenzyme for methylmalonyl CoA mutase). Alternatively, partially reduced cobalamin in the cytosol may interact with methionine synthase and methionine synthase reductase to form methylcobalamin (coenzyme for methionine synthase; see Fig. 85-3). The MMADHC protein (see *cbl*D) appears to play a role in determining whether cobalamin enters the mitochondria or remains in the cytoplasm.

Uptake of TC-Cbl by cells is impaired in individuals with mutations affecting transcobalamin receptor which is located on the cell surface. Individuals homozygous for mutations at the *CD320* gene, which encodes the transcobalamin receptor, have elevations of serum methylmalonic acid, which can be detected by newborn screening using tandem mass spectroscopy, but it is not clear whether there is a clinical phenotype associated with this disorder.

Nine different defects in the intracellular metabolism of cobalamin have been identified. These are designated *cbl*A through *cbl*G, *cbl*J, and *cbl*X (*cbl* stands for a defect in any step of cobalamin metabolism). The *cbl*A, *cbl*B, and *cbl*D variant 2 defects cause methylmalonic acidemia alone. In patients with *cbl*C, classic *cbl*D, *cbl*F, *cbl*J, and *cbl*X defects, synthesis of both adenosylcobalamin and methylcobalamin is impaired, causing homocystinuria in addition to methylmalonic acidemia. The *cbl*D variant 1, *cbl*E, and the *cbl*G defects affect only the synthesis of methylcobalamin, resulting in homocystinuria without methylmalonic aciduria, but usually with megaloblastic anemia (see Chapter 85.3).

Clinical manifestations of patients with methylmalonic acidemia caused by mut^0, mut^-, *cbl*A, *cbl*B, and *cblD* variant 2 are similar. There are wide variations in clinical presentation, ranging from very sick newborn infants to asymptomatic adults, regardless of the nature of the enzymatic defect or the biochemical abnormalities. In severe forms, lethargy, feeding problems, vomiting, tachypnea (from acidosis), and hypotonia may develop in the first few days of life and may progress to coma and death if untreated. Infants who survive the first attack may go on to develop similar acute metabolic episodes during a catabolic state (such as infection) or after ingestion of a high-protein diet. Between the acute attacks, the patient commonly continues to exhibit hypotonia and feeding problems with failure to thrive. In milder forms, patients may present later in life with hypotonia, failure to thrive, and developmental delay. Asymptomatic patients with typical biochemical abnormalities of methylmalonic acidemia are also reported. It is important to note that mental development and IQ of patients with methylmalonic acidemia may remain within the normal range despite repeated acute attacks and regardless of the nature of the enzyme deficiency. In a study of patients with different forms of the condition, developmental delay was noted in 47%. One adolescent girl with a mut^- deficiency had an IQ of 129.

The episodic nature of the condition and its biochemical abnormalities may be confused with those of ethylene glycol (antifreeze) ingestion. The peak of propionate in a blood sample from an infant with methylmalonic acidemia has been mistaken for ethylene glycol when the sample was assayed by gas chromatography without mass spectrometry.

Laboratory findings include ketosis, acidosis, anemia, neutropenia, thrombocytopenia, hyperglycinemia, hyperammonemia, hypoglycemia, and the presence of large quantities of methylmalonic acid in body fluids (see Fig. 85-6). Propionic acid and its metabolites 3-hydroxypropionate and methylcitrate are also found in the urine. Hyperammonemia may suggest the presence of genetic defects in the urea cycle enzymes; patients with defects in urea cycle enzymes are not acidotic (see Fig. 85-12). The reason for hyperammonemia is not well understood.

Diagnosis can be confirmed by measuring propionate incorporation and performing complementation analysis in cultured fibroblasts, by measuring the specific activity of the mutase enzyme in biopsies or cell extracts or by identifying the mutations in the causal gene.

Treatment of acute attacks is similar to that of attacks in patients with propionic acidemia (see above), except that large doses (1 mg/24 hr) of vitamin B_{12} are used instead of biotin. Long-term treatment consists of administration of a low-protein diet (1.0-1.5 g/

kg/24 hr), L-carnitine (50-100 mg/kg/24 hr orally), and vitamin B_{12} (1 mg/24 hr for patients with defects in vitamin B_{12} metabolism; the dose can be decreased depending on the clinical response). The protein composition of the diet is similar to that prescribed for patients with propionic acidemia. Chronic alkaline therapy is usually required to correct chronic acidosis, especially during infancy and early childhood. Blood levels of ammonia usually normalize between the attacks, and chronic treatment of hyperammonemia is rarely needed. Stressful situations that may trigger acute attacks (such as infection) should be treated promptly.

Inadequate oral intake secondary to poor appetite is a common and bothersome complication in long-term management of these patients. Consequently, enteral feeding (through a nasogastric tube or gastrostomy) should be considered early in the course of the treatment. Close monitoring of blood pH, amino acid levels, blood and urinary concentrations of methylmalonate, and growth parameters is necessary to ensure proper balance in the diet and the success of therapy. Glutathione deficiency, responsive to high doses of ascorbate, has been described. Liver, kidney, and combined liver and kidney transplantations have been attempted in a small number of affected patients. Liver transplantation reduced but did not eliminate the metabolic abnormalities and did not prevent the occurrence of metabolic stroke. Kidney transplantation alone restored the renal function but caused only minor improvement in the methylmalonic acidemia.

Prognosis depends on the severity of symptoms and the occurrence of complications (see below). In general, patients with complete deficiency of mutase apoenzyme (*mut*^{0}) have the least-favorable prognosis and those with *mut*$^-$ and *cbl*A defects have a better outcome than those with *cbl*B.

Complications have been noted in survivors. Metabolic strokes (see above) have been reported in a few patients during an acute episode of metabolic decompensation. These patients have survived with major extrapyramidal (tremor, dystonia) and pyramidal (paraplegia) sequelae.

Chronic renal failure necessitating renal transplant has been reported in a number of older patients with the condition. This complication has been observed in all genetic forms of the condition. **Tubulointerstitial nephritis** has been documented in some of these patients and is thought to be the major cause of renal failure. The pathogenesis remains unclear.

Acute and recurrent pancreatitis has been reported in affected patients as young as 13 mo of age. This complication may account for a fair number of hospitalizations of these children.

The prevalence of all forms of methylmalonic aciduria is estimated to be in the range of 1 in 48,000 live births. All defects causing isolated methylmalonic acidemia are inherited as autosomal recessive traits. Successful mass screening of newborn infants has been achieved by the tandem mass spectrometry method. The gene for the mutase (*MUT*) is on the short arm of chromosome 6p12.3; over 220 different mutations have been identified in the *MUT* gene, including a number of ethnic-specific mutations. Neonates with methylmalonic acidemia and severe diabetes owing to the absence of β cells, who have paternal uniparental isodisomy of chromosome 6, have been reported. Mutations in the genes for *cbl*A (*MMAA,* on chromosome 4q31-q31.2), *cbl*B (*MMAB,* on chromosome 12q24), and all forms of *cbl*D (*MMADHC,* on chromosome 2q23.2) have been identified in affected patients. The previously described *cbl*H group is identical to *cbl*D variant 2.

Successful pregnancy with normal outcomes for both the mother and the baby has been reported.

COMBINED METHYLMALONIC ACIDURIA AND HOMOCYSTINURIA (*cbl*C, *cbl*D, *cbl*F, *cbl*J, AND *cbl*X DEFECTS)

More than 550 patients with methylmalonic acidemia and homocystinuria because of *cbl*C have been reported. Indeed, with the advent of expanded newborn screening, it has become evident that *cbl*C may be as common as mutase deficiency. The other disorders are much rarer: 17 patients with *cbl*D, 15 with *cbl*F, 3 with *cbl*J, and 12 with *cbl*X have been identified to date (see Figs. 85-3 and 85-4). Neurologic findings are prominent in patients with *cbl*C and *cbl*D defects. Most patients with the *cbl*C defect present in the first year of life because of failure to thrive, lethargy, poor feeding, intellectual disability, and seizures. Intrauterine growth restriction and microcephaly may precede postnatal manifestations in some affected infants. Late-onset patients with sudden development of dementia and myelopathy have been reported, even with presentation in adulthood. Megaloblastic anemia is a common finding in patients with *cbl*C defect. Mild to moderate increases in concentrations of methylmalonic acid and homocysteine are found in body fluids. Unlike patients with classic homocystinuria, plasma levels of methionine are low to normal in these defects. Neither hyperammonemia nor hyperglycinemia are found in these patients. Like *cblC* patients, males with *cbl*X have elevations of both homocysteine and methylmalonic acid, but tend to have milder elevations of these metabolites. Clinically, patients with *cbl*X resemble those with *cbl*C but have more severe neurologic findings.

The **clinical findings** in the *cbl*F defect are quite variable; the first 2 patients had poor feeding, growth and developmental delay, and persistent stomatitis manifesting in the 1st 3 wk of life. One patient was not diagnosed until age 10 yr and had findings suggestive of rheumatoid arthritis, a pigmented skin abnormality, and encephalopathy. Vitamin B_{12} malabsorption has been noted in patients with *cbl*F defect. Clinical manifestations of *cbl*J are identical to those of *cbl*F.

Experience with **treatment** of patients with *cbl*C, *cbl*D, *cbl*F, *cblJ* and *cbl*X defects is limited. Large doses of hydroxycobalamin (1-2 mg/24 hr) in conjunction with betaine (6-9 g/24 hr) seem to produce biochemical improvement with variable clinical effect. Unexplained severe hemolytic anemia, hemolytic uremic syndrome, hydrocephalus, and congestive heart failure have been major complications in patients with *cbl*C defect.

The *cbl*C disorder is caused by mutations in the *MMACHC* gene located on chromosome 1p34.1. Approximately 75 different mutations have been identified, including a number of common mutations, and ones that are more common in specific ethnic groups. The *cbl*D disorder is caused by mutations in the *MMADHC* gene on chromosome 2q23.2. Mutations resulting in *cbl*D variant 1 (causing only homocystinuria) affect the C-terminal domain of the gene product; those resulting in *cbl*D variant 2 (causing only methylmalonic aciduria) affect the N terminus. Patients with classical form of *cbl*D, with both homocystinuria and methylmalonic, have mutations resulting in decreased protein expression. The *cbl*F disorder is caused by mutations in the *LMBRD1* gene (on chromosome 6q13) encoding a lysosomal membrane protein. The *cbl*J disorder is a phenocopy of *cbl*F and is associated with mutations in the *ABCD4* gene (on chromosome 14q24.3), encoding an adenosine triphosphate–binding cassette protein localized to the lysosomal membrane. Mutations in either *LMBRD1* or *ABCD4* genes result in failure of release of cobalamin from lysosomes. The *cbl*X disorder is caused by mutations in the *HCFC1* gene on the X chromosome, which encodes a DNA-binding protein that appears to be required for expression of the *MMACHC* gene.

Patients with *cbl*D variant 1, *cbl*E, and *cbl*G defects do not have methylmalonic acidemia (see Chapter 85.3).

85.7 Glycine

Iraj Rezvani

Glycine is a nonessential amino acid synthesized mainly from serine and threonine. Structurally, it is the simplest amino acid. It is involved in many reactions in the body, especially in the nervous system where it functions as a neurotransmitter (excitatory in the cortex, inhibitory in the brainstem and the spinal cord; see Chapter 85.11). Its main catabolic pathway requires the complex glycine cleavage enzyme to cleave the first carbon of glycine and convert it to carbon dioxide (see Fig. 85-8). The glycine cleavage protein, a mitochondrial multienzyme, is composed of 4 proteins: P protein (glycine decarboxylase), H protein, T protein, and L protein, which are encoded by 4 different genes.

HYPOGLYCINEMIA

Defects in the biosynthetic pathway of serine (see Chapter 85.8) cause deficiency of glycine in addition to that of serine in body fluids, especially in the CSF. Isolated primary deficiency of glycine has not been reported.

HYPERGLYCINEMIA

Elevated levels of glycine in body fluids occur in propionic acidemia and methylmalonic acidemia that are collectively referred to as ketotic hyperglycinemia because of coexistence of acidosis and ketosis. The pathogenesis of hyperglycinemia in these disorders is not fully understood, but inhibition of the glycine cleavage enzyme system by the various organic acids has been shown to occur in some of the patients. The term **nonketotic hyperglycinemia** (NKH) is reserved for the clinical condition caused by the genetic deficiency of the glycine cleavage enzyme system (see Fig. 85-8). In this condition, hyperglycinemia is present without ketosis.

NONKETOTIC HYPERGLYCINEMIA, GLYCINE ENCEPHALOPATHY

Four forms of this condition have been identified: neonatal, infantile, late onset, and transient.

Neonatal Hyperglycemia

This is the most common form of NKH. **Clinical manifestations** develop in the first few days of life (between 6 hr and 8 days after birth). Poor feeding, failure to suck, lethargy, and profound hypotonia may progress rapidly to a deep coma, apnea, and death. Convulsions, especially myoclonic seizures and hiccups, are common.

Laboratory findings reveal moderate to severe hyperglycinemia (as high as 8 times normal) and hyperglycinuria. The unequivocal elevation of glycine concentration in the spinal fluid (15-30 times normal) and the high ratio of glycine concentration in spinal fluid to that in plasma (a value >0.08) are diagnostic of NKH. Serum pH is normal; plasma serine levels are usually low.

Approximately 30% of affected infants die despite supportive therapy. Those who survive develop profound psychomotor retardation and intractable seizure disorders (myoclonic and/or grand mal seizures). Hydrocephalus, requiring shunting, and pulmonary hypertension have been noted in some survivors.

Infantile Nonketotic Hyperglycinemia

These previously normal infants develop **signs and symptoms** of neonatal NKH (see above) after 6 mo of age. Seizures are the common presenting signs. This condition appears to be a milder form of

neonatal hyperglycinemia; infants usually survive and intellectual disability is not as profound as in the neonatal form.

Laboratory findings in these patients are identical to those seen in the neonatal form.

Late-Onset Nonketotic Hyperglycinemia, Mild Episodic Form

Progressive spastic diplegia, optic atrophy, and choreoathetotic movements are the main **clinical manifestations**. Age of onset has been between 2 and 33 yr. Symptoms of delirium, chorea, and vertical gaze palsy may occur episodically in some patients during an intercurrent infection. Mental development is usually normal, but mild cognitive impairment has been reported in some patients. Seizures have been reported in only 1 patient.

Laboratory findings are similar to but not as pronounced as in the neonatal form.

Transient Nonketotic Hyperglycinemia

Most **clinical and laboratory manifestations** of this form are indistinguishable from those of the neonatal form. By 2-8 wk of age, however, the elevated glycine levels in plasma and CSF normalize and a complete clinical recovery may occur. Most of these patients develop normally with no neurologic sequelae, but intellectual disability has been noted in some. The etiology of this condition is not known, but it is believed to be a consequence of immaturity of the enzyme system.

All forms of NKH should be differentiated from ketotic hyperglycinemia, D-glyceric aciduria (see below), and ingestion of valproic acid. The latter compound causes a moderate increase in blood and urinary concentrations of glycine. Repeat assays after discontinuation of the drug should establish the diagnosis.

Diagnosis can be established by assay of the enzyme in liver or brain specimens or by identification of the mutation. Enzyme activity in the neonatal form is close to zero, whereas in the other forms, some residual activity is present. In most patients with the neonatal form, the enzyme defect resides in the P protein; defects in the T protein account for the rest. The enzyme assay in 3 patients with the infantile and late-onset forms has revealed 2 patients with a defect in the T protein and 1 with a defect in the H protein.

No effective **treatment** is known. Exchange transfusion, dietary restriction of glycine, and administration of sodium benzoate or folate have not altered the neurologic outcome. Drugs that counteract the effect of glycine on neuronal cells, such as strychnine, diazepam, and dextromethorphan, have shown some beneficial effects only in patients with the mild forms of the condition.

NKH is inherited as an autosomal recessive trait. The prevalence is not known, but high frequency of the disorder has been noted in northern Finland (1 in 12,000 live births). The newborn screening method using tandem mass spectrometry may not identify affected infants. The gene for P protein (*GLDC*) is on chromosome 9p24.1. The gene for H protein (*GCSH*) is mapped to chromosome 16q23.2 and that for T protein (*AMT*) is on chromosome 3p21.31. The L protein gene (*DLD*) is on chromosome 7q31.7. Several disease-causing mutations have been identified. Prenatal diagnosis has been accomplished by performing an assay of the enzyme activity in chorionic villous biopsy specimens or by identification of the mutant gene.

SARCOSINEMIA

Increased concentrations of sarcosine (*N*-methylglycine) are observed in both blood and urine, but no consistent clinical picture has been attributed to this metabolic defect. This is a recessively inherited metabolic condition caused by a defect in sarcosine dehydrogenase, the enzyme that converts sarcosine to glycine (see Fig. 85-8). The gene for this enzyme (*SARDH*) is on chromosome 9q34.2.

D-GLYCERIC ACIDURIA

D-Glyceric acid is an intermediate metabolite of serine and fructose metabolism. This rare condition is caused by deficiency of glycerate kinase enzyme (see Fig. 85-8). **Clinical manifestations** are highly variable. In the severe form of the condition, signs and symptoms of encephalopathy (hypotonia, seizures, and mental and motor deficits) with laboratory findings of hyperglycinemia and hyperglycinuria are suggestive of NKH. These patients have elevated levels of D-glyceric acid in all body fluids and excrete large quantities of D-glyceric acid in urine. This compound is not normally detectable in urine. Mild forms of the condition with mild speech delay or even normal development have also been reported.

No effective therapy is available. Restriction of fructose reduced the incidence of seizures in 1 patient. The gene for glycerate kinase *(GLYCTK)* is on chromosome 3p21.1.

TRIMETHYLAMINURIA

Trimethylamine is normally produced in the intestine from the breakdown of dietary choline and trimethylamine oxide by bacteria. Egg yolk and liver are the main sources of choline, and fish is the major source of trimethylamine oxide. Trimethylamine is absorbed and oxidized in the liver by trimethylamine oxidase (flavin-containing monooxygenases) to trimethylamine oxide, which is odorless and excreted in the urine (see Fig. 85-8). Deficiency of this enzyme results in massive excretion of trimethylamine in urine. There is a foul body odor that resembles that of a rotten fish, which may have significant social and psychosocial ramifications. Transient symptomatic trimethylaminuria can occur in normal individuals following ingestion of large quantities of the abovementioned foods. Restriction of fish, eggs, liver, and other sources of choline (such as nuts and grains) in the diet significantly reduces the odor. **Treatment** with short courses of oral metronidazole, neomycin, or lactulose cause temporary reduction in the body odor. The gene for trimethylamine oxidase *(FMO3)* has been mapped to chromosome 1q24.3.

HYPEROXALURIA AND OXALOSIS

Normally, oxalic acid is derived mostly from oxidation of glyoxylic acid and, to a lesser degree, from oxidation of ascorbic acid (see Fig. 85-8). Glyoxylic acid is formed from oxidation of glycolic acid and glycine in the peroxisomes, and catabolism of hydroxyproline in the mitochondria (Figs. 85-8 and 85-9). Vegetables and foods containing oxalic acid, such as spinach and rhubarb, are the main *exogenous* sources of glycolic and oxalic acids; most of glyoxylic and oxalic acids are produced endogenously. Normally, a major portion of glyoxylate produced in the body is shuttled to peroxisomes where it is converted to glycine by the action of the enzyme alanine-glyoxylate aminotransferase. Deficiency of this enzyme causes hyperoxaluria type 1. Most of the remaining glyoxylate in the cytosol is reduced to glycolate by the action of the enzyme glyoxylate reductase/hydroxypyruvate reductase. Deficiency of this enzyme causes hyperoxaluria type 2. These 2 pathways protect the body from excessive production of oxalic acid (see Fig. 85-8). Any glyoxylate that cannot be disposed of through these pathways is readily converted to oxalic acid by the action of the enzyme lactate dehydrogenase (LDH). Oxalic acid cannot be further metabolized in humans and is excreted in the urine as oxalates. Calcium oxalate is relatively insoluble in water and precipitates in tissues (kidneys and joints) if its concentration increases in the body.

Secondary hyperoxaluria has been observed in pyridoxine deficiency (cofactor for alanine-glyoxylate aminotransferase; see Fig. 85-8), in patients with inflammatory bowel disease, extensive resection of small bowel, or jejunoileal bypass *(enteric hyperoxaluria)*, after ingestion of ethylene glycol or high doses of vitamin C, and after administration of the anesthetic agent methoxyflurane (which oxidizes directly to oxalic acid). Acute, fatal hyperoxaluria may develop after ingestion of plants with high oxalic acid content such as sorrel or intentional ingestion of oxalic acid. Precipitation of calcium oxalate in tissues causes hypocalcemia, liver necrosis, renal failure, cardiac arrhythmia, and death. The lethal dose of oxalic acid is estimated to be between 5 and 30 g.

Primary hyperoxaluria is a genetic disorder in which large amounts of oxalates accumulate in the body. Three types of primary hyperoxaluria have been identified to date. The term **oxalosis** refers to deposition of calcium oxalate in parenchymal tissues.

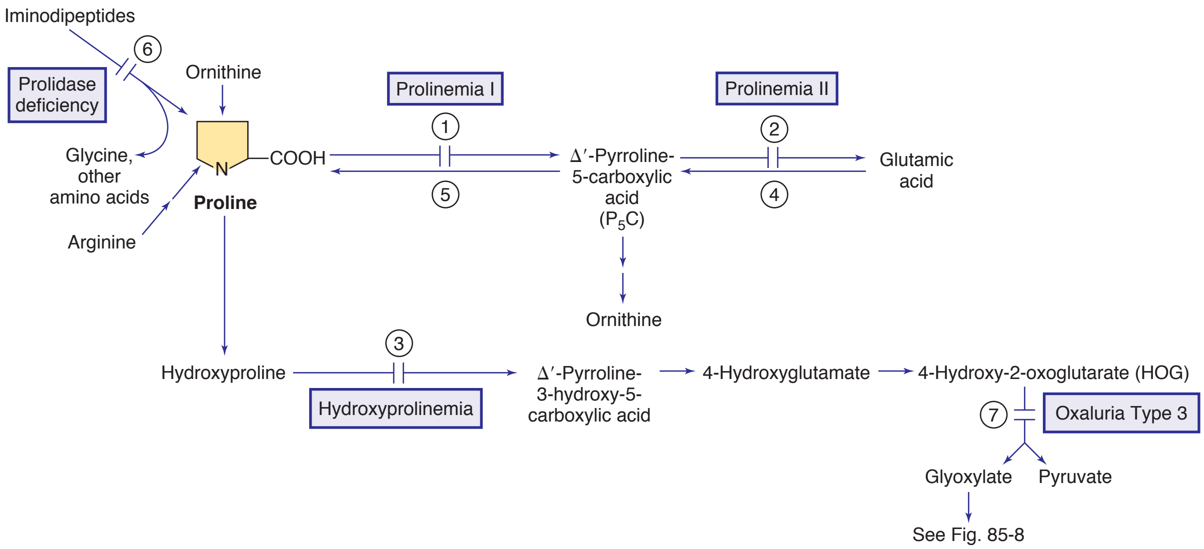

Figure 85-9 Pathways in the metabolism of proline. **Enzymes:** *(1)* Proline oxidase (dehydrogenase), *(2)* Δ^1-pyrroline-5-carboxylic acid (P5C) dehydrogenase, *(3)* hydroxyproline oxidase, *(4)* Δ^1-pyrroline-5-carboxylic acid (P5C) synthase, *(5)* Δ^1-pyrroline-5-carboxylic acid (P5C) reductase, *(6)* prolidase, *(7)* 4-hydroxyoxoglutarate aldolase (HOGA).

Primary Hyperoxaluria Type 1

This rare condition is the most common form of primary hyperoxaluria. It is caused by deficiency of the peroxisomal enzyme alanine-glyoxylate aminotransferase, which is expressed only in the liver peroxisomes and requires pyridoxine (vitamin B_6) as its cofactor. In the absence of this enzyme, glyoxylic acid, which cannot be converted to glycine, is transferred to the cytosol, where it is oxidized to oxalic acid (see above and Fig. 85-8).

There is a wide variation in the age of presentation (4 mo to 25 yr). The majority of patients become symptomatic in late childhood or early adolescence. In 19% of cases, symptoms develop before 1 yr of age (neonatal oxaluria). The initial **clinical manifestations** are related to renal stones and nephrocalcinosis. Renal colic and asymptomatic hematuria lead to a gradual deterioration of renal function, manifested by growth retardation and uremia. Most patients die before 20 yr of age from renal failure if the disorder is left untreated. Acute arthritis is a rare manifestation and may be misdiagnosed as gout because uric acid is usually elevated in patients with type 1 hyperoxaluria. Late forms of the disease presenting during adulthood have also been reported. Crystalline retinopathy and optic neuropathy causing visual loss have occurred in a few patients.

A marked increase in urinary excretion of oxalate (normal excretion 10-50 mg/24 hr) is the most important **laboratory finding**. The presence of oxalate crystals in urinary sediment is rarely helpful for diagnosis because such crystals are often seen in normal individuals. Urinary excretion of glycolic acid and glyoxylic acid is increased in most patients but not in all. **Diagnosis** can be confirmed by performing an assay of the enzyme in liver specimens or by identification of the mutant gene.

Treatment has been largely unsuccessful. In some patients (especially those whose condition is a result of mistargeting of the enzyme to the mitochondria; see below) administration of large doses of pyridoxine reduces urinary excretion of oxalate. Renal transplantation in patients with renal failure has not improved the outcome in most cases, because oxalosis has recurred in the transplanted kidney. Combined liver and kidney transplants have resulted in a significant decrease in plasma and urinary oxalate, and this may be the most effective treatment of this disorder, particularly in children.

The condition is inherited as an autosomal recessive trait. The gene for this enzyme *(AGXT)* is mapped to chromosome 2q37.3. Several mutations of the gene have been described in patients with this condition. The most common mutation results in the mistargeting of the enzyme to the mitochondria instead of the peroxisomes. The in vitro enzyme activity in these patients may reach the level found in obligate heterozygotes. In vivo function remains defective, however. Approximately 30% of patients with hyperoxaluria type 1 are estimated to have this defect.

Prenatal diagnosis has been achieved by the measurement of fetal hepatic enzyme activity obtained by needle biopsy or by DNA analysis of chorionic villous samples.

Primary Hyperoxaluria Type 2 (L-Glyceric Aciduria)

This rare condition is caused by a deficiency of D-glycerate dehydrogenase glyoxylate reductase/hydroxypyruvate reductase enzyme complex (see Fig. 85-8). A deficiency in the activity of this enzyme results in an accumulation of 2 intermediate metabolites, hydroxypyruvate (the ketoacid of serine) and glyoxylic acid. Both these compounds are further metabolized by LDH to L-glyceric acid and oxalic acid, respectively. Approximately 30% of reported patients are from the Saulteaux-Ojibway Indians of Manitoba.

These patients are indistinguishable from those with hyperoxaluria type 1. Renal stones presenting with renal colic and hematuria may develop before age 2 yr. Renal failure is less common in this condition than in hyperoxaluria type 1; the urine contains large amounts of L-glyceric acid in addition to high levels of oxalate. L-Glyceric acid is not normally present in urine. Urinary excretion of glycolic acid and glyoxylic acid is not increased. The presence of L-glyceric acid without increased levels of glycolic and glyoxylic acids in urine differentiate this type from type1 hyperoxaluria. **Diagnosis** can be confirmed by the enzyme assay in liver biopsy or by the identification of the mutant gene. The gene *(GRHPR)* is mapped to chromosome 9p13.2.

No effective **therapy** is available. As with the hyperoxaluria type 1 renal transplant does offer a cure because of recurrence of oxalosis in the transplanted kidney; no experience with kidney-liver transplantation is available at this time.

Primary Hyperoxaluria Type 3

Approximately 5% of patients with primary hyperoxaluria have neither type 1 nor type 2 hyperoxaluria. Genetic studies reveal mutations in the gene for 4-hydroxy-2-oxoglutarate aldolase enzyme. This mitochondrial enzyme catalyzes the final step in metabolic pathway of hydroxyproline generating pyruvate and glyoxylate from 4-hydroxy-2-oxoglutarate (HOG; see Figs. 85-8 and 85-9). In vitro studies show inhibition of glyoxylate reductase/hydroxypyruvate reductase enzyme activity by high concentration of HOG (the compound that

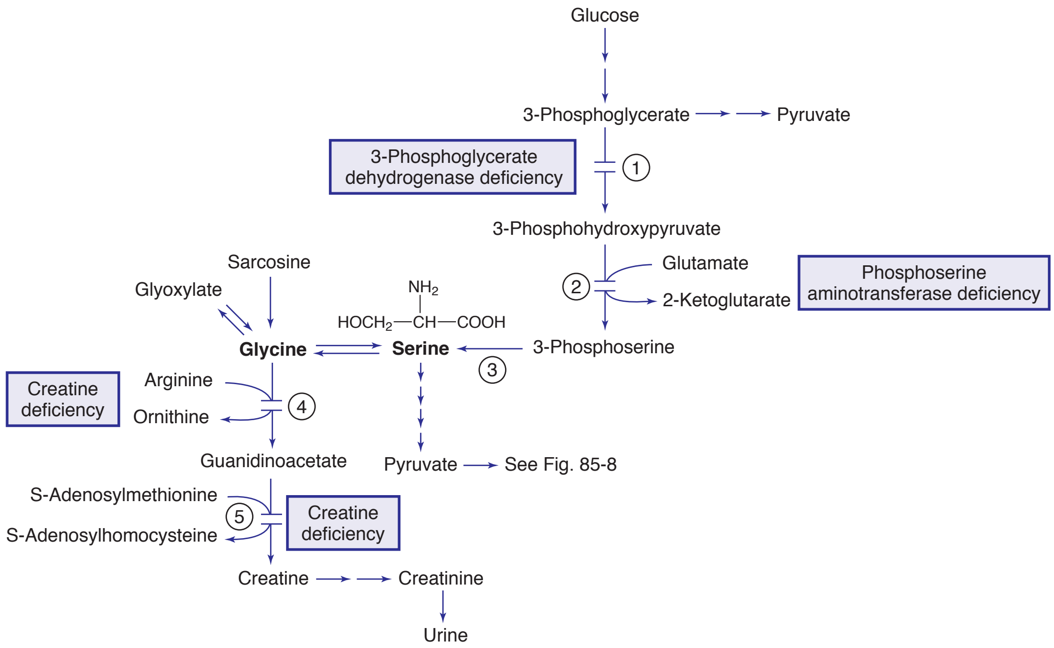

Figure 85-10 Pathways for the synthesis of serine and creatine. **Enzymes:** *(1)* 3-Phosphoglycerate dehydrogenase, *(2)* phosphoserine aminotransferase, *(3)* phosphoserine phosphatase, *(4)* arginine:glycine amidinotransferase (AGAT). *(5)* guanidinoacetate methyltransferase (GAMT).

accumulates in patients with hyperoxaluria type 3). This inhibition results in a biochemical phenotype similar to hyperoxaluria type 2 (see Fig. 85-8). It is also possible that the accumulated HOG is transferred into the cytosol and cleaved to form pyruvate and glyoxylate by the action of one of the cytosolic aldolases.

All probands in this cohort presented with calcium oxalate kidney stones in early childhood but asymptomatic older siblings were also identified. Renal function has remained normal in all patients. Increased levels of HOG have been found in urine, serum and liver biopsy samples of these patients. The gene for the enzyme *(HOGA1)* has been mapped to chromosome 10q24.2 and several different mutations have been identified in different families. The condition may be more common than type 2 hyperoxaluria.

Creatine Deficiency

Creatine is synthesized mainly in the liver, pancreas, and kidneys and to a lesser degree in the brain from arginine and glycine (Fig. 85-10) and is transported to muscles and the brain, where there is high activity of the enzyme creatine kinase. Phosphorylation and dephosphorylation of creatine in conjunction with adenosine triphosphate and diphosphate provide high-energy phosphate transfer reactions in these organs. Creatine is nonenzymatically metabolized to creatinine at a constant daily rate and is excreted in the urine. Three genetic conditions are known to cause creatine deficiency in the brain and other tissues. Two are because of deficiency of the enzymes involved in the biosynthesis of creatine. These enzymes are arginine:glycine amidinotransferase (AGAT) and guanidinoacetate methyltransferase (GAMT; Fig. 85-10). Both conditions respond well to creatine supplementation. The third condition, an X-linked inherited defect, is caused by deficiency of the creatinine transporter (CRTR) protein and is not responsive to creatine administration.

Clinical manifestations of the 3 defects, which are similar, relate to the brain and muscles, and may appear in the first few weeks or months of life. Developmental delay, intellectual disability, speech delay, psychiatric symptoms (autistic behavior, hallucination), hypotonia, ataxia, and seizures are common findings. Dystonic movements are seen in severe GAMT deficiency.

Laboratory findings include decreased creatine and creatinine in blood and urine in patients with AGAT and GAMT defects. The urinary ratio of creatine to creatinine is increased in patients with a CRTR defect. Marked elevations of guanidinoacetate in blood, urine, and especially in spinal fluid (CSF), are diagnostic of GAMT defects. In contrast, low levels of guanidinoacetate are found in body fluids in the AGAT defect. Absence of creatine and creatine phosphate (in all 3 defects) and high levels of guanidinoacetate (in the GAMT defect) can be demonstrated in the brain by magnetic resonance spectroscopy (MRS). MRI of the brain shows signal hyperintensity in the globus pallidus. **Diagnosis** of AGAT or GAMT defects may be confirmed by measurement of the enzyme in the liver, cultured fibroblasts, or stimulated lymphoblasts or by the identification of the mutant gene DNA analysis of the gene. Diagnosis of CRTR is confirmed by DNA analysis or creatine uptake by fibroblasts.

Treatment with creatine monohydrate (350 mg-2 g/kg/day) orally results in a dramatic improvement in muscle tone and overall mental development and normalizes MRI and electroencephalographic findings in patients with AGAT and GAMT defects. It is believed that early treatment may assure normal development. No therapy is available for the CRTR defect; administration of creatine and its precursors (arginine and glycine) has failed to change the clinical course of the condition in affected patients. AGAT and GAMT defects are inherited as autosomal recessive traits. The gene for AGAT *(GATM)* is on chromosome 15q21.1 and that for GAMT *(GAMT)* is on chromosome 19p13.3. CRTR is an X-linked trait and the gene (*SLC6A8*) is on Xq28. CRTR defect is the most common cause of creatine deficiency, accounting for up to 1% of males with intellectual disability of unknown cause. AGAT defect is very rare (only 7 patients reported to date). Creatine deficiency must be considered in any patient with concomitant brain and muscle dysfunction, as treatment can produce a dramatic response in some cases.

Bibliography is available at Expert Consult.

85.8 Serine

Iraj Rezvani

Serine is a nonessential amino acid supplied through dietary sources and through its endogenous synthesis, mainly from glucose and glycine (see Fig. 85-10). The endogenous production of serine comprises an

important portion of the daily requirement of this amino acid, especially in the synaptic junctions where it functions as a neurotransmitter (see Chapter 85.11). Consequently, deficiency of any of the enzymes involved in the biosynthesis of serine causes neurologic manifestations. Affected patients respond favorably to oral supplementation with serine and glycine provided that the treatment is initiated very early in life. Figure 85-8 shows the metabolic pathway for synthesis and catabolism of serine.

3-PHOSPHOGLYCERATE DEHYDROGENASE DEFICIENCY

Deficiency of this enzyme causes deficiencies of serine and glycine in the body. Three forms of the condition have been recognized: infantile, juvenile, and adult forms. In the infantile form, which is the most common phenotype, the **clinical manifestations** appear typically in utero with microcephaly and intrauterine growth retardation. In 1 infant who was normocephalic at birth, the head failed to grow normally postnatally. Feeding problems, failure to thrive, vomiting, irritability, intractable seizures, severe developmental delay, and hypertonia progressing into spastic tetraplegia are common findings that develop shortly after birth. Nystagmus, cataracts, hypogonadism, and megaloblastic anemia have been observed in some affected infants.

Laboratory findings include low levels of serine and glycine in plasma and very low levels of serine and glycine in CSF. No abnormal organic acid metabolite is found in the urine. MRI of the brain shows cerebral atrophy with enlarged ventricles, significant attenuation of white matter and impaired myelination.

The juvenile form of the condition has been reported in 2 siblings who presented at 5 and 9 yr of age with mild intellectual disability and absence seizures. Head size and MRI of the brain were normal.

Only 1 adult patient with congenital cataracts and intellectual disability has been reported. This patient developed progressive polyneuropathy resembling Charcot-Marie-Tooth disease type 2.

Diagnosis can be confirmed by measurement of the enzyme activity in cultured fibroblasts and by DNA analysis.

Treatment with high doses of serine (500-700 mg/kg/24 hr, orally) alone or in conjunction with glycine (200-300 mg/kg/24 hr) normalizes the serine levels in the blood and CSF. This treatment produces significant improvement in all clinical findings except for the psychomotor retardation; seizure activity subsides within a few days of therapy and may be halted completely. Microcephaly improves in young affected infants. There is evidence to indicate that psychomotor retardation may be prevented if the treatment starts in the first few days of life or, even better, in utero.

The condition is inherited as an autosomal recessive trait. The gene for 3-phosphoglycerate dehydrogenase enzyme (*PHGDH*) has been mapped to chromosome 1p12 and a few disease-producing mutations have been identified in different families. Prenatal diagnosis has been achieved by DNA analysis in a family with previously affected offspring; administration of serine to the mother corrected the microcephaly in the affected fetus as evidenced by ultrasound imaging. Treatment with supplemental serine has continued postnatally; the patient remains normal neurologically at 12 yr of age. The favorable response of this condition to a simple treatment makes this diagnosis an important consideration in any child with microcephaly and neurologic defects such as psychomotor delay or a seizure disorder. Measurements of serine and glycine in the CSF are critical for diagnosis because mild decreases of these amino acids in the plasma can be easily overlooked.

PHOSPHOSERINE AMINOTRANSFERASE DEFICIENCY

This enzyme catalyzes conversion of 3-phosphohydroxypyruvate to 3-phosphoserine (see Fig. 85-10). Deficiency of this enzyme has been reported in 2 siblings from an English family. Poor feeding, cyanotic episodes, and jerky movements developed shortly after birth in the first affected infant and progressed to intractable seizures by 9 wk of age. The infant was microcephalic. Electroencephalography (EEG) was consistent with multifocal seizures. Neuroimaging showed generalized cerebral and cerebellar atrophies. **Laboratory studies** were all within normal limits except for a mild decrease in plasma levels of serine and glycine with pronounced deficiencies of these 2 amino acids in the CSF. **Treatment** with serine (500 mg/kg/day) and glycine (200 mg/kg/day) was started at 11 wk of age but resulted in only marginal clinical improvement; the child died at 7 mo of age. The younger affected sibling, who was treated with serine and glycine within a few hours after birth, remained asymptomatic at 3 yr of age.

The condition is inherited as an autosomal recessive trait and the gene for the enzyme (PSAT1) is mapped to chromosome 9q21.2. Based on this single report one can assume that this is a treatable genetic condition with a favorable outcome if the treatment is initiated early in life.

Bibliography is available at Expert Consult.

85.9 Proline

Iraj Rezvani

Proline is a nonessential amino acid synthesized endogenously from glutamic acid, ornithine, and arginine (see Fig. 85-9). Proline and hydroxyproline are found in high concentrations in collagen. Neither of these amino acids is normally found in urine in the free form except in early infancy. Excretion of proline and hydroxyproline as iminopeptides (dipeptides and tripeptides containing proline or hydroxyproline) reflects collagen turnover and is increased in disorders of accelerated collagen turnover, such as rickets or hyperparathyroidism. Proline is also found at synaptic junctions and functions as a neurotransmitter (see Chapter 85.11). The catabolic pathway of proline/hydroxyproline produces glyoxylic acid which can be further metabolized to glycine or oxalic acid (see Fig. 85-8).

HYPERPROLINEMIA

Two types of primary hyperprolinemia have been described.

Hyperprolinemia Type I

This rare autosomal recessive condition is caused by deficiency of proline oxidase (proline dehydrogenase; see Fig. 85-9). Clinical manifestations are variable; some affected individuals are asymptomatic but patients with severe psychomotor retardation and seizures have been reported. Schizophrenia is a common finding in these patients. The gene for proline oxidase *(PRODH)* is located on chromosome 22q11.2 and several disease-causing mutations have been identified. Microdeletions involving this region of chromosome 22 cause velocardiofacial (DiGeorge, Shprintzen) syndrome; approximately 50% of patients with this syndrome have been reported to have hyperprolinemia type I. Therefore, all patients with hyperprolinemia type I should be screened (by fluorescence in situ hybridization analysis) for presence of DiGeorge syndrome.

Laboratory studies reveal high concentrations of proline in plasma, urine, and in the CSF. Approximately 30% of obligate heterozygous individuals (parents, siblings) also have hyperprolinemia. Increased urinary excretion of hydroxyproline and glycine is also present; this is from saturation of the shared tubular reabsorption mechanism by massive prolinuria.

No effective **treatment** has yet emerged. Restriction of dietary proline causes modest improvement in plasma proline with no proven clinical benefit.

Hyperprolinemia Type II

This is a rare autosomal recessive condition caused by the deficiency of pyrroline-carboxylic acid dehydrogenase (aldehyde dehydrogenase 4 [ALDH4]; see Fig. 85-9). Psychomotor retardation (modest to severe) and seizures (usually precipitated by an intercurrent infection) have been reported in most affected children, but asymptomatic patients have also been reported.

Laboratory studies reveal increased concentrations of proline and Δ^1-pyrroline-5-carboxylic acid (P5C) in blood, urine, and the CSF.

Bibliography

Tabatabaie L, Klomp LW, Rubio-Gozalbo ME, et al: Expanding the clinical spectrum of 3-phosphoglycerate dehydrogenase deficiency, *J Inherit Metab Dis* 34:181–184, 2011.

van der Crabben SN, Verhoeven-Duif NM, et al: An update on serine deficiency disorders, *J Inherit Metab Dis* 36:613–619, 2013.

Increased excretion of xanthurenic acid also has been reported in this condition. The presence of P5C differentiates this condition from hyperprolinemia type I (see above). Increased levels of P5C in body fluids, especially in the CNS, cause inactivation of vitamin B_6 and generate a state of vitamin B_6 dependency (see Chapter 85.14). Vitamin B_6 dependency is perhaps the main cause of seizures and neurologic findings in this condition and may explain the variability in clinical manifestations in different patients. **Treatment** with high doses of vitamin B_6 in conjunction with a diet low in proline is recommended but the experience remains very limited because of paucity of patients. The gene for P5C dehydrogenase (ALDH4) is on chromosome 1p36.13.

PROLIDASE DEFICIENCY

During collagen degradation, imidodipeptides (dipeptides containing proline such as glycylproline) are released and are normally cleaved by tissue prolidase. This enzyme requires manganese for its proper activity. Deficiency of prolidase, which is inherited as an autosomal recessive trait, results in the accumulation of imidodipeptides in body fluids.

The **clinical manifestations** of this rare condition and the age at onset are quite variable (19 mo to 19 yr) and include recurrent, painful skin ulcers, which are typically on hands and legs. Other skin lesions that may precede ulcers by several years may include scaly erythematous maculopapular rash, purpura, and telangiectasia. Most ulcers become infected. Healing of the ulcers may take 4-7 mo. Mild to severe cognitive and motor deficits and susceptibility to infections are also present in most patients (recurrent otitis media, sinusitis, respiratory infection, splenomegaly). Infection is the cause of death. Some patients may have craniofacial abnormalities such as ptosis, ocular proptosis, hypertelorism, small beaked nose and prominent cranial sutures. Asymptomatic cases have also been reported. Development of systemic lupus erythematosus has been noted in affected children of 1 family; young patients with systemic lupus erythematosus should be screened for prolidase deficiency. High levels of urinary excretion of imidodipeptides are diagnostic. Enzyme assay may be performed in erythrocytes or cultured skin fibroblasts.

Oral supplementation with proline, ascorbic acid, and manganese, and the topical use of proline and glycine, result in an improvement in leg ulcers. These treatments have not been found to be consistently effective in all patients.

The gene for prolidase enzyme *(PEPD)* has been mapped to chromosome 19q13.11 and several disease-causing mutations have been identified in different families.

Bibliography is available at Expert Consult.

85.10 Glutamic Acid

Iraj Rezvani

Glutamic acid and its aminated derivative glutamine have a wide range of functions in the body. One of the major products of glutamic acid is glutathione (γ-glutamyl cysteinylglycine). This ubiquitous tripeptide, with its function as the major antioxidant in the body, is synthesized and degraded through a complex cycle called the γ-glutamyl cycle (Fig. 85-11). Because of its free sulfhydryl (-SH) group and its abundance in the cell, glutathione protects other sulfhydryl-containing compounds (such as enzymes and CoA) from oxidation. It is also involved in the detoxification of peroxides, including hydrogen peroxide, and in keeping the intracellular milieu in a reduced state. The common consequences of glutathione deficiency are hemolysis and hemolytic anemia. In addition, glutathione participates in amino acid transport

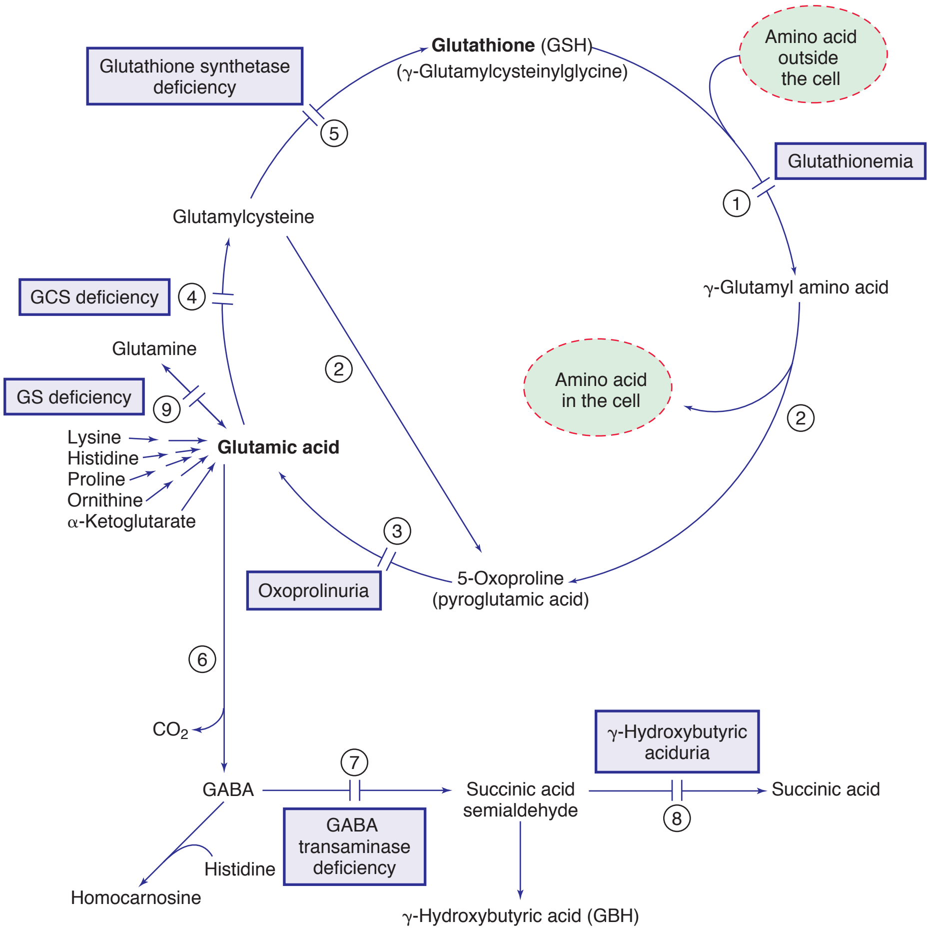

Figure 85-11 The γ-glutamyl cycle. Defects of the glutathione synthesis and degradation are noted. **Enzymes:** *(1)* γ-Glutamyl transpeptidase, *(2)* γ-glutamyl cyclotransferase, *(3)* 5-oxoprolinase, *(4)* γ-glutamyl-cysteine synthetase, *(5)* glutathione synthetase, *(6)* glutamic acid decarboxylase, *(7)* γ-aminobutyric acid (GABA) transaminase, *(8)* succinic semialdehyde dehydrogenase, *(9)* glutamine synthase.

across the cell membrane through the γ-glutamyl cycle. Glutamic acid is also the precursor of γ-aminobutyric acid (GABA), a major neurotransmitter in the nervous system (see Chapter 85.11).

GLUTATHIONE SYNTHETASE DEFICIENCY

See Figure 85-11.

Three forms of this rare condition have been reported. In the **severe form**, which is a result of generalized deficiency of the enzyme, severe acidosis and massive 5-oxoprolinuria are the rule. In the **mild form**, in which the enzyme deficiency causes glutathione deficiency only in erythrocytes, neither 5-oxoprolinuria nor acidosis has been observed. A **moderate form** has also been observed in which the hemolytic anemia is associated with variable degrees of acidosis and 5-oxoprolinuria. In all forms, patients have hemolytic anemia secondary to glutathione deficiency.

Glutathione Synthetase Deficiency, Severe Form (Pyroglutamic Acidemia, Severe 5-Oxoprolinuria) and Moderate Form

Affected newborn infants with this rare condition usually develop acute symptoms of metabolic acidosis, jaundice, and mild to moderate hemolytic anemia in the first few days of life. Chronic acidosis continues after recovery. Similar episodes of life-threatening acidosis may occur during an infection such as gastroenteritis or after a surgical procedure. Progressive neurologic damage, manifested by intellectual disability, spastic tetraparesis, ataxia, tremor, dysarthria, and seizures, develops with age. Susceptibility to infection, presumably as a consequence of granulocyte dysfunction, is observed in some patients. Patients with the moderate form of the condition have milder acidosis and less 5-oxoprolinuria than is seen in the severe form, with no neurologic manifestations.

Laboratory findings include metabolic acidosis, mild to moderate degrees of hemolytic anemia, and 5-oxoprolinuria. High concentrations of 5-oxoproline are also found in blood. The urinary and blood levels of 5-oxoproline is less pronounced in patients with moderate form of the condition. The glutathione content of erythrocytes is markedly decreased. Increased synthesis of 5-oxoproline in this disorder is believed to be a result of the conversion of γ-glutamylcysteine to 5-oxoproline by the enzyme γ-glutamyl cyclotransferase (see Fig. 85-11). γ-Glutamylcysteine production increases greatly because the normal inhibitory effect of glutathione on the γ-glutamylcysteine synthetase enzyme is removed. A deficiency of glutathione synthetase has been demonstrated in a variety of cells including erythrocytes.

Treatment of acute attack includes hydration, correction of acidosis (by infusion of sodium bicarbonate), and measures to correct anemia and hyperbilirubinemia. Chronic administration of alkali is usually needed indefinitely. Administration of large doses of vitamins C and E has been recommended. Drugs and oxidants that are known to cause hemolysis and stressful catabolic states should be avoided. Oral administration of glutathione analogs has been tried with variable success.

Prenatal diagnosis can be achieved by the measurement of 5-oxoproline in amniotic fluid, by enzyme analysis in cultured amniocytes or chronic villous samples, or by DNA analysis of the gene. Successful pregnancy in an affected female (moderate form), with favorable outcomes for both mother and infant, has been reported.

Glutathione Synthetase Deficiency, Mild Form

This form has been reported in only a few patients. Mild to moderate hemolytic anemia has been the only **clinical finding** in these patients. Splenomegaly has been reported in some patients. Cognitive development is normal; metabolic acidosis and increased concentrations of 5-oxoproline do not occur. Similar to other types of glutathione synthase deficiency, this form is caused by mutations in the gene that encodes the enzyme. These mutations, however, decrease the half-life of the enzyme, which causes an increased rate of protein turnover without affecting its catalytic function. The expedited rate of enzyme turnover caused by these mutations is of no consequence for tissues with protein synthetic capability. However, inability of mature erythrocytes to synthesize protein, results in glutathione deficiency in the erythrocytes. **Treatment** is that of hemolytic anemia and avoidance of drugs and oxidants that can trigger the hemolytic process.

All forms of the condition are inherited as an autosomal recessive trait. The gene for this enzyme *(GSSD)* is located on chromosome 20q11.2. Several disease-causing mutations have been identified in different families.

5-Oxoprolinase Deficiency (5-Oxoprolinuria)

The main cause of massive 5-oxoprolinuria is glutathione synthetase deficiency (see above). Moderate 5-oxoprolinuria has been found in a variety of metabolic and acquired conditions, such as in patients with severe burns, Stevens-Johnson syndrome, homocystinuria, urea cycle defects, and tyrosinemia type I.

A few individuals with moderate 5-oxoprolinuria (4-10 g/day) as a result of 5-oxoprolinase (see Fig. 85-11) deficiency have been identified. No specific **clinical picture** has yet emerged; completely asymptomatic affected individuals have also been identified. It is, therefore, not clear whether 5-oxoprolinase deficiency is of any clinical consequence. No **treatment** has been recommended. The gene for the enzyme *(OPLAH)* is on chromosome 8q24.3.

γ-Glutamylcysteine Synthetase Deficiency

Only a few patients with this enzyme deficiency have been reported. The most consistent **clinical manifestation** has been mild chronic hemolytic anemia. Acute attacks of hemolysis have occurred after exposure to sulfonamides. Peripheral neuropathy and progressive spinocerebellar degeneration have been noted in 2 siblings in adulthood. **Laboratory findings** of chronic hemolytic anemia were present in all patients. Generalized aminoaciduria is also present because the γ-glutamyl cycle is involved in amino acid transport in cells (see Fig. 85-11). **Treatment** is that of hemolytic anemia and avoidance of drugs and oxidants that may trigger the hemolytic process. The condition is inherited as an autosomal recessive trait; the gene *(GCLC)* is mapped to chromosome 6p12.1.

GLUTATHIONEMIA (γ-GLUTAMYL TRANSPEPTIDASE DEFICIENCY)

This enzyme is present in any cell that has secretory or absorptive functions. It is especially abundant in the kidneys, pancreas, intestines, and liver. The enzyme is also present in the bile. Measurement of this enzyme in the blood is commonly performed to evaluate liver and bile duct diseases.

Deficiency of this enzyme causes elevation in glutathione concentrations in body fluids, but the cellular levels remain normal (see Fig. 85-11). Because only a few patients with enzyme deficiency have been reported, the scope of **clinical manifestations** has not yet been defined. Mild to moderate intellectual disability and severe behavioral problems were observed in 3 patients. One of the 2 sisters with this condition had normal intelligence as an adult, however, and the other had Prader-Willi syndrome.

Laboratory findings include marked elevations in urinary concentrations of glutathione (up to 1 g/day), γ-glutamylcysteine, and cysteine. None of the reported patients has had generalized aminoaciduria, a finding that would have been expected to occur in this enzyme deficiency (see Fig. 85-11).

Diagnosis can be confirmed by measurement of the enzyme activity in leukocytes or cultured skin fibroblasts. No effective **treatment** is available.

The condition is inherited as an autosomal recessive trait. The enzyme GGT (γ-glutamyl transpeptidase) is a complex protein and is encoded by at least 7 genes.

GENETIC DISORDERS OF METABOLISM OF γ-AMINOBUTYRIC ACID

See also Chapter 85.11.

Congenital Glutamine Deficiency

Glutamine is synthesized endogenously from glutamate and ammonia by a ubiquitous enzyme, glutamine synthetase (see Fig. 85-11).

Glutamine is known to be involved in several important functions, including detoxification of ammonia. Deficiency of this enzyme, resulting in glutamine deficiency, has been reported in 3 infants from 3 unrelated families. All affected infants manifested multiorgan involvement including significant brain malformations (abnormal gyrations, hypomyelination), facial abnormalities (broad nasal root, low-set ears) hypotonia and seizures at birth. Two of the patients died from multiorgan failure (respiratory and heart failure) in the neonatal period; 1 child was alive at 3 yr of age with severe developmental delay. Glutamine was absent in plasma, urine, and CSF, but plasma levels of glutamic acid were normal. Genetic defects of this enzyme underline the critical role of glutamine in embryogenesis especially in normal brain development. The condition is inherited as an autosomal recessive trait; the gene for glutamine synthetase *(GLUL)* is mapped to chromosome 1q25.3

Bibliography is available at Expert Consult.

85.11 Genetic Disorders of Neurotransmitters

Iraj Rezvani and K. Michael Gibson

Neurotransmitters are chemical substances released from the axonal end of excited neurons at the synaptic junctions; they mediate initiation and amplification or inhibition of neural impulses. A number of amino acids and their metabolites comprise the bulk of neurotransmitters. Mutations in genes responsible for the synthesis or degradation of these substances may cause conditions that usually manifest neurologic and/or psychiatric abnormalities (Table 85-2). In the past, children affected by disorders of neurotransmitters have been given diagnoses such as cerebral palsy, seizure disorder, parkinsonism, dystonia, or autism. Diagnosis, in most cases, requires specialized laboratory studies of the **CSF,** because some of the neurotransmitters generated in the CNS (dopamine and serotonin) do not cross the blood–brain barrier and their abnormal concentrations are not detected in the serum or urine. An ever-growing number of these conditions are being identified; diseases that were once thought to be very rare are now diagnosed with increasing frequency.

TYROSINE HYDROXYLASE DEFICIENCY (INFANTILE PARKINSONISM, AUTOSOMAL RECESSIVE DOPA-RESPONSIVE DYSTONIA, SEGAWA SYNDROME, AUTOSOMAL RECESSIVE FORM)

Tyrosine hydroxylase catalyzes the formation of L-dopa from tyrosine. Deficiency of this enzyme, reported in several children, results in deficiencies of dopamine and norepinephrine (see Fig. 85-2). The clinical picture resembles that of autosomal dominant dystonia caused by GTP cyclohydrolase deficiency (see below); the clinical spectrum of the condition is still being elucidated.

Clinical manifestations range from mild to very severe. In general, 2 phenotypes have been recognized. In the mild form (dopa-responsive dystonia or type A), symptoms of unilateral limb dystonia causing gait incoordination and postural tremor occur in childhood and worsen with age if the condition remains untreated. Diurnal variation of symptoms (worse at the end of the day) may be present. Cognitive development is usually normal. In the severe form of the condition (infantile parkinsonism, infantile encephalopathy or type B), the clinical manifestations occur at birth or shortly thereafter. These include microcephaly, developmental delay, involuntary movements of the limbs with spasticity, dystonia, ptosis, expressionless face, oculogyric crises (upward rolling-eye movements) and autonomic dysfunction (temperature instability, excessive sweating, hypoglycemia, salivation, tremor, gastrointestinal reflux, constipation). Brisk reflexes, myoclonus, athetosis and distal chorea may be present. This form usually does not respond to treatment with L-dopa.

Laboratory findings include reduced levels of dopamine and its metabolite homovanillic acid (HVA), and normal concentrations of BH_4, neopterin, and 5-hydroxyindoleacetic acid (5-HIAA, a metabolite of serotonin) in the CSF. Serum prolactin levels are usually elevated. These findings are not diagnostic of the condition; diagnosis should be established by gene study.

Treatment with L-dopa/carbidopa results in significant clinical improvement in most patients, but is invariably associated with L-dopa induced dyskinesias. To minimize the side effects of therapy, the treatment should be started with a low dose and increased very slowly if needed. Other therapeutic interventions include anticholinergics, serotonergic agents and monoamine oxidase (MAO) B inhibitors, including amantadine, biperiden, and selegiline. Bilateral subthalamic nucleus deep brain stimulation has shown clinical efficacy in 1 case. The gene for tyrosine hydroxylase (TH) is located on chromosome 11p15.5; it is inherited as an autosomal-recessive trait.

Table 85-2 Genetic Disorders of Neurotransmitters in Children

TRANSMITTER	SYNTHESIS DEFECTS	DEGRADATION DEFECTS
MONOAMINES		
Dopamine	TH deficiency	MAO deficiency
Serotonin and dopamine	AADC deficiency	MAO deficiency
	BH_4 deficiency	
	With hyperphe	
	Without hyperphe	
Norepinephrine	DβH deficiency	MAO deficiency
GABA	?	GABA transaminase deficiency
		GHB aciduria
Histamine	HDC deficiency	?
TRANSPORTER PROTEINS		
Dopamine transporter	DAT deficiency	?
Vesicular monoamine transporter	VMAT2 deficiency	?
AMINO ACIDS		
Proline	?	Hyperprolinemia
Serine	3-PGD, PSAT deficiencies	?
Glycine	3-PDG, PSAT deficiencies	NKH

AADC, aromatic L-amino acid decarboxylase; BH_4, tetrahydrobiopterin; DAT, dopamine transporter; DβH, dopamine β-hydroxylase; GABA, γ-aminobutyric acid; GHB, γ-hydroxybutyric; HDC, histidine decarboxylase; hyperphe, hyperphenylalaninemia; MAO, monoamine oxidase; NKH, nonketotic hyperglycinemia; 3-PGD, 3-phosphoglycerate dehydrogenase; PSAT, phosphoserine aminotransferase; TH, tyrosine hydroxylase; VMAT2, vesicular monoamine transporter 2.

Aromatic L-Amino Acid Decarboxylase Deficiency

Aromatic L-amino acid decarboxylase (AADC) catalyzes the decarboxylation of both 5-hydroxytryptophan (to form serotonin, see Fig. 85-5) and L-dopa (to generate dopamine, see Fig. 85-2). **Clinical manifestations** are related to underproduction of dopamine and serotonin. Poor feeding, lethargy, hypotension, hypothermia, eye rolling (oculogyric crises), and ptosis have been observed in affected neonates. Clinical findings in infants and older children include developmental delay, truncal hypotonia with hypertonia of limbs, oculogyric crises, extrapyramidal movements (choreoathetosis, dystonia, myoclonus), and autonomic abnormalities (sweating, salivation, irritability, temperature instability, hypotension). Symptoms often have a diurnal variation becoming worse by the end of the day.

Laboratory findings include decreased concentrations of dopamine and serotonin and their metabolites (HVA, 5-HIAA, vanillylmandelic acid [VMA] and norepinephrine), and increased levels of 5-hydroxytryptophan, L-dopa and its metabolite (3-*O*-methyldopa) in body fluids, especially in CSF. Elevated serum concentrations of prolactin (a result of dopamine deficiency) have also been observed. MRI of the brain reveals cerebral atrophy with degenerative changes in the white matter. A urine screening program, focused on 3-*O*-methyldopa and VMA, has demonstrated diagnostic promise in high-prevalence populations.

Treatment with neurotransmitter precursors has produced limited clinical improvement. Dopamine and serotonin have no therapeutic value because of their inability to cross the blood–brain barrier. Dopamine agonists (L-dopa/carbidopa, bromocriptine), MAO inhibitors (tranylcypromine), serotonergic agents and high doses of pyridoxine (cofactor for AADC enzyme) have been tried. No treatment of choice has yet emerged. Pyridoxine supplementation in patients harboring the S250F variant may be beneficial. Preimplantation genetic diagnosis after in vitro fertilization has been achieved in the high-prevalence Taiwanese population. The gene encoding AADC (*DDC*) is on chromosome 7p12.1. The condition is inherited as an autosomal recessive trait; several disease-causing mutations have been reported in different families.

TETRAHYDROBIOPTERIN DEFICIENCY

See Chapter 85.1.

BH_4 is the cofactor for PAH (see Fig. 85-1), tyrosine hydroxylase (see Fig. 85-2), tryptophan hydroxylase (see Fig. 85-5), and nitric oxide synthase. It is synthesized from GTP in many tissues (see Fig. 85-1). Deficiencies of enzymes involved in the biosynthesis of BH_4 result in inadequate production of this cofactor which causes deficiencies of monoamine neurotransmitters with or without concomitant hyperphenylalaninemia.

Tetrahydrobiopterin Deficiency with Hyperphenylalaninemia

See Chapter 85.1.

Tetrahydrobiopterin Deficiency Without Hyperphenylalaninemia

Hereditary Progressive Dystonia, Autosomal Dominant Dopa-Responsive Dystonia, Segawa Syndrome, Autosomal Dominant Form

See also Chapter 597.3.

This form of dystonia is caused by GTP cyclohydrolase I deficiency. It is inherited as an autosomal dominant trait and is more common in females than males (4 : 1).

Clinical manifestations usually start in early childhood with tremor and dystonia of the lower limbs (toe gait), which may spread to all extremities within a few years. Torticollis, dystonia of the arms, and poor coordination may precede dystonia of the lower limbs. Early development is generally normal. Symptoms have an impressive diurnal variation, becoming worse by the end of the day and improving with sleep. Autonomic instability is not uncommon. Parkinsonism may also be present or develop with advancing age. Late presentation in adult life has also been reported, associated with action dystonia (writer's cramp), torticollis or generalized rigid hypertonia with tremor but without postural dystonia. Additionally, limited data on adults suggest symptoms related to serotonin deficiency (sleep disturbance, cognitive impairment and impulsivity).

Laboratory findings show reduced levels of BH_4 and neopterin in the CSF without hyperphenylalaninemia. Dopamine and its metabolite (HVA) may also be reduced in CSF. The serotonergic pathway is less affected by this enzyme deficiency; thus, concentrations of serotonin and its metabolites are usually normal. Plasma phenylalanine is normal but an oral phenylalanine loading test (100 mg/kg) produces an abnormally high plasma phenylalanine level with an elevated phenylalanine/tyrosine ratio. The ratio, obtained at the 2nd and 3rd hr postload, in combination with urine neopterin level, has optimal diagnostic specificity and sensitivity. The existence of asymptomatic carriers indicates that other factors or genes may play a role in pathogenesis. The asymptomatic carrier may be identified by the phenylalanine loading test (see above).

Diagnosis may be confirmed by reduced levels of BH_4 and neopterin in CSF, through measurement of the enzyme activity, and via molecular genetic analysis (see Chapter 85.1). Clinically, the condition should be differentiated from other causes of dystonias and childhood parkinsonism, especially tyrosine hydroxylase, sepiapterin reductase, and aromatic amino acid decarboxylase deficiencies.

Treatment with L-dopa/carbidopa usually produces dramatic clinical improvement. Oral administration of BH_4 is also effective but is rarely used. The gene for GTP cyclohydroxylase I (*GCH1*) is located on chromosome 14q22.2.

Sepiapterin Reductase Deficiency

Sepiapterin reductase is involved in conversion of 6-pyruvoyl-tetrahydropterin to BH_4, and also participates in the salvage pathway of BH_4 synthesis (see Fig. 85-1). Sepiapterin reductase deficiency results in accumulation of 6-lactoyl-tetrahydropterin, which is converted to sepiapterin nonenzymatically. The majority of sepiapterin is metabolized to BH_4 through the salvage pathway in peripheral tissues (see Fig. 85-1), but because of the low activity of dihydrofolate reductase in brain, the amount of BH_4 remains insufficient for proper synthesis of dopamine and serotonin. This explains the absence of hyperphenylalaninemia, as well as an explanation for the often delayed diagnosis. Sepiapterin reductase deficiency may also be underdiagnosed as highly specialized CSF assays are required.

Clinical manifestations usually appear within a few months of life. Cardinal manifestations include paroxysmal stiffening, oculogyric crises, and hypotonia. Additional findings include motor and language delays, weakness, limb hypertonia, dystonia, hyperreflexia, and early onset parkinsonism. The symptoms usually have a diurnal variation. Misdiagnosis as cerebral palsy is common.

Diagnosis is established by measurement of CSF neurotransmitters and pterin metabolites which reveal decreased dopamine, HVA, norepinephrine, 5-HIAA and marked elevations of sepiapterin and dihydrobiopterin. The serum concentration of prolactin is elevated. The phenylalanine loading test (see above) may have diagnostic utility. Diagnosis may be confirmed by enzyme assay in fibroblasts or via molecular genetic analysis.

Treatment with slowly increasing doses of L-dopa/carbidopa and 5-hydroxytryptophan usually produces dramatic clinical improvement.

The condition is inherited as an autosomal recessive trait; the gene (SPR) for the enzyme is located on chromosome 2p13.2.

DOPAMINE β-HYDROXYLASE DEFICIENCY

See Figure 85-2.

This rare condition has been reported in only a few adult subjects with profound deficits of cardiovascular autonomic regulation resulting in predisposition to orthostatic hypotension. Past histories reveal ptosis, hypotension, hypothermia, hypoglycemia and nasal stuffiness in the neonatal and childhood periods. Presyncopal symptomatology includes dizziness, blurred vision, dyspnea, nuchal discomfort and chest pain; olfactory function remains relatively intact.

Laboratory findings include absence of norepinephrine and epinephrine and their metabolites with elevated levels of dopamine and its metabolite (HVA) in plasma, CSF, and urine. Elevated plasma dopamine may be pathognomonic for this disease. MRI of the brain shows decreased brain volume, consistent with the neurotrophic role of norepinephrine. **Treatment** with 3,4-dihydroxyphenylserine, which is converted to norepinephrine directly in vivo by the action of AADC, leads to significant improvement in orthostatic hypotension and normalizes noradrenaline and its metabolites. The condition is inherited as an autosomal recessive trait; the gene *(DBH)* for the enzyme resides on chromosome 9q34.2.

MONOAMINE OXIDASE (MAO) DEFICIENCY

There are 2 MAO isoenzymes: MAO A and MAO B. Both enzymes catalyze oxidative deamination of most biogenic amines in the body, including serotonin (see Fig. 85-5), norepinephrine, epinephrine, and dopamine (see Fig. 85-2). The genes for both isoenzymes are on the X chromosome (A, Xp11.3; B, Xp11.23). Male patients with MAO A deficiency manifest borderline intellectual deficiency and impaired impulse control. MAO B deficiency is found in patients with Norrie disease (see Chapter 622). Patients with isolated MAO B deficiency exhibit normal clinical characteristics and behavior. Combined MAO A and B deficiency causes severe intellectual disability and behavioral problems, associated with more extreme laboratory abnormalities (4-6–fold serotonin elevation in physiologic fluids, elevated *O*-methylated amine metabolites, and reduced deamination products [VMA, HVA]). A de novo microdeletion in Xp11.3 has been reported twice; the microdeletion in 1 male infant manifested with severe intellectual disability and episodic hypotonia. Dietary intervention (low tyramine, phenylethylamine and dopa/dopamine intake) did not improve the patients' blood serotonin levels.

γ-AMINOBUTYRIC ACID (GABA)

GABA is the main inhibitory neurotransmitter, which is synthesized in the synapses through decarboxylation of glutamic acid by glutamic acid decarboxylase (GAD). The same pathway is responsible for production of GABA in other organs, especially the kidneys and the β cells of the pancreas. GAD enzyme requires pyridoxine (vitamin B_6) as cofactor. Two GAD enzymes (GAD_{65} and GAD_{67}) have been identified. GAD_{67} is the main enzyme in the brain and GAD_{65} is the major enzyme in the β cells. Antibodies against GAD_{65} and GAD_{67} are the major markers for type1 diabetes and **stiff-person syndrome**, respectively. Deficiency of neither form of the enzyme has been reported in humans. GABA is catabolized to succinic acid by 2 enzymes, GABA transaminase and succinic semialdehyde dehydrogenase (SSADH) (see Fig. 85-11).

γ-Aminobutyric Acid Transaminase Deficiency

See Figure 85-11.

Clinical manifestations in the 2 index infant siblings included severe psychomotor retardation, hypotonia, hyperreflexia, lethargy, refractory seizures, and increased linear growth. Increased concentrations of GABA and β-alanine were found in CSF. Evidence of leukodystrophy was noted in the postmortem examination of the brain. A third case showed severe psychomotor retardation, recurrent episodic lethargy and intractable seizures with comparable CSF metabolite abnormalities to those of the index probands. GABA transaminase deficiency is demonstrated in brain and lymphocytes. No effective **treatment** has been identified. Intervention with vitamin B_6, the cofactor for the enzyme, was without therapeutic benefit. The gene *(ABAT)*, maps to chromosome 16p13.2; the condition is inherited as an autosomal recessive trait.

Succinic Semialdehyde Dehydrogenase Deficiency (γ-Hydroxybutyric Aciduria)

SSADH deficiency is the most common genetic disorder of neurotransmitters (see Fig. 85-11). Clinical manifestations, which usually begin in early infancy, include intellectual disability with disproportionate deficit in expressive language, hypotonia and ataxia; seizures occur in approximately 50% of patients. A diagnosis of **autism spectrum** disorder occurs disproportionately. Neuropsychiatric morbidity (especially oppositional defiance, obsession-compulsion, and hyperactivity) can be disabling, especially in adolescents and adults. Abnormal EEG findings include background slowing and generalized spike-wave paroxysms, with variable lateralization in hemispheric onset and voltage predominance. Photosensitivity and electrographic status epilepticus of sleep have been reported in combination with difficulties in sleep maintenance and excessive daytime somnolence. MRI of the brain shows an increased T2-weighted hyperintensity involving the globus pallidi, cerebellar dentate nuclei, and subthalamic nuclei, usually in a bilaterally symmetrical distribution.

The biochemical hallmark, γ-hydroxybutyric acid (GHB), is elevated in physiologic fluids (CSF, plasma, urine) in all patients. Increased concentrations of GABA are also found in CSF. Heightened diagnostic suspicion evolves through documentation of elevated urinary γ-hydroxybutyric acid, and confirmation is achieved by molecular genetic testing.

Treatment remains elusive; vigabatrin (GABA-transaminase inhibitor) has been employed empirically, with mixed outcomes, and there is concern with its use as it further elevates CNS GABA in an already hyper-GABAergic disorder. Additionally, vigabatrin leads to constriction of the visual field and long-term use is contraindicated. Magnesium valproate has shown efficacy for behavioral problems and seizure control in a single case.

The gene for SSADH *(ALDH5A1)* is located on chromosome 6p22, and inheritance follows an autosomal-recessive pattern. Prenatal diagnosis has been achieved by measurement of GHB in the amniotic fluid, assay of the enzyme activity in the amniocytes or in biopsy specimens of chorionic villi or by DNA analysis.

DEFECTS IN NEUROTRANSMITTERS TRANSPORTER PROTEINS

More than 20 different proteins are involved in transporting different neurotransmitters across the neuronal membranes. The main function of most of these transporters is to remove the excess neurotransmitters from the synaptic junction (cleft) back into the presynaptic neurons (reuptake). This recycling process not only regulates the precise effect of neurotransmitters at the synaptic junction but also resupplies the presynaptic neurons with neurotransmitters for future use. A few transporter proteins are involved in shuttling neurotransmitters from the neuronal cytoplasm across the membrane of synaptic vesicles for storage (vesicular transporters). Upon neuronal stimulation, these vesicles release a bolus of neurotransmitters via exocytosis. As expected, mutations in transporter proteins interfere with the proper reuptake and storage of neurotransmitters and may result in clinical manifestations similar to those seen in deficiencies of neurotransmitters metabolism themselves. Two conditions caused by mutations of neurotransmitter protein transporters have been described.

Dopamine Transporter Protein Deficiency

This transporter protein is involved in reuptake of dopamine by the presynaptic neurons, and its deficiency causes depletion of dopamine, and hence a dopamine deficiency state. Dopamine transporter protein (DAT) is encoded by *SLC6A3* gene on chromosome 5p15.33. Mutation of this gene has been reported in 3 children from 2 unrelated consanguineous families. These children presented with **symptoms** of infantile parkinsonism-dystonia syndrome. Symptoms of irritability and feeding difficulties started shortly after birth and progressed to hypotonia, lack of head control, parkinsonism, dystonia and global developmental delay by early infancy. Two of the patients were misdiagnosed as having cerebral palsy. MRI of the brain showed no abnormalities.

Examination of the CSF revealed marked elevation of HVA and normal level of 5-HIAAs. The urinary level of HVA, as well as the serum concentration of prolactin, were increased. Diagnosis was established by demonstrating the loss of function mutation in the *SLC6A3* gene. No effective treatment has been identified. **Treatment** with L-dopa/carbidopa did not result in any improvements in clinical or biochemical parameters.

Dopamine–Serotonin Vesicular Transporter Disease (Vesicular Monoamine Transporter Deficiency)

This autosomal recessive condition, described in 8 children from a consanguineous Saudi Arabian family is caused by a mutation in the *SLC18A2* gene. This gene encodes the vesicular monoamine transporter 2 (*VMAT2*), which is involved in transporting dopamine and serotonin from the cytoplasm into the synaptic storage vesicles located in the axonal terminals of the presynaptic neurons. Affected children manifested symptoms consistent with deficiencies of dopamine (hypotonia progressing into dystonia, parkinsonism, oculogyric crises), serotonin (sleep and psychiatric disturbances), and norepinephrine-epinephrine (excessive sweating, tremors, temperature instability, postural hypotension and ptosis). Symptoms started at 4 mo of age with hypotonia, lack of head control, inconsolable crying and oculogyric crises. Cognitive development was initially normal but deteriorated with age. No diurnal variation of the symptoms was noted. EEG, MRI, and MRS of the brain, as well as concentrations of all neurotransmitters and their metabolites in the CSF, were within normal limits. Urinary concentrations of 5-HIAA and HVA were moderately increased, whereas those of norepinephrine and epinephrine were decreased.

The phenotype resembles that seen in AADC and BH_4 deficiencies (see above). Proper diagnosis requires mutation analysis of the *SLC18A2* gene (located on chromosome 10q25.3). **Treatment** with L-dopa/carbidopa caused exacerbation of symptoms, whereas treatment with pramipexole, a dopamine receptor agonist, resulted in a favorable clinical response.

HISTIDINE DECARBOXYLASE DEFICIENCY

Decarboxylation of histidine by histidine decarboxylase produces histamine, which functions as a neurotransmitter in the brain. Deficiency of this enzyme (expressed mainly in the posterior hypothalamus) results in deficiency of histamine in the CNS, and in 1 family caused an autosomal dominant form of Tourette syndrome (see Chapter 85.13).

HYPERPROLINEMIA

Psychomotor retardation and seizures are common findings in most patients with hyperprolinemia type I and type II. Patients with type I hyperprolinemia also have an increased risk of developing schizophrenia. The contribution of increased concentration of proline to the pathogenesis of these conditions, however, remains unclear. The neurologic abnormalities observed in hyperprolinemia type II are mainly because of development of vitamin B_6 dependency in this condition (see Chapter 85.9).

3-PHOSPHOGLYCERATE DEHYDROGENASE DEFICIENCY

See Chapter 85.8.

PHOSPHOSERINE AMINOTRANSFERASE DEFICIENCY

See Chapter 85.8.

NONKETOTIC HYPERGLYCINEMIA

See Chapter 85.7.

Bibliography is available at Expert Consult.

85.12 Urea Cycle and Hyperammonemia (Arginine, Citrulline, Ornithine)

Iraj Rezvani and Marc Yudkoff

Catabolism of amino acids results in the production of free ammonia, which, in high concentration, is toxic to the CNS. Mammals detoxify ammonia to urea through a series of reactions known as the urea cycle (Fig. 85-12), which is composed of 5 enzymes: carbamyl phosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinate synthetase (ASS), argininosuccinate lyase (ASL), and arginase. A 6th enzyme, *N*-acetylglutamate (NAG) synthetase, catalyzes synthesis of NAG, which is an obligatory activator (effector) of the CPS enzyme. Individual deficiencies of these enzymes have been observed and, with an overall estimated prevalence of 1 in 35,000 live births, they are the most common genetic causes of hyperammonemia in infants.

GENETIC CAUSES OF HYPERAMMONEMIA

Hyperammonemia, sometimes severe, occurs in inborn errors of metabolism other than the urea cycle defects (Table 85-3). The pathogenesis for hyperammonemia in some of these conditions is not fully understood, although it is probable that the accumulation of a toxic metabolite–usually an organic acid–compromises function of the urea cycle.

CLINICAL MANIFESTATIONS OF HYPERAMMONEMIA

In the **neonatal period**, *symptoms and signs* are mostly related to brain dysfunction and are similar regardless of the cause of the hyperammonemia. The affected infant is normal at birth but becomes symptomatic following the introduction of dietary protein. Refusal to eat, vomiting, tachypnea, and lethargy can quickly progress to a deep coma. Convulsions are common. Physical examination may reveal hepatomegaly in addition to obtundation. Hyperammonemia can trigger increased intracranial pressure that may be manifested by a bulging fontanelle and dilated pupils.

In **infants and older children** acute hyperammonemia is manifested by vomiting and neurologic abnormalities such as ataxia, mental confusion, agitation, irritability, and combativeness. These manifestations may alternate with periods of lethargy and somnolence that ultimately progress to coma.

Routine **laboratory studies** show no specific findings when hyperammonemia is caused by defects of the urea cycle enzymes. Blood urea nitrogen is usually low in these patients; serum pH is usually normal or mildly elevated. There may be mild increases in serum transaminases (alanine aminotransferase, aspartate aminotransferase) because ammonia can cause swelling of hepatic mitochondria. In some patients with severe OTC deficiency, criteria may be met for acute liver failure, as patients with severe OTC-related liver injury may have moderate hyperammonemia (100-400 µmol/L). In infants with organic acidemias, hyperammonemia is commonly associated with severe acidosis as well as ketonuria. Newborn infants with hyperammonemia are often misdiagnosed as having sepsis; they may succumb without a correct diagnosis. Neuroimaging with CT scanning may reveal cerebral edema. Autopsy is usually unremarkable. It is imperative to measure plasma ammonia levels in any ill infant whose clinical manifestations cannot be explained by an obvious infection.

DIAGNOSIS

The main criterion for diagnosis is hyperammonemia. Each clinical laboratory should establish its own normal values for blood ammonia. Normal newborn values are higher than those of the older child or adult. Levels as high as 100 µmole/L occur in healthy term infants and as high as 150 µmole/L in premature infants. An ill infant usually manifests a blood ammonia level >200 µmole/L. Figure 85-13 illustrates an approach to the differential diagnosis of hyperammonemia in the newborn infant. Careful inspection of individual plasma amino acids commonly reveals abnormalities that may help the diagnosis. In patients with deficiencies of either CPS, OTC, or NAG synthetase, frequent findings include elevations in plasma glutamine and alanine with concurrent decrements in citrulline and arginine. These disorders cannot be differentiated from one another by the plasma amino acid levels alone. A marked increase in urinary orotic acid in patients with OTC deficiency differentiates this defect from CPS deficiency. Differentiation between the CPS deficiency and the NAG synthetase deficiency may require an assay of the respective enzymes or sequencing of the relevant genes. Clinical improvement occurring after oral administration of carbamylglutamate, however, may suggest

Isovaleric acidemia
β-Ketothiolase deficiency
Multiple carboxylase deficiencies
Medium-chain fatty acid acyl-coenzyme A dehydrogenase deficiency
Glutaric acidemia type I
3-Hydroxy-3-methylglutaric aciduria
Lysinuric protein intolerance
Hyperammonemia-hyperornithinemia-homocitrullinemia syndrome
Transient hyperammonemia of the newborn
Congenital hyperinsulinism with hyperammonemia

NAG synthetase deficiency. Patients with a deficiency of ASS, ASL, or arginase have marked increases in the plasma levels of citrulline, argininosuccinic acid, or arginine, respectively. Indeed, the combination of hyperammonemia and marked hypercitrullinemia or argininosuccinic acidemia is virtually pathognomonic for these disorders. Children with urea cycle defects often self-select a low-protein, high-carbohydrate diet, especially those with late-onset disease or symptomatic females with OTC deficiency.

Mass screening of newborn infants identifies patients with ASS, ASL, and arginase deficiencies.

TREATMENT OF ACUTE HYPERAMMONEMIA

Clinical outcome depends mainly on the severity and the duration of hyperammonemia. Serious neurologic sequelae are likely in newborns with severe elevations in blood ammonia (>300 µmole/L) for more than 12 hr. Thus, acute hyperammonemia should be treated promptly and vigorously. The goal of therapy is to lower the concentration of ammonia. This is accomplished in 2 ways: (a) removal of ammonia from the body in a form other than urea and (b) minimizing endogenous protein breakdown and favoring endogenous protein synthesis by providing adequate calories and essential amino acids (Table 85-4). Fluid, electrolytes, glucose (5-15%), and lipids (1-2 g/kg/24 hr) should be infused intravenously together with minimal amounts of protein (0.25 g/kg/24 hr), preferably including essential amino acids. Oral feeding with a low-protein formula (0.5-1.0 g/kg/24 hr) through a nasogastric tube should be started as soon as sufficient improvement in the clinical condition is seen.

Because the kidneys clear ammonia poorly, its removal from the body must be expedited by formation of compounds with a high renal clearance. An important advance in the treatment of hyperammonemia has been the introduction of acylation therapy by using an exogenous organic acid which is acylated endogenously with nonessential amino acids to form a nontoxic compound with high renal clearances. The main organic acids used for this purpose are sodium salts of benzoic acid and phenylacetic acid. Benzoate forms hippurate with endogenous glycine in the liver (see Fig. 85-12). Each mole of benzoate

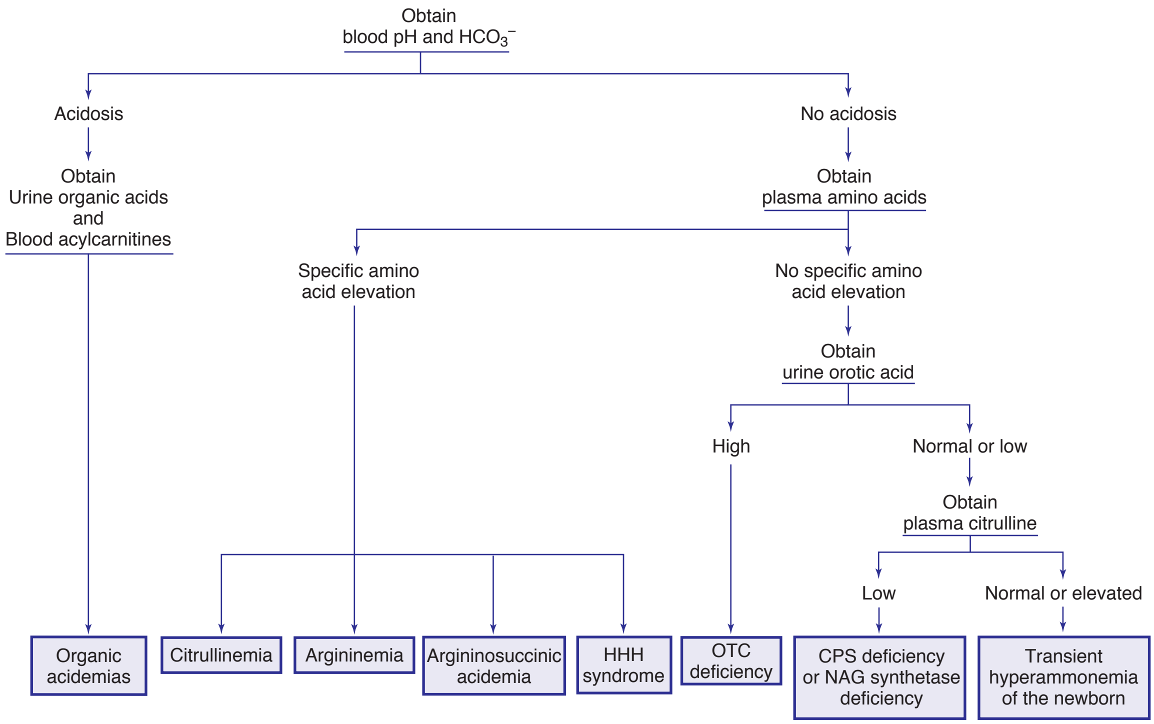

Figure 85-13 **Clinical approach to a newborn infant with symptomatic hyperammonemia.** CPS, carbamyl phosphate synthetase; HHH syndrome, hyperammonemia-hyperornithinemia-homocitrullinemia; NAG, *N*-acetylglutamate; OTC, ornithine transcarbamylase.

Table 85-4 Treatment of Acute Hyperammonemia in an Infant

1. Provide adequate calories, fluid, and electrolytes intravenously (10% glucose, NaCl* and intravenous lipids 1 g/kg/24 hr). Add minimal amounts of protein preferably as a mixture of essential amino acids (0.25 g/kg/24 hr) during the 1st 24 hr of therapy.
2. Give priming doses of the following compounds:
   (To be added to 20 mL/kg of 10% glucose and infused within 1-2 hr)
   - Sodium benzoate 250 mg/kg†
   - Sodium phenylacetate 250 mg/kg†
   - Arginine hydrochloride 200-600 mg/kg as a 10% solution
3. Continue infusion of sodium benzoate† (250-500 mg/kg/24 hr), sodium phenylacetate† (250-500 mg/kg/24 hr), and arginine (200-600 mg/kg/24 hr‡) following the above priming doses. These compounds should be added to the daily intravenous fluid.
4. Initiate peritoneal dialysis or hemodialysis if above treatment fails to produce an appreciable decrease in plasma ammonia.

*The concentration of sodium chloride should be calculated to be 0.45-0.9% including the amount of the sodium in the drugs.
†Sodium from these drugs should be included as part of the daily sodium requirement.
‡The higher dose is recommended in the treatment of patients with citrullinemia and argininosuccinic aciduria. Arginine is not recommended in patients with arginase deficiency and in those whose hyperammonemia is secondary to organic acidemia.

removes 1 mole of ammonia as glycine. Phenylacetate conjugates with glutamine to form phenylacetylglutamine, which is readily excreted in the urine. One mole of phenylacetate removes 2 moles of ammonia as glutamine from the body (see Fig. 85-12). A combined formulation of benzoate and phenylacetate (Ammonul) is commercially available for intravenous use.

Another valuable therapeutic adjunct is intravenous infusion of arginine, which is effective in all patients (except those with arginase deficiency). Arginine administration supplies the urea cycle with ornithine and NAG (see Fig. 85-12). In patients with citrullinemia, 1 mole of arginine reacts with 1 mole of ammonia (as carbamyl phosphate) to form citrulline. In patients with argininosuccinic acidemia, 2 moles of ammonia (as carbamyl phosphate and aspartate) react with arginine to form argininosuccinic acid. Citrulline and argininosuccinate are less toxic than ammonia and more readily excreted by the kidneys. In patients with CPS or OTC deficiency, arginine administration is indicated because this amino acid is not produced in sufficient amounts to enable endogenous protein synthesis. Patients with OTC deficiency benefit from supplementation with citrulline (200 mg/kg/24 hr) because 1 mole of citrulline reacts with 1 mole of ammonia (as aspartic acid) to form arginine. Administration of arginine or citrulline is **contraindicated** in patients with arginase deficiency, a rare condition in which the presenting clinical picture is one of spastic diplegia rather than hyperammonemia (see below). Arginine therapy is of no benefit if hyperammonemia is secondary to an organic acidemia. In a newborn infant with an initial episode of hyperammonemia, arginine should be used until the diagnosis is established.

Benzoate, phenylacetate, and arginine may be administered together for maximal therapeutic effect. A priming dose of these compounds is followed by continuous infusion until recovery from the acute state occurs (see Table 85-4). Both benzoate and phenylacetate are usually supplied as concentrated solutions and should be properly diluted (1-2% solution) for intravenous use. The recommended therapeutic doses of both compounds deliver a substantial amount of sodium to the patient; this amount should be included in calculation of the daily sodium requirement. Benzoate and phenylacetate (or the combined formulation, Ammonul) should be used with caution in newborn infants with hyperbilirubinemia because they may displace bilirubin from albumin; however, there are no documented cases of kernicterus (see Chapter 102.4) reported in neonates with hyperammonemia who have received such therapies. In infants at risk, it is advisable to reduce bilirubin to a safe level before administering benzoate or phenylacetate.

If the foregoing therapies fail within hours to produce any appreciable change in the blood ammonia level, peritoneal dialysis or, preferably, hemodialysis should be used. Exchange transfusion has little effect on reducing total body ammonia; it should be used only if dialysis cannot be employed promptly or when the patient is a newborn infant with hyperbilirubinemia (see above). Hemodialysis dramatically lowers blood ammonia within a few hours, but if it is unavailable or technically

unfeasible, peritoneal dialysis may be used as an alternative. When hyperammonemia is caused by an organic acidemia, peritoneal dialysis effectively removes both the offending organic acid and ammonia.

Oral administration of neomycin limits growth of intestinal bacteria that can produce ammonia. However, this modality is of limited use in patients (such as affected neonates) in whom reduction of hyperammonemia is an urgent priority. Oral lactulose acidifies the intestinal lumen, thereby reducing the diffusion of ammonia across the intestinal epithelium. This agent is of limited applicability in newborns in whom the risks of acidemia and dehydration are high.

There has been interest in the use of cooling as a therapeutic adjunct in newborn infants with metabolic encephalopathies like that caused by hyperammonemia. Clinical studies are in progress to evaluate the efficacy of this approach. There may be considerable lag between the normalization of ammonia and an improvement in the neurologic status of the patient. Several days may be needed before the infant becomes fully alert.

Long-Term Therapy

Once the infant is alert, therapy should be tailored to the underlying cause of the hyperammonemia. In general, all patients, regardless of the enzymatic defect, require some degree of protein restriction (1-2 g/kg/24 hr). In patients with defects in the urea cycle, chronic administration of benzoate (250-500 mg/kg/24 hr), phenylacetate (250-500 mg/kg/24 hr), and arginine (200-400 mg/kg/24 hr) or citrulline (in patients with OTC deficiency, 200-400 mg/kg/24 hr) is effective in maintaining blood ammonia levels within the normal range. Arginine and citrulline are contraindicated in patients with argininemia. Phenylbutyrate may be used in place of phenylacetate, because the patient and the family may not accept the latter owing to its offensive odor. A commercial preparation of the compound is available for oral use (Buphenyl). A significant innovation is the introduction of glycerol phenylbutyrate. This compound, unlike Buphenyl, is not a sodium salt and avoids the consequent coadministration of large amounts of sodium. It is approved for children ≥2 yr but is not yet approved for use in newborns. Benzoate and phenylacetate may lower carnitine levels, but clinical signs of carnitine deficiency or benefit from carnitine supplementation have not yet been demonstrated.

These compounds have been used during pregnancy without obvious teratogenic effect. However, experience is still quite limited and appropriate caution should be exercised.

Growth parameters, especially head circumference, and nutritional indices (blood albumin, prealbumin, pH, electrolytes, amino acids, zinc, selenium) should be followed closely. Long-term care of these patients is best achieved by a team of experienced professionals (pediatrician, nutritionist, child neurologist, metabolic geneticist). Skin lesions resembling **acrodermatitis enteropathica** (see Chapter 671) have been noted in a few patients with different types of urea cycle defects, presumably from deficiency of essential amino acids, especially arginine, caused by overzealous dietary protein restriction. Catabolic states (infections, fasting) that may trigger hyperammonemia should be avoided. They must be treated vigorously should they occur. It is important that all children with urea cycle defects avoid valproic acid (Depakote) because this drug elevates blood ammonia even in healthy subjects. In patients with CPS, OTC, and ASS deficiencies, acute hyperammonemic attacks may be precipitated by valproate administration.

CARBAMYL PHOSPHATE SYNTHETASE AND *N*-ACETYLGLUTAMATE SYNTHETASE DEFICIENCIES

See Figures 85-12 and 85-13.

Deficiencies of these 2 enzymes produce similar **clinical and biochemical manifestations**. There is a wide variation in severity of symptoms and in the age at presentation. In near complete enzymatic deficiency, symptoms appear during the first few days or even hours of life with signs and symptoms of hyperammonemia (refusal to eat, vomiting, lethargy, convulsion, and coma). Increased intracranial pressure is frequent. Late forms (as late as 32 yr of age) may present as an acute bout of hyperammonemia (lethargy, headache, seizures, psychosis) in a seemingly normal individual. Coma and death may occur during these episodes (a previously asymptomatic 26 yr old female died from hyperammonemia during childbirth). Diagnostic confusion with migraine is frequent. Intermediate forms with intellectual disability and chronic subclinical hyperammonemia interspersed with bouts of acute hyperammonemia have also been observed.

Laboratory findings include hyperammonemia. The plasma aminogram commonly shows a marked increase of glutamine and alanine with relatively low levels of citrulline and arginine. These are nondiagnostic changes that occur in hyperammonemia of diverse cause. Urinary orotic acid is usually low or may be absent (see Fig. 85-13).

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition is outlined above (see Table 85-4). Patients with NAG synthetase deficiency benefit from oral administration of carbamylglutamate. It is therefore important to differentiate between CPS and NAG synthetase deficiencies by gene sequencing. Deficiency of NAG synthetase is rare in North America.

CPS and NAG synthetase deficiencies are inherited as an autosomal recessive trait; the CPS enzyme is normally present in liver and intestine. The gene *(CPS1)* is mapped to chromosome 2q34; several disease-causing mutations have been found in different families. The prevalence of the condition is not known. The gene for NAG synthetase *(NAGS)* is located on chromosome 17q21.31. Neither of these conditions is identified by the mass screening of the newborn infants.

ORNITHINE TRANSCARBAMYLASE DEFICIENCY

See Figures 85-12 and 85-13.

In this X-linked partially dominant disorder, the hemizygous males are more severely affected than heterozygous females. The heterozygous females may have a mild form of the disease, but the majority (approximately 75%) is asymptomatic, although investigations indicate subtle neurologic defects even in women without a frank history of hyperammonemia. This is the most common form of all the urea cycle disorders, comprising approximately 40% of cases.

Clinical manifestations in a male newborn are usually those of severe hyperammonemia (see above) occurring in the first few days of life. Milder forms of the condition are commonly seen in heterozygous females and in some affected males. **Mild** forms characteristically have episodic manifestations, which may occur at any age (usually after infancy). Episodes of hyperammonemia (manifested by vomiting and neurologic abnormalities such as ataxia, mental confusion, agitation, combativeness and frank psychosis) are separated by periods of wellness. These episodes usually occur after ingestion of a high-protein diet or as a result of a catabolic state such as infection. Hyperammonemic coma, cerebral edema, and death may occur during one of these attacks. Cognitive development may proceed normally. Mild to moderate intellectual disability, however, is common. Gallstones have been seen in the survivors; the mechanism remains unclear.

The major **laboratory finding** during the acute attack is hyperammonemia accompanied by marked elevations of plasma concentrations of glutamine and alanine with low levels of citrulline and arginine. The blood level of urea is usually low. A marked increase in the urinary excretion of orotic acid differentiates this condition from CPS deficiency (see Fig. 85-13). Orotate may precipitate in urine as a pink-colored gravel or stones. In the mild form, these laboratory abnormalities may revert to normal between attacks. This form should be differentiated from all the episodic conditions of childhood. In particular, patients with lysinuric protein intolerance (see Chapter 85.14) may demonstrate some features of OTC deficiency, but the former can be differentiated by increased urinary excretion of lysine, ornithine, and arginine and elevated blood concentrations of citrulline.

The **diagnosis** is most conveniently confirmed by identification of the mutant gene, for which several commercial laboratories offer sequencing. As many as 20% of affected patients demonstrate a normal sequence, perhaps because the mutation involves an intron or a leader peptide. For these cases enzyme assay in a liver biopsy may be indicated. Prenatal diagnosis is feasible by analysis of DNA in amniocytes or chorionic villous samples. An oral protein load, which increases

plasma ammonia and urinary orotic acid levels, may identify asymptomatic heterozygous female carriers. A marked increase in urinary excretion of orotidine after an allopurinol loading test also detects obligate female carriers. Mild cerebral dysfunction may be present in asymptomatic female carriers. The importance of a detailed family history should be emphasized. A history of migraine or protein aversion is common in maternal female relatives of the proband. Indeed, careful scrutiny of the family history may reveal a pattern of unexplained deaths in male newborns in the maternal lineage.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined above. Citrulline is used in place of arginine in patients with OTC deficiency. Liver transplantation is a successful treatment for patients with OTC deficiency. It even has been performed during infancy.

The gene for OTC has been mapped to the X chromosome (Xp21.1). Many disease-causing mutations (>300) have been identified. The degree of enzyme deficiency and the genotype determine severity of the phenotype in most cases. Mothers of affected infants are expected to be carriers of the mutant gene unless a de novo mutation has occurred. A mother who gave birth to 2 affected male offspring was found to have a normal genotype, suggesting gonadal mosaicism in the mother. This condition is not identified by the mass screening of newborn infants.

ARGININOSUCCINATE SYNTHETASE (ASS) DEFICIENCY (CITRULLINEMIA)

See Figures 85-12 and 85-13.

Two clinically and genetically distinct forms of citrullinemia have been identified. The classic form (type I) is caused by the deficiency of the ASS enzyme. The adult form (type II) is caused by the deficiency of a mitochondrial transport protein named citrin.

Citrullinemia Type I (Classic Citrullinemia)

This condition is caused by the deficiency of ASS (see Fig. 85-12) and has variable **clinical manifestations** depending on the degree of the enzyme deficiency. Two major forms of the condition have been identified. The **severe or neonatal form**, which is most common, appears in the first few days of life with signs and symptoms of hyperammonemia (see above). In the **subacute or mild form**, clinical findings such as failure to thrive, frequent vomiting, developmental delay, and dry, brittle hair appear gradually after 1 yr of age. Acute hyperammonemia, triggered by an intercurrent catabolic state, may bring the diagnosis to light.

Laboratory findings are similar to those found in patients with OTC deficiency except that the plasma citrulline concentration is markedly elevated (50-100 times normal) (Fig. 85-13). Urinary excretion of orotic acid is moderately increased; crystalluria as a result of precipitation of orotates may also occur. The **diagnosis** is confirmed by assay of enzyme activity in cultured fibroblasts or by DNA analysis. Prenatal diagnosis is feasible with enzyme assay in cultured amniotic cells or by DNA analysis of cells obtained from chorionic villous biopsy.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this chapter and in Table 85-3. Plasma concentration of citrulline remains elevated at all times and may increase further after administration of arginine. Although prognosis is poor for symptomatic neonates, patients with the mild disease usually do well on a protein-restricted diet in conjunction with sodium benzoate, phenylbutyrate, and arginine therapy. Mild to moderate cognitive impairment is a common sequela, even in a well-treated patient.

Citrullinemia is inherited as an autosomal recessive trait. The gene *(ASS 1)* is located on chromosome 9q34.11. Several disease-causing mutations have been identified in different families. The majority of patients are compound heterozygotes for 2 different alleles. The prevalence of the condition is not known. The recent introduction of neonatal screening for urea cycle defects has disclosed affected patients who are ostensibly asymptomatic, even with ingestion of a regular diet. Long-term follow-up is needed to be certain that these individuals do not sustain neurologic sequelae.

Citrullinemia Resulting From Citrin Deficiency (Citrullinemia Type II)

Citrin (aspartate-glutamate carrier protein) is a mitochondrial transporter encoded by a gene *(SLC25A13)* located on chromosome 7q21.3. One this protein's functions is to transport aspartate from mitochondria into cytoplasm; aspartate is required for converting citrulline to argininosuccinic acid (see Fig. 85-12). If aspartate is unavailable to the cytoplasmic component of the urea cycle, urea will not be formed at a normal rate and citrulline will accumulate. ASS activity is deficient in the liver of these patients, but no mutation in the gene for ASS has been found. It is postulated that citrin deficiency or its mutated gene interferes with translation of messenger RNA for ASS enzyme in the liver. Mutation in the gene for citrin produces 2 distinct clinical entities. The condition initially was reported almost exclusively in Japan but a few non-Japanese patients have been identified. Two clinical forms of citrin deficiency have been described.

Neonatal Intrahepatic Cholestasis (Citrullinemia Type II—Neonatal Form)

Clinical and laboratory manifestations, which usually start before 1 yr of age, include cholestatic jaundice with mild to moderate direct (conjugated) hyperbilirubinemia, marked hypoproteinemia, clotting dysfunction (increased prothrombin time and partial thromboplastin time), and increased serum GGTP and alkaline phosphatase activities; liver transaminases are usually normal. Plasma concentrations of ammonia and citrulline are usually normal, but moderate elevations are reported. There may be increases in plasma concentrations of methionine, tyrosine, alanine, and threonine. Elevated levels of serum galactose have been found even though the enzymes of galactose metabolism are normal. The reason for hypergalactosemia is not known. Marked elevation in the serum level of α-fetoprotein is also present. These findings resemble those of tyrosinemia type I, but unlike the latter condition, urinary excretion of succinylacetone is not elevated (see Chapter 85.2). Liver biopsy shows fatty infiltration, cholestasis with dilated canaliculi, and a moderate degree of fibrosis. The condition is usually self-limiting and the majority of infants recover spontaneously by 1 yr of age with only supportive and symptomatic treatment. Hyperammonemia and hypercitrullinemia, if present, should be treated with a low-protein diet and other appropriate measures (see above). Hepatic failure requiring liver transplantation has occurred in a few cases. Although the condition is commonly seen in Japan, the diagnosis should be considered in any case of unexplained neonatal hepatitis with cholestasis. Data on the long-term prognosis and the natural history of the condition are limited; development into the adult form of the condition (see below) after several years of seemingly asymptomatic hiatus has been observed.

Citrullinemia Type II, Adult Form (Adult-Onset Citrullinemia, Citrullinemia Type II—Mild Form)

This form starts suddenly in a previously normal individual and manifests with neuropsychiatric symptoms such as disorientation, delirium, delusion, aberrant behavior, tremors, and frank psychosis. Moderate degrees of hyperammonemia and hypercitrullinemia are present. The age at onset is usually between 20 and 40 yr (range: 11-85 yr). Patients who recover from the first episode may have recurrent attacks and most will die within a few years of diagnosis, mainly from cerebral edema. Pancreatitis, hyperlipidemia, and hepatoma are major complications among the survivors. Medical **treatment** has been mostly ineffective for prevention of future attacks. Indeed, some have speculated that the administration of large amounts of glucose might even prove deleterious, as the citrin transporter is important to the glycolytic pathway. Liver transplantation is the most effective therapy.

Several disease-causing mutations of the gene have been identified in affected Japanese families. The pathogenesis of citrullinemia type II (neonatal and adult forms) remains enigmatic. Although the frequency of homozygosity is relatively high in Japan (1 : 20,000 people), the clinical condition has a frequency of only 1 : 100,000 people. This indicates that a substantial number of homozygous individuals remain asymptomatic. Only a few non-Japanese patients have been identified.

ARGININOSUCCINATE LYASE DEFICIENCY (ARGININOSUCCINIC ACIDURIA)

See Figures 85-12 and 85-13.

The severity of the **clinical and biochemical manifestations** varies considerably. In the **neonatal form**, signs and symptoms of severe hyperammonemia (see above) develop in the first few days of life and mortality is high. Infants who survive the initial acute episode pursue a **subacute or late form** that is characterized by intellectual disability, failure to thrive, and hepatomegaly. A common finding is dry and brittle hair (trichorrhexis nodosa). Gallstones have been seen in some survivors. Acute attacks of severe hyperammonemia may occur during a catabolic state.

Laboratory findings include hyperammonemia, moderate elevations in liver enzymes, nonspecific increases in plasma levels of glutamine and alanine, a moderate increase in plasma levels of citrulline (less than that seen in citrullinemia), and marked increase in the concentration of argininosuccinic acid in plasma, urine and spinal fluid (see Fig. 85-13). The levels in the spinal fluid are usually higher than those in plasma. The enzyme is normally present in erythrocytes, the liver and cultured fibroblasts. Prenatal diagnosis is possible by measurement of the enzyme activity in cultured amniotic cells or by identification of the mutant gene. Argininosuccinic acid is also elevated in the amniotic fluid of affected fetuses.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this chapter. Intellectual disability, persistent hepatomegaly with mild increases in liver enzymes, and bleeding tendencies as a result of abnormal clotting factors are common sequelae. This deficiency is inherited as an autosomal recessive trait with a prevalence of about 1 in 70,000 live births. The gene *(ASL)* is located on chromosome 7q11.21. Early detection is achieved through mass screening of newborn infants.

ARGINASE DEFICIENCY (HYPERARGININEMIA)

See Figures 85-12 and 85-13.

This defect is inherited as an autosomal recessive trait. There are 2 genetically distinct arginases in humans. One is cytosolic (ARG1) and is expressed in the liver and erythrocytes, and the other (ARG2) is found in renal and brain mitochondria. The gene for ARG1, the enzyme that is deficient in patients with arginase deficiency, is mapped to chromosome 6q23.2. The role of the mitochondrial enzyme is not well understood; its activity increases in patients with argininemia but has no protective effect. Several disease-causing mutations have been identified in different families.

Clinical manifestations of this rare condition are quite different from those of other urea cycle enzyme defects. The onset is insidious; the infant usually remains asymptomatic in the first few months or years of life. A **progressive spastic diplegia** with scissoring of the lower extremities, choreoathetotic movements, and loss of developmental milestones in a previously normal infant may suggest a degenerative disease of the CNS. Some children were treated for years as cases of cerebral palsy before their arginase deficiency was confirmed. Intellectual disability is progressive; seizures are common, but episodes of severe hyperammonemia are not usually seen. Hepatomegaly may be present. The acute neonatal form with intractable seizures, cerebral edema, and death has also been reported.

Laboratory findings include marked elevations of arginine in plasma and CSF (see Fig. 85-13). Urinary orotic acid is increased. Plasma ammonia levels may be normal or mildly elevated. Urinary excretion of arginine, lysine, cystine, and ornithine is usually increased, but normal levels have also been noted. Therefore, determination of amino acids in plasma is a critical step in the diagnosis of argininemia. The guanidino compounds (α-keto-guanidinovaleric acid and α-keto-argininic acid) are markedly increased in urine. The **diagnosis** is confirmed by assaying arginase activity in erythrocytes or by the identification of the mutant gene.

Treatment consists of a low-protein diet devoid of arginine. The composition of the diet and the daily intake of protein should be monitored by frequent plasma amino acid determinations. Sodium benzoate (250-375 mg/kg/24 hr) is also effective in controlling hyperammonemia and lowering plasma arginine levels. Intellectual disability is a common sequela of the condition. One patient developed type 1 diabetes at age 9 yr while his argininemia was under good control. Liver transplantation has produced promising results but no experience with long term outcome is available. Early detection is feasible through mass screening of newborn infants.

TRANSIENT HYPERAMMONEMIA OF THE NEWBORN

See Figure 85-13.

The blood concentration of ammonia in full-term infants may be as high as 100 µmole/L, or 2-3 times greater than that of the older child or adult. In premature infants, the upper limit of normal for blood ammonia may be as high as 150 µmole/L. Blood levels approximate the adult normal values after a few weeks of life. These infants are asymptomatic, and follow-up studies up to 18 mo of age have not revealed any significant neurologic deficits.

Severe transient hyperammonemia is observed in some newborn infants. The majority of affected infants are premature and have mild respiratory distress syndrome. Hyperammonemic coma may develop within 2-3 days of life, and the infant may succumb to the disease if treatment is not started immediately. **Laboratory studies** reveal marked hyperammonemia (plasma ammonia as high as 4,000 µmole/L) with moderate increases in plasma levels of glutamine and alanine. Plasma concentrations of urea cycle intermediate amino acids are usually normal except for citrulline, which may be moderately elevated. The cause of the disorder is unknown. Urea cycle enzyme activities are normal. **Treatment** of hyperammonemia should be initiated promptly and continued vigorously (see above). Recovery without sequelae is common, and hyperammonemia does not recur even with a normal protein diet.

ORNITHINE

Ornithine, a key intermediate of the urea cycle, is not incorporated into natural proteins. Rather, it is generated in the cytosol from arginine and must be transported into mitochondria, where it is a substrate for the OTC reaction, which forms citrulline. Excess ornithine is catabolized by 2 enzymes, ornithine 5-aminotransferase, which is a mitochondrial enzyme and converts ornithine to a proline precursor, and ornithine decarboxylase, which resides in the cytosol and converts ornithine to putrescine (see Fig. 85-12). Two genetic disorders feature hyperornithinemia: gyrate atrophy of the retina and hyperammonemia-hyperornithinemia-homocitrullinemia syndrome.

Gyrate Atrophy of the Retina and Choroid

This is a rare, autosomal recessive disorder caused by a deficiency of ornithine 5-aminotransferase (see Fig. 85-12). Approximately 30% of the reported cases are from Finland. **Clinical manifestations** are limited to the eyes and include night blindness, myopia, loss of peripheral vision, and posterior subcapsular cataracts. These eye changes start between 5 and 10 yr of age and progress to complete blindness by the 4th decade of life. Atrophic lesions in the retina resemble cerebral gyri. These patients usually have normal intelligence and a 10-20–fold increase in plasma levels of ornithine (400-1,400 µmole/L). They have neither hyperammonemia nor increases in plasma concentrations of any other amino acids; plasma levels of glutamate, glutamine, lysine, creatine, and creatinine are moderately decreased. Some patients respond partially to high doses of pyridoxine. An arginine-restricted diet in conjunction with supplemental lysine, proline, and creatine has been successful in reducing plasma ornithine concentration and has produced some clinical improvement. The gene for ornithine 5-aminotransferase *(OAT)* is mapped to chromosome 10q26.13. Many (at least 60) disease-causing mutations have been identified in different families.

HYPERAMMONEMIA-HYPERORNITHINEMIA-HOMOCITRULLINEMIA SYNDROME

In this rare autosomal recessive disorder, the defect is in the transport system of ornithine from the cytosol into the mitochondria, resulting in accumulation of ornithine in the cytosol and a deficiency of this

amino acid in mitochondria. The former causes hyperornithinemia and the latter results in disruption of the urea cycle and hyperammonemia (see Fig. 85-12). Homocitrulline is presumably formed from the reaction of mitochondrial carbamyl phosphate with lysine, which can become a substrate for the OTC reaction when ornithine is deficient. **Clinical manifestations** of hyperammonemia may develop shortly after birth or may be delayed until adulthood. Acute episodes of hyperammonemia manifest as refusal to feed, vomiting, and lethargy; coma may occur during infancy. Progressive neurologic signs, such as lower limb weakness, increased deep tendon reflexes, spasticity, clonus, seizures, and varying degrees of psychomotor retardation may develop if the condition remains undiagnosed. No clinical ocular findings have been observed in these patients.

Laboratory findings reveal marked increases in plasma levels of ornithine and homocitrulline in addition to hyperammonemia (see Fig. 85-13). Acute episodes of hyperammonemia should be treated promptly (see above). Restriction of protein intake improves hyperammonemia. Oral supplementation with ornithine and arginine (or citrulline) has produced clinical improvement in some patients. The gene for this disorder *(SLC25A15)* is located on chromosome 13q14.11.

Bibliography is available at Expert Consult.

85.13 Histidine

Iraj Rezvani

Histidine is an essential amino acid only during infancy. Its biosynthetic pathway in older children and adults is poorly understood. Histidine is degraded through the urocanic acid pathway to glutamic acid. Several genetic biochemical aberrations involving the degradative pathway of histidine have been reported, but none has any clinical consequence.

Decarboxylation of histidine by histidine decarboxylase produces histamine. Deficiency of this enzyme is the cause of familial form of **Tourette syndrome** (see Chapter 85.11).

Bibliography is available at Expert Consult.

85.14 Lysine

Iraj Rezvani

Lysine is catabolized through 2 pathways. In the first pathway, lysine is condensed with α-ketoglutaric acid to form saccharopine. Saccharopine is then catabolized to α-aminoadipic acid semialdehyde and glutamic acid. These first 2 steps are catalyzed by α-aminoadipic semialdehyde synthase, which has 2 activities: lysine-ketoglutarate reductase, and saccharopine dehydrogenase (see Fig. 85-14). In the second pathway, lysine is first transaminated and then condensed to its cyclic forms, pipecolic acid and piperidine-6-carboxylic acid (P6C). The latter compound (P6C) and its linear form, α-aminoadipic acid semialdehyde, are oxidized to α-aminoadipic acid by the enzyme antiquitin. This is the major pathway for D-lysine in the body and for the L-lysine in the brain (see Fig. 85-14).

Hyperlysinemia, *α-aminoadipic acidemia*, and *α-ketoadipic acidemia* are 3 biochemical conditions that are caused by inborn errors of metabolism of lysine. Individuals with these conditions are usually asymptomatic.

PYRIDOXINE (VITAMIN B_6)-DEPENDENT EPILEPSY

Pyridoxal 5′-phosphate, the active form of pyridoxine, is the cofactor for many enzymes including those involved in the metabolism of neurotransmitters. Intracellular deficiency of pyridoxal 5′-phosphate in the brain may result in a seizure disorder that is refractory to common anticonvulsant agents but is responsive to high doses of pyridoxine. This pyridoxine-dependent epilepsy is seen in the following genetic metabolic conditions:

Antiquitin (α-Aminoadipic Semialdehyde Dehydrogenase) Deficiency

This is the most common cause of pyridoxine-dependent epilepsy. Deficiency of antiquitin results in accumulation of P6C in brain tissue (see Fig. 85-14); P6C reacts with pyridoxal 5′-phosphate and renders it inactive. Large doses of pyridoxine are, therefore, needed to overcome this inactivation.

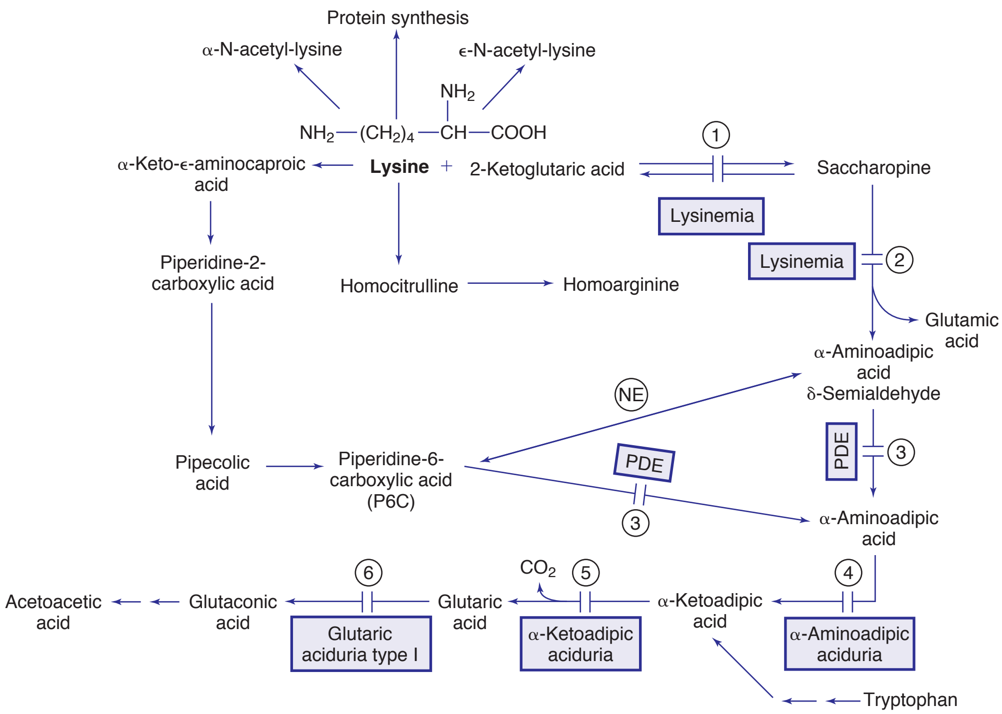

Figure 85-14 Pathways in the metabolism of lysine. **Enzymes:** *(1)* Lysine ketoglutarate reductase, *(2)* saccharopine dehydrogenase, *(3)* α-aminoadipic semialdehyde/piperidine-6-carboxylic acid (P6C) dehydrogenase (antiquitin), *(4)* α-aminoadipic acid transferase, *(5)* α-ketoadipic acid dehydrogenase, *(6)* glutaryl-CoA-dehydrogenase. NE, nonenzymatic; PDE, pyridoxine-dependent epilepsy.

Sulfite Oxidase Deficiency (Molybdenum Cofactor Deficiency)

In this rare condition (see Chapter 85.4), accumulation of sulfites causes inhibition of enzymatic activity of antiquitin and accumulation of P6C, which, in turn, causes inactivation of pyridoxal-5′-phospate and vitamin B_6 dependency.

Hyperprolinemia Type II

In this condition, accumulation of P5C in brain tissue causes inactivation of pyridoxal-5′-phosphate and hence pyridoxine dependency (see Chapter 85.9 and Fig. 85-9).

Hypophosphatasia

Pyridoxal-5′-phosphate is the main circulating form of pyridoxine. Alkaline phosphatase is required for dephosphorylation of pyridoxal-5′-phosphate to generate free pyridoxine which is the only form of vitamin B_6 that can cross the blood–brain barrier and enter the brain cells. Pyridoxine is rephosphorylated intracellularly to form pyridoxal-5′-phosphate. In the infantile form of hypophosphatasia, pyridoxal-5′-phosphate cannot be dephosphorylated to free pyridoxine because of marked deficiency of tissue nonspecific alkaline phosphatase. This results in deficiency of pyridoxine in the brain and pyridoxine-dependent epilepsy (see Chapters 593 and 705).

The main **clinical manifestation** of pyridoxine-dependent epilepsy caused by antiquitin deficiency is generalized seizures, which usually occur in the first few hours of life and are unresponsive to conventional anticonvulsant therapies. Some mothers of affected fetuses report abnormal intrauterine fluttering movements. The seizures are usually tonic-clonic in nature but can be almost any type. Other manifestations such as dystonia, respiratory distress, and abdominal distention with vomiting, hepatomegaly, hypoglycemia and hypothermia may be present. Late-onset forms of the condition (as late as 5 yr of age) have been reported. Consequently, a trial with vitamin B_6 is recommended in any infant with intractable convulsions (see Chapters 593.4 and 593.6).

Laboratory studies reveal increased concentrations of α-aminoadipic semialdehyde and pipecolic acid in the CSF, plasma, and urine. EEG shows abnormalities corresponding to the type of seizures; these changes usually normalize after treatment. Neuroimaging may be normal but cerebellar and cerebral atrophy, periventricular hyperintensity, intracerebral hemorrhage, and hydrocephalus may be present.

Treatment with large doses of vitamin B_6 (50-100 mg/kg) usually results in a dramatic improvement of both seizures and the EEG abnormalities. The dependency and hence the therapy are lifelong. The therapeutic benefit of a lysine-restricted diet remains to be determined. Learning problems and speech delay are common sequelae. The condition is inherited as an autosomal recessive trait; the gene for antiquitin *(ALDH7A1)* is on chromosome 5q31.

GLUTARIC ACIDURIA TYPE I

Glutaric acid is an intermediate in the degradation of lysine (see Fig. 85-14), hydroxylysine, and tryptophan. Glutaric aciduria type I, a disorder caused by a deficiency of glutaryl CoA dehydrogenase, should be differentiated from glutaric aciduria type II, a distinct clinical and biochemical disorder caused by defects in the electron transport system (see Chapter 86.1).

Clinical Manifestations

Affected infants with glutaric aciduria type I may develop normally up to 2 yr of life; macrocephaly is a common finding in these infants and precedes onset of neurologic manifestations. Some affected infants may also show subtle neurologic symptoms, such as hypotonia, irritability, and feeding problems, during this seemingly asymptomatic period. The onset of the condition is usually heralded by acute encephalopathic findings such as loss of normal developmental milestones (head control, sitting), choreoathetosis, seizures, generalized rigidity, opisthotonos, and dystonia. These symptoms may occur suddenly in a seemingly normal infant after a minor infection. Recovery from the first attack usually occurs slowly, but some residual neurologic abnormalities, especially dystonia and extrapyramidal movements may persist. Additional acute attacks resembling the first one usually occur during episodes of intercurrent infections or catabolic states. In some patients, these signs and symptoms may develop gradually in the first few years of life; hypotonia and choreoathetosis may gradually progress into rigidity and dystonia (“insidious form”). Acute episodes of metabolic decompensation with vomiting, ketosis, seizures, and coma also occur in this form after infection or other catabolic states. Death usually occurs in the 1st decade of life during one of these episodes. The affected infants are prone to development of subdural hematoma and retinal hemorrhage following minor falls and head traumas. This may be misdiagnosed as child abuse. The intellectual abilities usually remain relatively normal in most patients.

Laboratory Findings

During acute episodes, mild to moderate metabolic acidosis and ketosis may occur. Hypoglycemia, hyperammonemia, and elevations of serum transaminases are seen in some patients. High concentrations of glutaric acid are usually found in urine, blood, and CSF. 3-Hydroxyglutaric acid may also be present in the urine. Plasma concentrations of amino acids are usually within normal limits. Laboratory findings may be unremarkable between attacks. Severely affected children without glutaric aciduria have also been reported (“low excretors”). In some of these patients, the glutaric acid is elevated only in the spinal fluid. In any child with progressive dystonia and dyskinesia, activity of the enzyme glutaryl CoA dehydrogenase should be measured in leukocytes or cultured fibroblasts as urinary glutaric acid may not be elevated in those patients who are the “low excretors.” Neuroimaging of the brain may reveal macrocephaly, increased extraaxial (particularly frontal) fluid, striatal lesions, dilated lateral ventricles, cortical atrophy (mainly in frontotemporal region), and fibrosis.

Treatment

A low-protein diet (especially a diet restricted in lysine and tryptophan) and high doses (200-300 mg/24 hr) of riboflavin (the coenzyme for glutaryl CoA dehydrogenase) and L-carnitine (50-100 mg/kg/24 hr orally) produce a dramatic decrease in the levels of glutaric acid in body fluids, but their effects on the clinical outcome have been variable. Early diagnosis (through newborn screening) with prevention and aggressive treatment of intercurrent catabolic states (infections) are shown to minimize striatal insults and assure a more favorable prognosis. The addition of a GABA analog (baclofen) and valproic acid to the therapeutic regimen produces improvement in some affected children.

The condition is inherited as an autosomal recessive trait. The prevalence is estimated at 1 : 100,000 live births worldwide. The condition is more prevalent in some ethnic populations (Canadian Oji-Cree Indians, Irish travelers, black South Africans, Swedes, and the Old Order Amish population in the United States). The gene for glutaryl CoA dehydrogenase *(GCDH)* is located on chromosome 19p13.2 and many disease-causing mutations have been reported in different families. A single mutation *(A421V)* accounts for all the patients from the Lancaster County (Pennsylvania) Old Order Amish community.

Prenatal diagnosis may be accomplished by demonstrating increased concentrations of glutaric acid in amniotic fluid, by the assay of the enzyme activity in amniocytes or chorionic villous samples, or by identification of the mutant gene.

LYSINURIC PROTEIN INTOLERANCE (FAMILIAL PROTEIN INTOLERANCE)

This rare autosomal recessive disorder is caused by a defect in the transport of the cationic amino acids lysine, ornithine, and arginine in both intestine and kidneys. Unlike patients with cystinuria, urinary excretion of cystine is not increased in these patients. Deficiency of the transporter protein in this condition causes multisystem manifestations, which start initially with gastrointestinal symptoms. Refusal to feed, nausea, aversion to protein, vomiting, and mild diarrhea, which may result in failure to thrive, wasting, and hypotonia, start shortly

after birth. Breastfed infants usually remain asymptomatic until shortly after weaning. This may be because of the low protein content of breast milk. Episodes of hyperammonemia may occur after ingestion of a high-protein diet. Mild to moderate hepatosplenomegaly, osteoporosis, sparse brittle hair, thin extremities with moderate centripetal adiposity, and growth retardation are common physical findings in patients whose condition has remained undiagnosed. Mental development is usually normal, but moderate intellectual disability has been observed in 20% of patients.

Progressive **interstitial pneumonitis with bouts of acute exacerbation commonly occurs in these patients.** This usually progresses to severe **alveolar proteinosis**. **Clinical manifestations** include progressive exertional dyspnea, fatigue, cough, diminished breath sound, and inspiratory rales; cyanosis may develop in older patients. Some patients have remained undiagnosed until the appearance of pulmonary manifestations. Radiographic evidence of pulmonary fibrosis has been observed in up to 65% of patients without clinical manifestations of pulmonary involvement.

Renal involvement is manifested initially by proteinuria, hematuria, and elevation of serum creatinine, which may progress to end-stage renal failure. Renal tubular involvement with findings compatible with Fanconi syndrome may also be present. Renal biopsy reveals pathologic findings consistent with glomerulonephritis and tubulointerstitial nephritis. Hematologic findings of anemia, leukopenia, and thrombocytopenia may also be present. A condition resembling hemophagocytic lymphohistiocytosis/macrophage activation syndrome has also been reported. Immunologic abnormalities (impaired lymphocyte function, abnormalities in immune globulins, hypocomplementemia), hypercholesterolemia, hypertriglyceridemia, and acute pancreatitis have also been reported in these patients.

Laboratory findings may reveal hyperammonemia and an elevated concentration of urinary orotic acid, which develop after protein feeding. Plasma concentrations of lysine, arginine, and ornithine are usually mildly decreased, but urinary levels of these amino acids, especially lysine, are greatly increased. The pathogenesis of hyperammonemia is not well understood. All enzymes of the urea cycle are normal. Hyperammonemia may be related to disruption of the urea cycle secondary to deficiency of arginine and ornithine. However, in patients with cystinuria who also have defects in the transport of lysine, arginine, and ornithine in both intestine and kidneys, hyperammonemia is not observed. Plasma concentrations of alanine, glutamine, serine, glycine, proline, and citrulline are usually increased. Anemia, increased serum levels of ferritin, LDH, and thyroxine-binding globulin, have also been observed in these patients. This condition should be differentiated from hyperammonemia caused by urea cycle defects (see Chapter 85.12), especially in heterozygous females with OTC deficiency. Increased urinary excretion of lysine, ornithine, and arginine and elevated blood levels of citrulline are not seen in patients with OTC deficiency.

The transport defect in this condition resides in the basolateral (antiluminal) membrane of enterocytes and renal tubular epithelia. This explains the observation that cationic amino acids are unable to cross these cells even when administered as dipeptides. Lysine in the form of dipeptide crosses the luminal membrane of the enterocytes but hydrolyzes to free lysine molecules in the cytoplasm. Free lysine, unable to cross the basolateral membrane of the cells, diffuses back into the lumen.

Treatment with a low-protein diet (1.0-1.5 g/kg/24 hr) supplemented with citrulline (100 mg/kg/day) has produced biochemical and clinical improvements. Episodes of hyperammonemia should be treated promptly (see Chapter 85.12). Supplementation with lysine is not useful because it is poorly absorbed and tends to produce diarrhea and abdominal pain. Diet therapy has no effect in prevention or amelioration of the multisystem manifestations. Treatment with high doses of prednisone has been effective in the management of acute pulmonary complications in some patients. Bronchopulmonary lavage is the treatment of choice for patients with alveolar proteinosis. The condition is most prevalent in Finland and Japan where the prevalence is 1 : 60,000 and 1 : 57,000 live births, respectively.

The gene for lysinuric protein intolerance *(SLC7A7)* is mapped to chromosome 14q11.2, and several disease-causing mutations have been identified in different families. Pregnancies in affected mothers have been complicated by anemia, thrombocytopenia, toxemia, and bleeding, but offspring have been normal.

Bibliography is available at Expert Consult.

85.15 Aspartic Acid (Canavan Disease)

Kimberlee M. Matalon and Reuben K. Matalon

N-Acetylaspartic acid, a derivative of aspartic acid, is synthesized in the brain and is found in a high concentration similar to glutamic acid. The exact function of *N*-acetylaspartic acid is unknown, but it may serve as a reservoir for acetate, which is needed for myelin synthesis. Aspartoacylase, cleaves the *N*-acetyl group from *N*-acetylaspartic acid. Deficiency of aspartoacylase, leads to Canavan disease, a severe **leukodystrophy**, characterized by excessive excretion of *N*-acetylaspartic acid and spongy degeneration of the white matter of the brain. Canavan disease is an autosomal recessive disorder and is more prevalent in individuals of Ashkenazi Jewish descent than in other ethnic groups. Aspartoacylase deficiency can be determined in skin fibroblasts, but the diagnosis is easy to ascertain by increased excretion of *N*-acetylaspartic acid in the urine. The gene for Canavan disease has been cloned, and mutations can be measured in patients, family members, and at-risk populations.

ETIOLOGY AND PATHOLOGY

The deficiency of the enzyme aspartoacylase leads to the accumulation of *N*-acetylaspartic acid in the brain, especially in white matter, and massive urinary excretion of this compound. Excessive amounts of *N*-acetylaspartic acid are also present in the blood and CSF. Brain biopsies of patients with Canavan disease show spongy degeneration of the myelin fibers, astrocytic swelling, and elongated mitochondria. There is striking vacuolization and astrocytic swelling in white matter. Electron microscopy reveals distorted mitochondria. As the disease progresses, the ventricles enlarge, owing to cerebral atrophy.

CLINICAL MANIFESTATIONS

The severity of Canavan disease covers a wide spectrum. Infants usually appear normal at birth and may not manifest symptoms of the disease until 3-6 mo of age, when they develop **progressive macrocephaly**, severe hypotonia, persistent head lag, and delayed milestones. As the disease progresses, there is spasticity, joint stiffness, and contractures. Optic atrophy and seizures develop. Feeding difficulties, poor weight gain, and gastroesophageal reflux may occur in the 1st yr of life; swallowing deteriorates, and nasogastric feeding or permanent gastrostomy may be required. Most patients die in the 1st decade of life; with improved nursing care, they may survive through the second decade.

ATYPICAL CANAVAN DISEASE

Juvenile or mildly affected patients with Canavan disease usually present with mild developmental delay, although 1 patient also had a large head and retinitis pigmentosa. These children have moderately increased urinary excretion of *N*-acetylaspartic acid, which suggests Canavan disease. Brain MRI demonstrates increased signal intensity in the basal ganglia rather than global white matter disease, sometimes leading to confusion with mitochondrial disease.

Diagnosis

In a typical patient with Canavan disease, CT scan and MRI reveal diffuse white matter degeneration, primarily in the cerebral hemispheres, with less involvement of the cerebellum and brainstem (Fig. 85-15). Repeated evaluations may be required. MRS performed at the time MRI is done can show the high peak of *N*-acetylaspartic acid, suggesting Canavan disease. The definitive diagnosis can be established by finding elevated amounts of *N*-acetylaspartic acid in the urine or

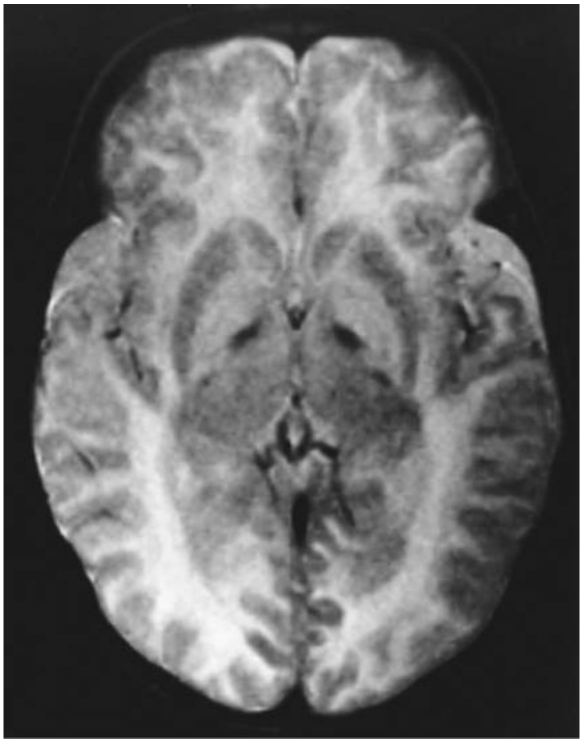

Figure 85-15 Axial T-weighted MRI of a 2 yr old patient with **Canavan disease.** Extensive thickening of the white matter is seen.

blood. A deficiency of aspartoacylase can be found in cultured skin fibroblasts. The biochemical method is the preferred choice for diagnosis. *N*-acetylaspartic acid is found only in trace amounts (24 ± 16 µmol/mmol creatinine) in the urine of unaffected individuals, whereas in patients with Canavan disease its concentration is in the range of 1,440 ± 873 µmol/mmol creatinine. High levels of *N*-acetylaspartic acid can also be detected in plasma, CSF, and brain tissue. The activity of aspartoacylase in the fibroblasts of obligate carriers is less than or equal to half of the activity found in normal individuals. The differential diagnosis of Canavan disease should include Alexander disease, which is another leukodystrophy associated with macrocephaly. Alexander disease is caused by a defect in the synthesis of glial fibrillary acidic protein and the diagnosis can be ruled out by molecular diagnosis on blood lymphocytes.

There are 2 mutations leading to Canavan disease predominant in the Ashkenazi Jewish population. The first is an amino acid substitution (E285A) in which glutamic acid is substituted for alanine. This mutation is the most frequent and encompasses 83% of 100 mutant alleles examined in Ashkenazi Jewish patients. The second common mutation is a change from tyrosine to a nonsense mutation, leading to a stop in the coding sequence (Y231X). This mutation accounts for 13% of the 100 mutant alleles. In the non-Jewish population, more diverse mutations have been observed, and the 2 mutations common in Jewish people are rare. A different mutation (A305E), the substitution of alanine for glutamic acid, accounts for 40% of 62 mutant alleles in non-Jewish patients. More than 50 mutations are described in the non-Jewish population. With Canavan disease, it is important to obtain a molecular diagnosis because this will lead to accurate counseling and prenatal guidance for the family. If the mutations are not known, prenatal diagnosis relies on the level of *N*-acetylaspartic acid in the amniotic fluid. In Ashkenazi Jewish patients, the carrier frequency can be as high as 1:36, which is close to that of Tay-Sachs disease. Carrier screening for Canavan disease is available for Jewish individuals. Genotype phenotype correlation and aspartoacylase expression show that expression studies may aid in understanding the disease.

Patients with juvenile or mild forms of Canavan disease have been compound heterozygotes with a mild mutation on one allele and a severe mutation on the other mutation. Mild mutations include p.Tyr288Cys and p.Arg71His.

Treatment and Prevention

No specific treatment is available. Feeding problems and seizures should be treated on an individual basis. Genetic counseling, carrier testing, and prenatal diagnosis are the only methods of prevention. Gene therapy attempts in children with Canavan disease have shown lack of long-term adverse events, some decrease in the brain elevation of *N*-acetylaspartic acid, improved seizure frequency, and stabilization of overall clinical status. There are ongoing trials of glycerol-triacetate as a supplement for acetate deficiency.

Bibliography is available at Expert Consult.

Chapter 86

Defects in Metabolism of Lipids

86.1 Disorders of Mitochondrial Fatty Acid β-Oxidation

Charles A. Stanley and Michael J. Bennett

Mitochondrial β-oxidation of fatty acids is an essential energy-producing pathway. It is a particularly important pathway during prolonged periods of starvation, and during periods of reduced caloric intake because of gastrointestinal illness or increased energy expenditure during febrile illness. Under these conditions, the body switches from using predominantly carbohydrate to predominantly fat as its major fuel. Fatty acids are also important fuels for exercising skeletal muscle and are the preferred substrate for the heart. In these tissues, fatty acids are completely oxidized to carbon dioxide and water. The end products of hepatic fatty acid oxidation are the ketone bodies β-hydroxybutyrate and acetoacetate. These cannot be oxidized by the liver but are exported to and serve as important fuels in peripheral tissues, particularly the brain, which can partially substitute ketone bodies for glucose during periods of fasting.

Genetic defects have been identified in nearly all of the known steps in the fatty acid oxidation pathway; all are recessively inherited (Table 86-1).

Clinical manifestations characteristically involve those tissues with a high β-oxidation flux, including liver, skeletal, and cardiac muscle. The most common presentation is an acute episode of life-threatening coma and hypoglycemia induced by a period of fasting because of defective hepatic ketogenesis. Other manifestations may include chronic cardiomyopathy and muscle weakness or exercise-induced acute rhabdomyolysis. The fatty acid oxidation defects can often be asymptomatic during periods when there is no fasting stress. Acutely presenting disease may be misdiagnosed as **Reye syndrome** or, if fatal, as **sudden unexpected infant death**. Fatty acid oxidation disorders are easily overlooked because the only specific clue to the diagnosis may be the finding of inappropriately low concentrations of urinary ketones in an infant who has hypoglycemia. Genetic defects in ketone body utilization may also be overlooked because ketosis is an expected finding with fasting hypoglycemia. In some circumstances, clinical manifestations appear to arise from toxic effects of fatty acid metabolites rather than inadequate energy production. These include disorders (long chain 3-hydroxyacyl dehydrogenase

Table 86-1 Mitochondrial Fatty Acid Oxidation Disorders—Clinical and Biochemical Features

ENZYME DEFICIENCY	GENE	CLINICAL PHENOTYPE	LABORATORY FINDINGS
Carnitine transporter	*OCTN2 SLC22A5*	Cardiomyopathy, skeletal myopathy, liver disease, sudden death, endocardial fibroelastosis, prenatal and newborn screening diagnosis reported	↓ Total and free carnitine, normal acylcarnitines, acylglycine, and organic acids
Long-chain fatty acid transporter	*FATP1-6*	Rare, acute liver failure in childhood requiring liver transplantation	Reduced intracellular C_{14}-C_{18} fatty acids, reduced fatty acid oxidation
Carnitine palmitoyl transferase-I	*CPT-IA*	Liver failure, renal tubulopathy, and sudden death. Prenatal and newborn screening diagnosis reported, maternal preeclampsia, HELLP syndrome association described in a few patients	Normal or ↑ free carnitine, normal acylcarnitines, acylglycine, and organic acids
Carnitine acylcarnitine translocase	*CACT SLC25A20*	Chronic progressive liver failure, persistent ↑ NH_3, hypertrophic cardiomyopathy. Newborn screening diagnosis reported	Normal or ↓ free carnitine, abnormal acylcarnitine profile
Carnitine palmitoyl transferase-II	*CPT-II*	Early and late onset types. Liver failure, encephalopathy, skeletal myopathy, cardiomyopathy, renal cystic changes, newborn screening diagnosis reported. Adult form with acute rhabdomyolysis, myoglobinuria	Normal or ↓ free carnitine, abnormal acylcarnitine profile
Short-chain acyl-CoA dehydrogenase	*SCAD ACADS*	Clinical phenotype is unclear. Many individuals appear to be normal. Others have a variety of inconsistent signs and symptoms. Subset may have severe manifestations of unclear relationship to biochemical defects. Newborn screening diagnosis reported; significance being questioned	Normal or ↓ free carnitine, elevated urine ethylmalonic acid, inconsistently abnormal acylcarnitine profile
Medium-chain acyl-CoA dehydrogenase	*MCAD ACADM*	Hypoglycemia, hepatic encephalopathy, sudden death. Newborn screening diagnosis possible, maternal preeclampsia, HELLP syndrome association described rarely	Normal or ↓ free carnitine, ↑ plasma acylglycine, plasma C_6-C_{10} free fatty acids, ↑ C_8-C_{10} acyl-carnitine
Very long-chain acyl-CoA dehydrogenase	*VLCAD ACADVL*	Dilated cardiomyopathy, arrhythmias, hypoglycemia, and hepatic steatosis. Late-onset, stress-induced rhabdomyolysis, episodic myopathy. Prenatal and newborn screening diagnosis possible.	Normal or ↓ free carnitine, ↑ plasma $C_{14:1}$, C_{14} acylcarnitine, ↑ plasma C_{10}-C_{16} free fatty acids
ETF dehydrogenase*	*ETF-DH*	Nonketotic fasting hypoglycemia, congenital anomalies, milder forms of liver disease, cardiomyopathy, and skeletal myopathy. Newborn screening diagnosis reported	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ acylcarnitine, urine organic acid and acylglycines
ETF-α*	*α-ETF*	Nonketotic fasting hypoglycemia, congenital anomalies, liver disease, cardiomyopathy, and skeletal myopathy also described. Newborn screening diagnosis reported	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ acylcarnitine, urine organic acid and acylglycines
ETF-β*	*β-ETF*	Fasting hypoglycemia, congenital anomalies, liver disease, cardiomyopathy, and skeletal myopathy also described. Newborn screening diagnosis reported	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ acylcarnitine, urine organic acid and acylglycines
Short-chain L-3-hydroxyacyl-CoA dehydrogenase	*SCHAD HADH*	Hyperinsulinemic hypoglycemia, cardiomyopathy, myopathy. Newborn screening diagnosis reported	Normal or ↓ free carnitine, elevated free fatty acids, inconsistently abnormal urine organic acid, ↑3-OH glutarate. ↑ plasma C_4-OH acylcarnitine
Long-chain L-3-hydroxyacyl-CoA dehydrogenase	*LCHAD HADH-A*	Newborn screening diagnosis reported, maternal preeclampsia, HELLP syndrome, and AFLP association described frequently. See also MTP below for clinical manifestations	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ C_{16}-OH and C_{18}-OH carnitines
MTP	*HADH-A, HADH-B*	Severe cardiac and skeletal myopathy, hypoglycemia, acidosis, hyper NH_3, sudden death, elevated liver enzymes, retinopathy. Maternal preeclampsia, HELLP syndrome, and AFLP association described frequently	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ C_{16}-OH and C_{18}-OH carnitines
Long-chain 3-ketoacyl-CoA thiolase	*LKAT HADH-B*	Severe neonatal presentation, hypoglycemia, acidosis, ↑ creatine kinase, cardiomyopathy, neuropathy, and early death	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ 2-*trans*, 4-*cis*-decadienoylcarnitine
2,4-Dienoyl-CoA reductase	*DECR1*	Only 1 patient described, hypotonia in the newborn, mainly severe skeletal myopathy and respiratory failure. Hypoglycemia rare	Normal or ↓ free carnitine, ↑ acyl:free carnitine ratio, normal urine organic acids and acylglycines

Continued

Table 86-1 Mitochondrial Fatty Acid Oxidation Disorders—Clinical and Biochemical Features—cont'd

ENZYME DEFICIENCY	GENE	CLINICAL PHENOTYPE	LABORATORY FINDINGS
HMG CoA synthetase	*HMGCS2*	Hypoketosis and hypoglycemia, rarely myopathy	Elevated total plasma fatty acids, enzyme studies in biopsied liver may be diagnostic, genetic testing is preferred
HMG CoA lyase	*HMGCL*	Hypoketosis and hypoglycemia, rarely myopathy	Normal free carnitine, ↑ C_5-OH, and methylglutaryl-carnitine, enzymes studies in fibroblasts may be diagnostic

*Also known as glutaric acidemia type II or multiple acyl-CoA dehydrogenase deficiency (MADD).

AFLP, acute fatty liver of pregnancy; CoA, coenzyme A; ETF, electron transport flavoprotein; HELLP, hemolysis, elevated liver enzymes, low platelets; MTP, mitochondrial trifunctional protein; NH_3, ammonia.

From Shekhawat PS, Matern D, Strauss AW: Fetal fatty oxidation disorders, their effect on maternal health and neonatal outcome: impact of expanded newborn screening on their diagnosis and management, Pediatr Res *57:78R–84R, 2005.*

[LCHAD], carnitine palmitoyltransferase-1A [CPT-IA], mitochondrial trifunctional protein [MTP; also known as TFP] deficiencies) in which the presence of a homozygous affected fetus increases the risk of a life-threatening illness in the heterozygote mother, resulting in acute fatty liver of pregnancy or **preeclampsia with HELLP** (hemolysis, elevated liver enzymes, low platelets) syndrome. Malformations of the brain and kidneys have been described in severe electron transfer flavoprotein (ETF), ETF dehydrogenase (ETF-DH), and carnitine palmitoyltransferase-2 (CPT-II) deficiencies that might reflect in utero toxicity of fatty acid metabolites or a developmental role for these enzymes. Progressive retinal degeneration, peripheral neuropathy, and chronic progressive liver disease have been identified in LCHAD and MTP deficiency. Newborn screening programs using tandem mass spectrometry detect characteristic acylcarnitines seen in many of these disorders and permit presymptomatic diagnosis. Screening programs have provided evidence to demonstrate that all the fatty acid oxidation disorders combined are among the most common inborn errors of metabolism.

Figures 86-1 and 86-2 outline the steps involved in the oxidation of a typical long-chain fatty acid. In the *carnitine cycle*, fatty acids are transported across the barrier of the inner mitochondrial membrane as acylcarnitine esters. Within the mitochondria, successive turns of the 4-step β-*oxidation cycle* convert the coenzyme A (CoA)-activated fatty acid to acetyl-CoA units. Two to 3 different chain-length specific isoenzymes are needed for each of these β-oxidation steps to accommodate the different-sized fatty acyl-CoA species. The electron transfer pathway carries electrons generated in the first β-oxidation step (acyl-CoA dehydrogenase) to the *electron transport chain* at the level of coenzyme Q for adenosine triphosphate production, while electrons generated from the third step (3-hydroxyacyl-CoA dehydrogenase) enter the *electron transport chain* at the level of complex 1. Most of the acetyl-CoA generated from hepatic β-oxidation flows through the *pathway of ketogenesis* to form β-hydroxybutyrate and acetoacetate.

DEFECTS IN THE β-OXIDATION CYCLE

Medium-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common fatty acid oxidation disorder. The disorder shows a strong founder effect; most patients have a northwestern European ancestry, and the majority of patients are homozygous for a single common missense mutation, an A-G transition at complementary DNA position 985 that changes a lysine to glutamic acid at residue 329 (K329E).

Clinical Manifestations

Previously undiagnosed affected patients usually present in the first 3 mo-5 yr of life with episodes of acute illness triggered by prolonged fasting (longer than 12-16 hr). Signs and symptoms include vomiting and lethargy, which rapidly progress to coma or seizures and cardiorespiratory collapse. Sudden unexpected infant death may occur. The liver may be slightly enlarged with fat deposition. Attacks are rare until the infant is beyond the first few months of life, presumably because of more frequent feedings at a younger age. Affected older infants are at higher risk of illness as they begin to fast through the night or are exposed to fasting stress during an intercurrent childhood illness. Presentation in the first days of life with neonatal hypoglycemia has been reported in newborns that were fasted inadvertently. Diagnosis of MCAD has occasionally been documented in previously healthy teenage and adult individuals, indicating that even patients who have been asymptomatic in infancy are still at risk for metabolic decompensation if exposed to sufficient periods of fasting. An unknown number may remain asymptomatic. Prior to routine newborn screening testing, as many as 25% of MCAD deficient cases died or suffered severe brain damage from their first episode. Most patients are now diagnosed in the newborn period by blood spot acylcarnitine screening, allowing the initiation of early treatment and prevention of many of the severe signs and symptoms.

Laboratory Findings

During acute episodes, hypoglycemia is usually present. Plasma and urinary ketone concentrations are inappropriately low (**hypoketotic hypoglycemia**). Because of the hypoketonemia, there is little or no metabolic acidosis, which is expected to be present in many children with hypoglycemia. Tests of liver function are abnormal, with elevations of liver enzymes (alanine aminotransferase, aspartate aminotransferase), elevated blood ammonia, and prolonged prothrombin and partial thromboplastin times. Liver biopsy at times of acute illness shows microvesicular or macrovesicular steatosis from triglyceride accumulation. During fasting stress or at times of acute illness, urinary organic acid profiles by gas chromatography/mass spectrometry show inappropriately low concentrations of ketones and elevated levels of medium-chain dicarboxylic acids (adipic, suberic, and sebacic acids) that derive from microsomal and peroxisomal omega oxidation of accumulated medium-chain fatty acids. Plasma and tissue concentrations of total carnitine are reduced to 25-50% of normal, and the fraction of total esterified carnitine is increased. This pattern of **secondary carnitine deficiency** is seen in most fatty acid oxidation defects and reflects competition between increased acylcarnitine levels and free carnitine for transport at the plasma membrane. Significant exceptions to this rule are the plasma membrane carnitine transporter, CPT-IA and β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase deficiencies that do not manifest secondary carnitine deficiency.

Diagnostic metabolite patterns include increased plasma $C_{8:0}$, $C_{10:0}$, and $C_{10:1}$ acylcarnitine species and increased urinary acylglycines including hexanoyl-propionyl, suberyl-propionyl, and 3-phenylpropionyl glycines. Newborn screening programs using tandem mass spectrometry, which almost all babies born in the United States receive, can diagnose presymptomatic MCAD deficiency based on the detection of the abnormal acylcarnitines in filter paper blood spots. In many cases, the diagnosis can be confirmed by finding the common A985G mutation. A second common variant, T199C, has been detected in infants with

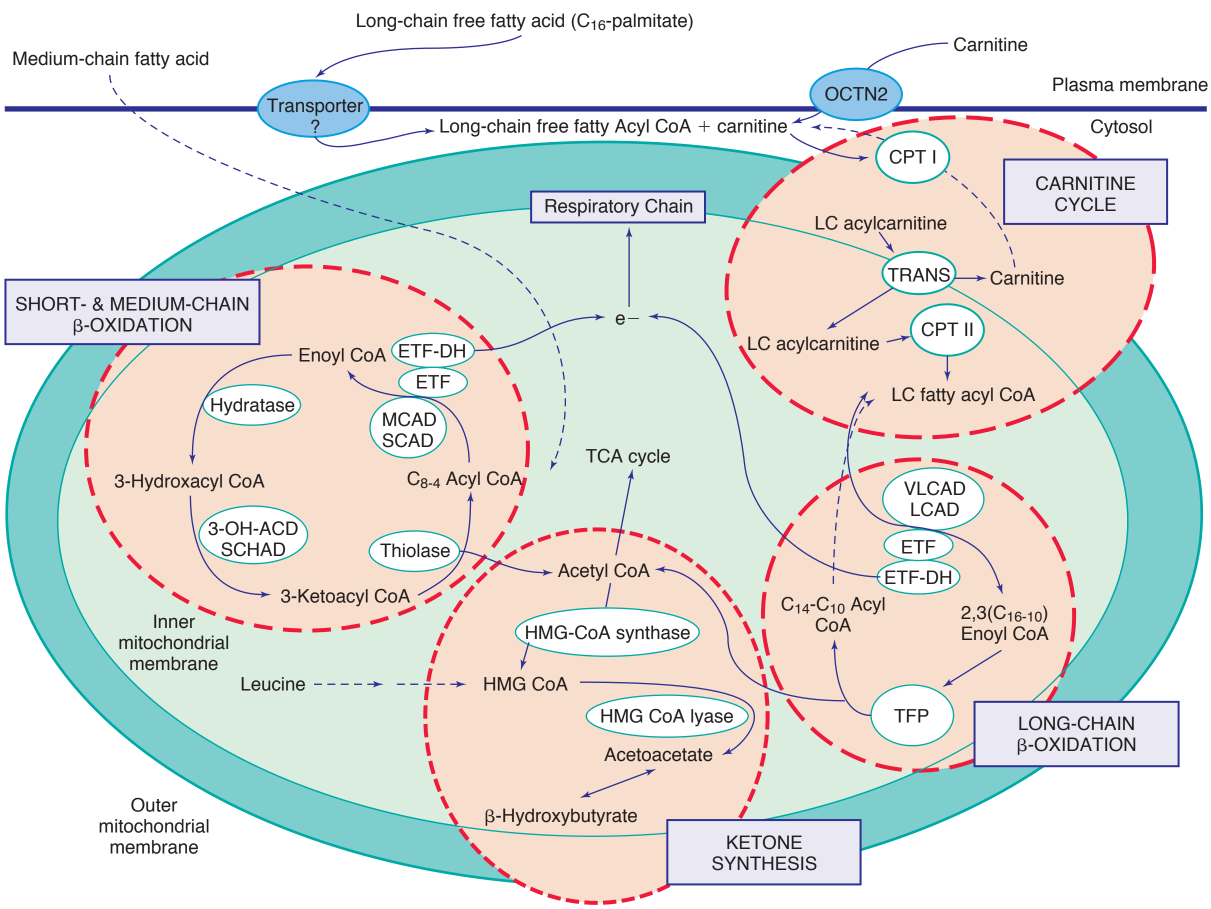

Figure 86-1 **Mitochondrial fatty acid oxidation.** Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long-chain fatty acid, is transported across the plasma membrane and can be activated to form a long-chain (LC) fatty acyl coenzyme A (CoA). It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into a long-chain fatty acyl-CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo β-oxidation. Very-long-chain acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of (C_{16}-C_{10}) 2,3 enoyl CoA. Mitochondrial trifunctional protein (MTP) contains the activities of enoyl CoA hydratase (hydratase), 3-OH-hydroxyacyl-CoA dehydrogenase (3-OH-ACD), and β-ketothiolase (thiolase). Acetyl-CoA, reduced form of flavin adenine dinucleotide (FADH), and reduced form of nicotinamide adenine dinucleotide (NADH) are produced. Medium- and short-chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short-chain acyl-CoA dehydrogenase (SCAD), and short-chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron transfer flavoprotein (ETF) and the electron transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. In liver, acetyl-CoA can be converted into hydroxymethylglutaryl (HMG) CoA by β-hydroxy-β-methylglutaryl-CoA synthase (HMG CoA synthase) and then the ketone body acetoacetate by the action of β-hydroxy-β-methylglutaryl-CoA lyase (HMG-CoA lyase).

characteristic acylcarnitines in newborn screening tests. Interestingly, this allele has not been seen to date in symptomatic MCAD patients; it may represent a milder mutation.

Treatment

Acute illnesses should be promptly treated with intravenous fluids containing 10% dextrose to treat or prevent hypoglycemia and to suppress lipolysis as rapidly as possible (see Chapter 92). Chronic therapy consists of avoiding fasting. This usually requires simply adjusting the diet to ensure that overnight fasting periods are limited to <10-12 hr. Restricting dietary fat or treatment with carnitine is controversial. The necessity for active therapeutic intervention for individuals with the T199C variant has not yet been established.

Prognosis

Up to 25% of unrecognized patients may die during their first attack of illness. There is frequently a history of a previous sibling death that is presumed to be from an unrecognized MCAD deficiency. Some patients may suffer permanent brain injury during an attack of profound hypoglycemia. The prognosis for survivors without brain damage is excellent because progressive cognitive impairment or cardiomyopathy does not occur in MCAD deficiency. Muscle pain and reduced exercise tolerance may become evident with increasing age. Fasting tolerance improves with age and the risk of illness decreases. Because as many as 35% of affected patients have never had an episode, testing of siblings of affected patients is important to detect asymptomatic family members.

Very-Long-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency is the second most commonly diagnosed disorder of fatty acid oxidation. It was originally termed long-chain acyl-CoA dehydrogenase deficiency before the existence of the inner mitochondrial membrane-bound VLCAD was known. *All patients previously diagnosed as having long-chain acyl-CoA dehydrogenase deficiency have VLCAD gene defects.* Patients with VLCAD deficiency have no ability to oxidize physiologic long-chain fatty acids and are usually more severely affected than those with MCAD deficiency who have a milder oxidative defect. VLCAD deficiency presents earlier in infancy and has more chronic problems

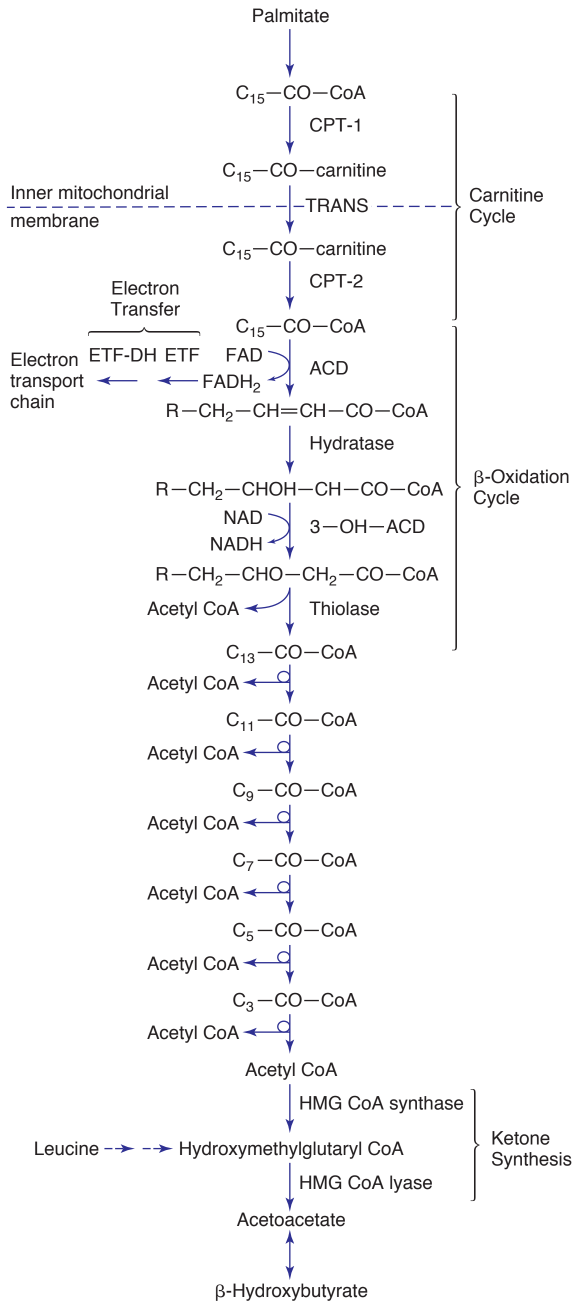

Figure 86-2 Pathway of mitochondrial oxidation of palmitate, a typical 16-carbon long-chain fatty acid. Enzyme steps include carnitine palmitoyltransferase (CPT) 1 and 2, carnitine/acylcarnitine translocase (TRANS), electron transfer flavoprotein (ETF), ETF dehydrogenase (ETF-DH), acyl-CoA dehydrogenase (ACD), enoyl CoA hydratase (hydratase), 3-hydroxy-acyl-CoA dehydrogenase (3-OH-ACD), β-ketothiolase (thiolase), β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase, and lyase.

with muscle weakness or episodes of muscle pain and rhabdomyolysis. Cardiomyopathy may be present during acute attacks provoked by fasting. The left ventricle may be hypertrophic or dilated and show poor contractility on echocardiography. Sudden unexpected death has occurred in several patients, but most who survived the initial episode showed improvement, including normalization of cardiac function. Other physical and routine laboratory features are similar to those of MCAD deficiency, including secondary carnitine deficiency. The urinary organic acid profile shows a nonketotic dicarboxylic aciduria with increased levels of $C_{6\text{-}12}$ dicarboxylic acids. Diagnosis may be suggested by an abnormal acylcarnitine profile with plasma or blood spot $C_{14:0,\ 14:1,\ 14:2}$ acylcarnitine species; however, the specific diagnosis requires mutational analysis of the VLCAD gene. Treatment is based primarily on avoidance of fasts for longer than 10-12 hr. Continuous intragastric feeding is useful in some patients.

Short-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

A small number of patients with 2 clear null mutations in the short-chain acyl-CoA dehydrogenase (SCAD) gene have been described with variable phenotype. Most individuals classified as being SCAD deficient have polymorphic DNA changes in the SCAD gene; for example, 2 common polymorphisms are G185S and R147W, which are homozygously present in 7% of the population. Some investigators argue that these may be susceptibility changes, which require a second, as yet unknown, genetic mutation to express a clinical phenotype; while others believe that SCAD deficiency is a harmless biochemical condition. This autosomal recessive disorder presents with neonatal hypoglycemia and may have normal levels of ketone bodies. The diagnosis is indicated by elevated levels of butyrylcarnitine (C4-carnitine) on newborn blood spots or plasma and increased excretion of urinary ethylmalonic acid and butyrylglycine. These metabolic abnormalities are most pronounced in patients with null mutations and variably present in patients who are homozygous for the common polymorphisms.

The necessity for treatment in SCAD deficiency has not yet been established. It has been proposed that long-term evaluation of asymptomatic individuals is necessary to determine whether this is or is not a real disease. Although most individuals with SCAD deficiency remain asymptomatic throughout life, it has been proposed that there is a subset of individuals with SCAD deficiency with severe manifestations, including dysmorphic facial features, feeding difficulties/failure to thrive, metabolic acidosis, ketotic hypoglycemia, lethargy, developmental delay, seizures, hypotonia, dystonia, and myopathy.

Long-Chain 3-Hydroxyacyl-CoA Dehydrogenase/Mitochondrial Trifunctional Protein Deficiency

The LCHAD enzyme is part of a MTP, which also contains 2 other steps in β-oxidation: long-chain enoyl CoA hydratase and long-chain β-ketothiolase. It is a heterooctameric protein composed of 4 α and 4 β chains that derive from distinct contiguous genes with a common promoter region. In some patients, only the LCHAD activity of the MTP is affected (LCHAD deficiency), whereas others have deficiencies of all 3 activities (MTP deficiency).

Clinical manifestations include attacks of acute hypoketotic hypoglycemia similar to MCAD deficiency; patients often show evidence of more severe disease, including cardiomyopathy, muscle cramps and weakness, and abnormal liver function (cholestasis). Toxic effects of fatty acid metabolites may produce pigmented retinopathy leading to blindness, progressive liver failure, peripheral neuropathy, and rhabdomyolysis. Life-threatening obstetric complications, acute fatty liver of pregnancy, and **HELLP** syndrome are observed in heterozygous mothers carrying homozygotic fetuses affected with LCHAD/MTP deficiency. Sudden unexpected infant death may occur. The diagnosis is indicated by elevated levels of blood spot or plasma 3-hydroxy acylcarnitines of chain lengths C_{16}-C_{18}. Urinary organic acid profile in patients may show increases in levels of 3-hydroxydicarboxylic acids of chain lengths C_6-C_{14}. Secondary carnitine deficiency is common. A common mutation in the α subunit, E474Q, is seen in more than 60% of LCHAD-deficient patients. This mutation in the fetus is especially associated with the obstetric complications, but other mutations in either subunit may also be linked to maternal illness.

Treatment is similar to that for MCAD or VLCAD deficiency; that is, avoiding fasting stress. Some investigators have suggested that dietary supplements with medium-chain triglyceride oil to bypass the defect in long-chain fatty acid oxidation and docosahexaenoic acid (for protection against the retinal changes) may be useful. Liver transplantation has been attempted in cases with severe liver failure, but does

not ameliorate the metabolic abnormalities or prevent the myopathic or retinal complications.

Short-Chain 3-Hydroxyacyl-Coenzyme A Dehydrogenase Deficiency

Only 12 patients with proven mutations of short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) have been reported, although a few additional unpublished cases are known to the authors. Most cases with recessive mutations of the SCHAD gene have presented with episodes of hypoketotic hypoglycemia that was caused by hyperinsulinism. In contrast to patients with other forms of fatty acid oxidation disorders, these cases required specific therapy with diazoxide for hyperinsulinism to avoid recurrent hypoglycemia. A single case with compound heterozygous mutations presented with fulminant hepatic failure at age 10 mo. The SCHAD protein has a nonenzymatic function (moonlighting) in which it directly interacts with glutamate dehydrogenase (GDH) to inhibit its activity. In the absence of an SCHAD protein, this inhibition is removed leading to upregulation of GDH enzyme activity, a recognized cause of hyperinsulinism usually caused by activating mutations of the GDH gene. This severe deficiency of SCHAD protein often presents predominantly as protein sensitive hypoglycemia rather than as fasting hypoglycemia. It appears that if a SCHAD protein is present the inhibition of GDH is maintained even when there is no SCHAD enzyme activity; these patients may present with a more traditional fatty acid oxidation defect. Specific metabolic markers for SCHAD deficiency include elevated plasma C4-hydroxy acylcarnitine and urine 3-hydroxyglutaric acid.

Treatment of SCHAD deficient patients with hyperinsulinism is with diazoxide. There is insufficient experience with the non-hyperinsulinemic form of SCHAD deficiency at present to recommend treatment modalities, but prevention of fasting seems advisable, which is similar to other fatty acid oxidation disorders.

DEFECTS IN THE CARNITINE CYCLE

Plasma Membrane Carnitine Transport Defect (Primary Carnitine Deficiency)

Primary carnitine deficiency is the only genetic defect in which carnitine deficiency is the cause, rather than the consequence, of impaired fatty acid oxidation. The most common presentation is progressive **cardiomyopathy** with or without **skeletal muscle weakness** beginning at 1-4 yr of age. A smaller number of patients may present with fasting hypoketotic hypoglycemia in the 1st yr of life before the cardiomyopathy becomes symptomatic. The underlying defect involves the plasma membrane sodium gradient-dependent carnitine transporter that is present in heart, muscle, and kidney. This transporter is responsible both for maintaining intracellular carnitine concentrations 20-50–fold higher than plasma concentrations and for renal conservation of carnitine.

Diagnosis of the carnitine transporter defect is aided by the fact that patients have extremely reduced carnitine levels in plasma and muscle (1-2% of normal). Heterozygote parents have plasma carnitine levels approximately 50% of normal. Fasting ketogenesis may be normal because liver carnitine transport is normal, but it may become impaired if dietary carnitine intake is interrupted. The fasting urinary organic acid profile may show a hypoketotic dicarboxylic aciduria pattern if hepatic fatty acid oxidation is impaired, but it is otherwise unremarkable. The defect in carnitine transport can be demonstrated clinically by the severe reduction in renal carnitine threshold or by in vitro assay of carnitine uptake using cultured fibroblasts or lymphoblasts. Mutations in the organic cation/carnitine transporter *(OCTN2)* underlie this disorder. Treatment with pharmacologic doses of oral carnitine (100-200 mg/kg/day) is highly effective in correcting the cardiomyopathy and muscle weakness, as well as any impairment in fasting ketogenesis. Muscle total carnitine concentrations remain <5% of normal on treatment.

Carnitine Palmitoyltransferase-IA Deficiency

Several dozen infants and children have been described with a deficiency of the liver and kidney carnitine palmitoyltransferase-I (CPT-I) isozyme (CPT-IA). Clinical manifestations include fasting hypoketotic hypoglycemia, occasionally with markedly abnormal liver function tests and, rarely, with renal tubular acidosis. The heart and skeletal muscle are not involved because the muscle isozyme is unaffected. Fasting urinary organic acid profile sometimes shows a hypoketotic C_6-C_{12} dicarboxylic aciduria but may be normal. Plasma acylcarnitine analysis demonstrates mostly free carnitine with very little acylated carnitine. This observation has been used to establish CPT-IA diagnosis on newborn screening by tandem mass spectrometry. CPT-IA deficiency is the only fatty acid oxidation disorder in which plasma total carnitine levels are elevated often to 150-200% of normal. This may be explained by the fact that the inhibitory effects of long-chain acylcarnitines on the renal tubular carnitine transporter are absent in CPT-IA deficiency. The enzyme defect can be demonstrated in cultured fibroblasts or lymphoblasts. CPT-IA deficiency in the fetus has been associated with acute fatty liver of pregnancy in the mother in a single case report. A common variant in the CPT-IA gene has been identified in individuals of Inuit background in the United States and First Nations tribes in Canada and Greenland. The variant is detected by a positive newborn acylcarnitine screen; enzyme activity is reduced by 80% and regulation by malonyl-CoA is lost. It has not been established if this is a pathologic DNA variant or an adaptation to ancient Inuit and First Nations high-fat diets. This variant is associated with an increased risk for sudden infant death syndrome. Treatment for the severe form of CPT-IA deficiency is similar to that for MCAD deficiency with avoidance of situations where fasting ketogenesis is necessary.

Carnitine:Acylcarnitine Translocase Deficiency

This defect of the inner mitochondrial membrane carrier protein for fatty acylcarnitines blocks the entry of long-chain fatty acids into the mitochondria for oxidation. The clinical phenotype of this disorder is characterized by a severe and generalized impairment of fatty acid oxidation. Most newborn patients present with attacks of fasting-induced hypoglycemia, hyperammonemia, and cardiorespiratory collapse. All symptomatic newborns have had evidence of cardiomyopathy and muscle weakness. Several patients with a partial translocase deficiency and milder disease without cardiac involvement have also been identified. No distinctive urinary or plasma organic acids are noted, although increased levels of plasma long-chain acylcarnitines of chain lengths C_{16}-C_{18} are reported. Diagnosis can be confirmed using genetic analysis. Functional carnitine:acylcarnitine translocase activity can be measured in cultured fibroblasts or lymphoblasts. Treatment is similar to that of other long-chain fatty acid oxidation disorders.

Carnitine Palmitoyltransferase-II Deficiency

Three forms of CPT-II deficiency have been described. The **severe neonatal lethal** presentation of this disorder is associated with a profound enzyme deficiency, and early death has been reported in several newborns with dysplastic kidneys, cerebral malformations, and mild facial anomalies. A milder, second defect, is associated with an **adult presentation** of episodic rhabdomyolysis. The first episode usually does not occur until late childhood or early adulthood. Attacks may be precipitated by prolonged exercise. There is aching muscle pain and myoglobinuria that may be severe enough to cause renal failure. Serum levels of creatine kinase are elevated to 5,000-100,000 units/L. Fasting hypoglycemia has not been described, but fasting may contribute to attacks of myoglobinuria. Muscle biopsy shows increased deposition of neutral fat. The myopathic presentation of CPT-II deficiency is associated with a common mutation S113L. This mutation produces a heat-labile protein that is unstable to increased muscle temperature during exercise resulting in the myopathic presentation. The **third intermediate** form of CPT-II deficiency presents in infancy/early childhood with fasting-induced hepatic failure, cardiomyopathy, and skeletal myopathy with hypoketotic hypoglycemia, but does not have the severe developmental changes seen in the neonatal lethal presentation. This pattern is similar to that seen in VLCAD deficiency and management is identical.

Diagnosis of all forms of CPT-II deficiency can be made by a combination of molecular analysis and demonstrating deficient enzyme activity in muscle or other tissues and in cultured fibroblasts.

DEFECTS IN THE ELECTRON TRANSFER PATHWAY

Electron Transfer Flavoprotein and Electron Transfer Flavoprotein Dehydrogenase Deficiencies (Glutaric Acidemia Type 2, Multiple Acyl-Coenzyme A Dehydrogenation Defects)

ETF and ETF-DH function to transfer electrons into the mitochondrial electron transport chain from dehydrogenation reactions catalyzed by VLCAD, MCAD, and SCAD, as well as by glutaryl-CoA dehydrogenase and 4 enzymes involved in branched-chain amino acid oxidation. Deficiencies of ETF or ETF-DH produce illness that combines the features of impaired fatty acid oxidation and impaired oxidation of several amino acids. Complete deficiencies of either protein are associated with severe illness in the newborn period, characterized by acidosis, hypoketotic hypoglycemia, coma, hypotonia, cardiomyopathy, and an unusual odor of sweaty feet caused by isovaleryl-CoA dehydrogenase inhibition. Some affected neonates have had facial dysmorphism and polycystic kidneys similar to that seen in severe CPT-II deficiency, which suggests that toxic effects of accumulated metabolites may occur in utero.

Diagnosis can be made from the urinary organic acid profile, which shows abnormalities corresponding to blocks in oxidation of fatty acids (ethylmalonate and C_6-C_{10} dicarboxylic acids), lysine (glutarate), and branched-chain amino acids (isovaleryl-, isobutyryl-, and α-methylbutyryl-glycine) and by molecular testing. Most severely affected infants do not survive the neonatal period.

Partial deficiencies of ETF and ETF-DH produce a disorder that may mimic MCAD deficiency or other milder fatty acid oxidation defects. These patients have attacks of fasting hypoketotic coma. The urinary organic acid profile reveals primarily elevations of dicarboxylic acids and ethylmalonate, derived from short-chain fatty acid intermediates. Secondary carnitine deficiency is present. Some patients with mild forms of ETF/ETF-DH deficiency benefit from treatment with high doses of riboflavin, which is a cofactor for the pathway of electron transfer.

DEFECTS IN KETONE SYNTHESIS PATHWAY

β-Hydroxy-β-Methylglutaryl-Coenzyme A Synthase Deficiency

See Chapter 85.6.

HMG-CoA synthase is the rate-limiting step in the conversion of acetyl-CoA derived from fatty acid β-oxidation in the liver to ketones. Several patients with this defect have recently been identified. The presentation is one of fasting **hypoketotic hypoglycemia** without evidence of impaired cardiac or skeletal muscle function. Urinary organic acid profile showed only a hypoketotic dicarboxylic aciduria. Plasma and tissue carnitine levels are normal, in contrast to all the other disorders of fatty acid oxidation. A separate synthase enzyme, present in cytosol for cholesterol biosynthesis, is not affected. The HMG-CoA synthase defect is expressed only in the liver and cannot be demonstrated in cultured fibroblasts. The gene has been cloned, and mutations in the affected patients have been characterized. Avoiding fasting is usually a successful treatment.

β-Hydroxy-β-Methylglutaryl-Coenzyme A Lyase Deficiency

See Chapter 85.6.

DEFECTS IN KETONE BODY UTILIZATION

The ketone bodies, β-hydroxybutyrate and acetoacetate, are the end products of hepatic fatty acid oxidation and are important metabolic fuels for the brain during fasting. Two defects in utilization of ketones in brain and other peripheral tissues present as episodes of **hyperketotic** coma, with or without hypoglycemia.

Succinyl-Coenzyme A:3-Ketoacid-Coenzyme A Transferase Deficiency

See Chapter 85.6.

Several patients with succinyl-CoA:3-ketoacid-CoA transferase (SCOT) deficiency have been reported. The characteristic presentation is an infant with recurrent episodes of severe ketoacidosis induced by fasting. Plasma acylcarnitine and urine organic acid abnormalities do not distinguish SCOT deficiency from other causes of ketoacidosis. Treatment of episodes requires infusion of glucose and large amounts of bicarbonate until metabolically stable. Patients usually exhibit inappropriate hyperketonemia even between episodes of illness. SCOT is responsible for activating acetoacetate in peripheral tissues using succinyl CoA as a donor to form acetoacetyl-CoA. Deficient enzyme activity can be demonstrated in brain, muscle, and fibroblasts from affected patients. The gene has been cloned, and numerous mutations have been characterized.

β-Ketothiolase Deficiency

See Chapter 85.6.

86.2 Disorders of Very Long Chain Fatty Acids

Gerald V. Raymond

PEROXISOMAL DISORDERS

The peroxisomal diseases are genetically determined disorders caused either by the failure to form or maintain the peroxisome or by a defect in the function of a single protein that is normally located in this organelle. These disorders cause serious disability in childhood and occur more frequently and present a wider range of phenotype than has been recognized in the past.

Etiology

Peroxisomal disorders are subdivided into 2 major categories (Table 86-2).

In category A, the **peroxisomal biogenesis disorders (PBDs)**, the basic defect is the failure to import 1 or more proteins into the organelle. In category B, **defects affect a single peroxisomal protein**. The peroxisome is present in all cells except mature erythrocytes and is a subcellular organelle surrounded by a single membrane; more than 50

Table 86-2 Classification of Peroxisomal Disorders

A: DISORDERS OF PEROXISOME IMPORT
A1: Zellweger syndrome
A2: Neonatal adrenoleukodystrophy
A3: Infantile Refsum disease
A4: Rhizomelic chondrodysplasia punctata
B: DEFECTS OF SINGLE PEROXISOMAL ENZYME
B1: X-linked adrenoleukodystrophy
B2: Acyl-CoA oxidase deficiency
B3: Bifunctional enzyme deficiency
B4: Peroxisomal thiolase deficiency
B5: Classic Refsum disease
B6: 2-Methylacyl-CoA racemase deficiency
B7: DHAP acyltransferase deficiency
B8: Alkyl-DHAP synthase deficiency
B9: Mevalonic aciduria
B10: Glutaric aciduria type III
B11: Hyperoxaluria type I
B12: Acatalasemia

peroxisomal enzymes are identified. Some enzymes are involved in the production and decomposition of hydrogen peroxide; others are concerned with lipid and amino acid metabolism. Most peroxisomal enzymes are first synthesized in their mature form on free polyribosomes and enter the cytoplasm. Proteins that are destined for the peroxisome contain specific peroxisome targeting sequences (PTSs). Most peroxisomal matrix proteins contain PTS1, a 3-amino acid sequence at the carboxyl terminus. PTS2 is an aminoterminal sequence that is critical for the import of enzymes involved in plasmalogen and branched-chain fatty acid metabolism. Import of proteins involves a complex series of reactions that involves at least 23 distinct proteins. These proteins, referred to as peroxins, are encoded by *PEX* genes.

Epidemiology

Except for X-linked adrenoleukodystrophy (ALD), all the peroxisomal disorders in Table 86-2 are **autosomal recessive traits**. ALD is the most common peroxisomal disorder, with an estimated incidence of 1 in 17,000 live births. The combined incidence of the other peroxisomal disorders is estimated to be 1 in 50,000 live births.

Pathology

Absence or reduction in the number of peroxisomes is pathognomonic for disorders of peroxisome biogenesis. In most disorders, there are membranous sacs that contain peroxisomal integral membrane proteins, which lack the normal complement of matrix proteins; these are peroxisome "ghosts." Pathologic changes are observed in most organs and include profound and characteristic defects in neuronal migration; micronodular cirrhosis of the liver; renal cysts; chondrodysplasia punctata; sensorineural hearing loss; retinopathy; congenital heart disease; and dysmorphic features.

Pathogenesis

It is likely that all pathologic changes are secondary to the peroxisome defect. Multiple peroxisomal enzymes fail to function in the PBDs (Table 86-3). The enzymes that are diminished or absent are synthesized but are degraded abnormally fast because they may be unprotected outside of the peroxisome. It is not clear how defective peroxisome functions lead to the widespread pathologic manifestations.

Mutations in 12 different *PEX* genes have been identified in PBDs. The pattern and severity of pathologic features vary with the nature of the import defects and the degree to which import is impaired. These gene defects lead to disorders that were named before their relationship to the peroxisome was recognized, namely, Zellweger syndrome, neonatal ALD, infantile Refsum disease, and rhizomelic chondrodysplasia punctata (RCDP). The first 3 disorders are considered to form a clinical continuum, with Zellweger syndrome the most severe, infantile Refsum disease the least severe, and neonatal ALD intermediate. They can be caused by mutations in any of the 11 genes involved in peroxisome assembly. The specific gene defects cannot be distinguished on the basis of clinical features. The clinical severity varies with the degree to which protein import is impaired. Mutations that abolish import completely are often associated with the Zellweger syndrome phenotype, whereas a missense mutation, in which some degree of import function is retained, leads to the somewhat milder phenotypes. A defect in *PEX7,* which involves the import of proteins that utilize PTS2, is associated with RCDP. *PEX7* defects that leave import partially intact are associated with milder phenotypes, some of which resemble classic Refsum disease.

The genetic disorders that involve single peroxisomal enzymes usually have clinical manifestations that are more restricted and relate to the single biochemical defect. The primary adrenal insufficiency of ALD is caused by accumulation of very-long-chain fatty acids (VLCFAs) in the adrenal cortex, and the peripheral neuropathy in Refsum disease is caused by the accumulation of phytanic acid in Schwann cells and myelin.

Table 86-3	Abnormal Laboratory Findings Common to Disorders of Peroxisome Biogenesis
Peroxisomes absent to reduced in number	
Catalase in cytosol	
Deficient synthesis and reduced tissue levels of plasmalogens	
Defective oxidation and abnormal accumulation of very-long-chain fatty acids	
Deficient oxidation and age-dependent accumulation of phytanic acid	
Defects in certain steps of bile acid formation and accumulation of bile acid intermediates	
Defects in oxidation and accumulation of L-pipecolic acid	
Increased urinary excretion of dicarboxylic acids	

Peroxisomal Biogenesis Disorders with Milder or Atypical Phenotypes

Newborn infants with **Zellweger syndrome** show striking and consistent recognizable abnormalities. Of central diagnostic importance are the typical facial appearance (high forehead, unslanting palpebral fissures, hypoplastic supraorbital ridges, and epicanthal folds; Fig. 86-3), severe weakness and hypotonia, neonatal seizures, and eye abnormalities. Because of the hypotonia and craniofacial appearance, Down syndrome may be suspected. Infants with Zellweger syndrome rarely live more than a few months. More than 90% show postnatal growth failure. Table 86-4 lists the main clinical abnormalities.

Patients with **neonatal ALD** show fewer, less-prominent craniofacial features. Neonatal seizures occur frequently. Some degree of psychomotor developmental delay is present; function remains in the severely or profoundly retarded range, and development may regress after 3-5 yr of age, probably from a progressive leukodystrophy. Hepatomegaly, impaired liver function, pigmentary degeneration of the retina, and severely impaired hearing are invariably present. Adrenocortical function is usually impaired and may require adrenal hormone replacement. Chondrodysplasia punctata and renal cysts are absent.

Figure 86-3 **Four patients with Zellweger cerebrohepatorenal syndrome.** Note the high forehead, epicanthal folds, and hypoplasia of supraorbital ridges and midface. *(Courtesy of Hans Zellweger, MD.)*

Table 86-4 Main Clinical Abnormalities in Zellweger Syndrome

ABNORMAL FEATURE	Cases in Which the Feature Was Present NO.	%
High forehead	58	97
Flat occiput	13	81
Large fontanelle(s), wide sutures	55	96
Shallow orbital ridges	33	100
Low/broad nasal bridge	23	100
Epicanthus	33	92
High arched palate	35	95
External ear deformity	39	97
Micrognathia	18	100
Redundant skin fold of neck	13	100
Brushfield spots	5	83
Cataract/cloudy cornea	30	86
Glaucoma	7	58
Abnormal retinal pigmentation	6	40
Optic disc pallor	17	74
Severe hypotonia	94	99
Abnormal Moro response	26	100
Hyporeflexia or areflexia	56	98
Poor sucking	74	96
Gavage feeding	26	100
Epileptic seizures	56	92
Psychomotor retardation	45	100
Impaired hearing	9	40
Nystagmus	30	81

From Heymans HAS: Cerebro-hepato-renal (Zellweger) syndrome: clinical and biochemical consequences of peroxisomal dysfunctions. *Thesis, University of Amsterdam, 1984.*

Patients with **infantile Refsum disease** have survived to adulthood. They are able to walk, although gait may be ataxic and broad based. Cognitive function is in the severely impaired range. All have sensorineural hearing loss and pigmentary degeneration of the retina. They have moderately dysmorphic features that may include epicanthal folds, a flat bridge of the nose, and low-set ears. Early hypotonia and hepatomegaly with impaired function are common. Levels of plasma cholesterol and high- and low-density lipoprotein are often moderately reduced. Chondrodysplasia punctata and renal cortical cysts are absent. Postmortem study in infantile Refsum disease reveals micronodular liver cirrhosis and small hypoplastic adrenals. The brain shows no malformations, except for severe hypoplasia of the cerebellar granule layer and ectopic locations of the Purkinje cells in the molecular layer. The mode of inheritance is autosomal recessive.

Some patients with PBDs have milder and atypical phenotypes. They may present with peripheral neuropathy or with retinopathy, impaired vision, or cataracts in childhood, adolescence, or adulthood and have been diagnosed to have **Charcot-Marie-Tooth** disease or **Usher syndrome**. Some patients have survived to the 5th decade. Defects in *PEX7,* which most commonly lead to the RCDP phenotype, may also lead to a milder phenotype with clinical manifestations similar to those of classical Refsum disease (phytanoyl-CoA hydroxylase deficiency).

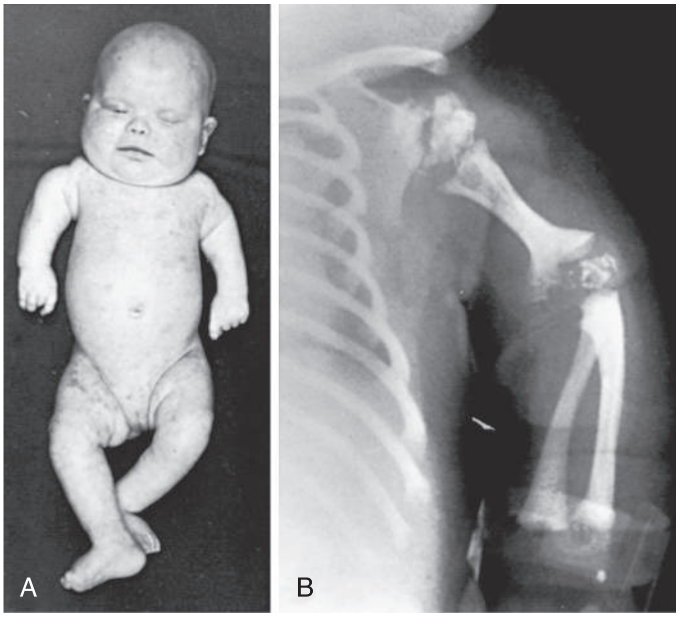

Figure 86-4 **A,** Newborn infant with rhizomelic chondrodysplasia punctata. Note the severe shortening of the proximal limbs, the depressed bridge of the nose, hypertelorism, and widespread scaling skin lesions. **B,** Note the marked shortening of the humerus and epiphyseal stippling at the shoulder and elbow joints. *(Courtesy of John P. Dorst, MD.)*

Rhizomelic Chondrodysplasia Punctata

RCDP is characterized by the presence of stippled foci of calcification within the hyaline cartilage and is associated with dwarfing, cataracts (72%), and multiple malformations caused by contractures. Vertebral bodies have a coronal cleft filled by cartilage that is a result of an embryonic arrest. Disproportionate short stature affects the proximal parts of the extremities (Fig. 86-4*A*). Radiologic abnormalities consist of shortening of the proximal limb bones, metaphyseal cupping, and disturbed ossification (Fig. 86-4*B*). Height, weight, and head circumference are less than the 3rd percentile, and these children have a severe intellectual disability. Skin changes such as those observed in ichthyosiform erythroderma are present in approximately 25% of patients.

Isolated Defects of Peroxisomal Fatty Acid Oxidation

The disorders labeled B1 through B3 (see Table 86-2) each involve 1 of 3 enzymes involved in peroxisomal fatty acid oxidation. Their clinical manifestations resemble those of the Zellweger spectrum disorder continuum; they can be distinguished from disorders of peroxisome biogenesis only by laboratory tests. Defects of bifunctional enzyme are common and are found in approximately 15% of patients with the Zellweger spectrum disorder. Patients with isolated acyl-CoA oxidase deficiency have a somewhat milder phenotype that resembles and come to attention because of the development of a childhood leukodystrophy.

Isolated Defects of Plasmalogen Synthesis

Plasmalogens are lipids in which the first carbon of glycerol is linked to an alcohol rather than a fatty acid. They are synthesized through a complex series of reactions, the first 2 steps of which are catalyzed by the peroxisomal enzymes dihydroxyacetone phosphate alkyl transferase and synthase. Deficiency of either of these enzymes (B4 and B5 in Table 86-2) leads to a phenotype that is clinically indistinguishable from the peroxisomal import disorder RCDP. This latter disorder is caused by a defect in *PEX7,* the receptor for PTS2. It shares the severe deficiency of plasmalogens with disorders B4 and B5 but, in addition, has defects of phytanic oxidation. The fact that disorders B4 and B5 are associated with the full phenotype of RCDP suggests that a deficiency of plasmalogens is sufficient to produce it.

Classic Refsum Disease

The defective enzyme (phytanoyl-CoA oxidase) is localized to the peroxisome. The manifestation of classic adult Refsum disease includes impaired vision from retinitis pigmentosa, ichthyosis, peripheral neuropathy, ataxia, and, occasionally, cardiac arrhythmias. In contrast to infantile Refsum disease, cognitive function is normal and there are no congenital malformations. Classic Refsum disease often does not manifest until young adulthood, but visual disturbances such as night blindness, ichthyosis, and peripheral neuropathy may already be present in childhood and adolescence. Early diagnosis is important because institution of a phytanic acid-restricted diet can reverse the peripheral neuropathy and prevent the progression of the visual and central nervous system manifestations. The classic Refsum disease phenotype may also be caused by defects in *PEX7*.

2-Methylacyl-Coenzyme A Racemase Deficiency

This disorder is caused by an enzyme defect that leads to the accumulation of the branched-chain fatty acids (phytanic and pristanic acid) and bile acids. Patients present with adult-type peripheral neuropathy and may also have pigmentary degeneration of the retina.

Laboratory Findings

Laboratory tests for peroxisomal disorders can be viewed at 3 levels of complexity.

Level 1: Does the Patient Have a Peroxisomal Disorder?

This can be resolved by noninvasive tests that are generally available (see Table 86-4). *Measurement of plasma VLCFA is the most commonly used assay*. Whereas plasma VLCFA levels are elevated in many patients with peroxisomal disorders, this is not always the case. The most important exception is RCDP, in which VLCFA levels are normal, but plasma phytanic acid levels are increased and red blood cell plasmalogen levels are reduced. In some other peroxisomal disorders, the biochemical abnormalities are still more restricted. Therefore, a panel of tests is recommended and includes plasma levels of VLCFA and phytanic, pristanic, and pipecolic acids and red blood cell levels of plasmalogens. Tandem mass spectrometry techniques also permit convenient quantitation of bile acids in plasma and urine. This panel of tests can be performed on 2 mL samples of venous blood and permits detection of most peroxisomal disorders. Furthermore, normal results make the presence of the typical peroxisomal disorder unlikely.

Level 2: What Is the Precise Nature of the Peroxisomal Disorder?

Table 86-5 lists the main biochemical abnormalities in the various peroxisomal disorders. When combined with the clinical presentation, the panel of level 1 tests (see above) is often sufficient to identify the precise nature of the defect. Marked reduction of erythrocyte plasmalogen levels combined with elevated plasma phytanic acid permits precise diagnosis in a patient with the clinical features of RCDP. Classic Refsum disease can be diagnosed by demonstration of increased plasma phytanic acid combined with normal or reduced levels of pristanic acid levels, while in D-bifunctional enzyme deficiency and 2-methylacyl-CoA racemase deficiency, the levels of pristanic and phytanic acid are both increased. Precise identification of some peroxisomal disorders may require more extensive studies in cultured skin fibroblasts. This may be required for the differentiation of PBDs from defects in bifunctional enzyme. In PBDs, the patient's peroxisomes are absent and catalase is in the soluble fraction, whereas in bifunctional enzyme defect, peroxisomes are present and catalase is in the particulate fraction. Fibroblast studies are required to identify the nature of the molecular defect in PBDs. Whether such specialized studies are clinically warranted depends on individual circumstances. Precise definition of the defect in a proband may improve the precision of prenatal diagnosis in at-risk pregnancies, and it is required for carrier detection. It is also of value in setting prognosis.

Level 3: What Is the Molecular Defect?

Definition of the molecular defect in the proband, which is now offered in several laboratories, is essential for carrier detection and speeds prenatal diagnosis. Characterization of the mutation may be of prognostic value in patients with *PEX1* defects. This defect is present in approximately 60% of PBD patients, and about half of the *PEX1* defects have the G843D allele, which is associated with a significantly milder phenotype than is found in other mutations.

Diagnosis

There are several noninvasive laboratory tests that permit precise and early diagnosis of peroxisomal disorders (see Table 86-4). The challenge in PBDs is to differentiate them from the large variety of other conditions that can cause hypotonia, seizures, failure to thrive, or dysmorphic features. Experienced clinicians can readily recognize classic Zellweger syndrome by its clinical manifestations. However, more mildly affected PBD patients often do not show the full clinical spectrum of disease and may be identifiable only by laboratory assays. Clinical features that serve as indications for these diagnostic assays include severe intellectual disability; weakness and hypotonia; dysmorphic features; neonatal seizures; retinopathy, glaucoma, or cataracts; hearing deficits; enlarged liver and impaired liver function; and chondrodysplasia punctata. The presence of 1 or more of these abnormalities increases the likelihood of this diagnosis. Atypical milder forms presenting as peripheral neuropathy have also been described.

Some patients with the isolated defects of peroxisomal fatty acid oxidation (group B) resemble those with group A disorders and can be detected by the demonstration of abnormally high levels of VLCFAs.

Patients with RCDP must be distinguished from patients with other causes of chondrodysplasia punctata. In addition to warfarin embryopathy and Zellweger syndrome, these disorders include the milder autosomal dominant form of chondrodysplasia punctata (Conradi-Hünermann syndrome), which is characterized by longer survival, absence of severe limb shortening, and usually intact intellect; an X-linked dominant form; and an X-linked recessive form associated with a deletion of the terminal portion of the short arm of the X chromosome. RCDP is suspected clinically because of the shortness of limbs, psychomotor retardation, and ichthyosis. The most decisive laboratory test is the demonstration of abnormally low plasmalogen levels in red blood cells and an impaired capacity to synthesize plasmalogens in cultured skin fibroblasts. These biochemical defects are not present in other types of chondrodysplasia punctata. Chondrodysplasia punctata may also be associated with a defect of 3β-hydroxysteroid-Δ^8,Δ^7-isomerase, an enzyme involved in biosynthesis of cholesterol.

Complications

Patients with Zellweger cerebrohepatorenal syndrome have multiple disabilities involving muscle tone, swallowing, cardiac abnormalities, liver disease, and seizures. These conditions are treated symptomatically, but the prognosis is poor, and most patients succumb in the first year of life. Patients with RCDP may develop quadriparesis owing to compression at the base of the brain.

Treatment

The most effective therapy is the dietary treatment of classic Refsum disease with a phytanic acid-restricted diet.

For patients with the somewhat milder variants of the peroxisome import disorders, success has been achieved with multidisciplinary early intervention, including physical and occupational therapy, hearing aids or cochlear implants, alternative communication, nutrition, and support for the parents. Although most patients continue to function in the severely delayed range, some make significant gains in self-help skills, and several are in stable condition in their teens or even early 20s.

Attempts to mitigate some of the secondary biochemical abnormalities include the oral administration of docosahexaenoic acid. The levels of this substance are greatly reduced in patients with disorders of peroxisome biogenesis and this therapy normalizes the plasma levels of

Table 86-5 Peroxisomal Disorders That Involve Fatty Acid Oxidation: Diagnostic Assays

DISEASE	ASSAY		FINDING
Zellweger syndrome Neonatal adrenoleukodystrophy Infantile Refsum disease	Plasma	VLCFA	Increased
		Phytanic acid	Age-dependent increase
		Pristanic acid	Age-dependent increase
		Pipecolic acid	Increased
		Bile acid	Increased, abnormal pattern
	RBCs	Plasmalogen levels	Variably decreased
	Fibroblasts	VLCFA levels	Increased

ALD, adrenoleukodystrophy; ALDP, adrenoleukodystrophy protein; CoA, coenzyme A; RBC, red blood cell; VLCFA, very-long-chain fatty acid.

this substance. Although there were anecdotal reports of clinical improvement, a randomized placebo-controlled study failed to find benefit.

Genetic Counseling

All the peroxisomal disorders, except hyperoxaluria type 1, can be diagnosed prenatally in the 1st or 2nd trimester. The tests are similar to those described for postnatal diagnosis (see Table 86-5) and use chorionic villus sampling or amniocytes. Because of the 25% recurrence risk, couples with an affected child must be advised about the availability of prenatal diagnosis. Heterozygotes can be identified in ALD and in those disorders in which the molecular defect has been identified.

ADRENOLEUKODYSTROPHY (X-LINKED)

ALD is a genetically determined disorder associated with the accumulation of saturated VLCFAs and a progressive dysfunction of the adrenal cortex and central and peripheral nervous system white matter.

Etiology

The key biochemical abnormality is the tissue accumulation of saturated VLCFAs, with a carbon chain length of 24 or more. Excess hexacosanoic acid ($C_{26:0}$) is the most striking and characteristic feature. This accumulation of fatty acids is caused by genetically deficient peroxisomal degradation of fatty acid. The gene that is defective *(ABCD1)* codes for a peroxisomal membrane protein (ALDP, the ALD protein). Most families have a mutation that is "private" (unique to that kindred)

and these are updated on the website, http://x-ald.nl. The mechanism by which the ALDP defect leads to VLCFA accumulation appears to be a disruption of transport of saturated fatty acids into the peroxisome with resultant continued elongation of progressively longer fatty acids.

Epidemiology

The minimum incidence of ALD in males is 1 in 21,000, and the combined incidence of ALD males and heterozygous females in the general population is estimated to be 1 in 17,000. All races are affected. The various phenotypes often occur in members of the same kindred.

Pathology

Characteristic lamellar cytoplasmic inclusions can be demonstrated with the electron microscope in adrenocortical cells, testicular Leydig cells, and nervous system macrophages. These inclusions probably consist of cholesterol esterified with VLCFA. They are most prominent in cells of the zona fasciculata of the adrenal cortex, which at first are distended with lipid and later atrophy.

The nervous system can display 2 types of lesions. In the severe childhood cerebral form and in the rapidly progressive adult forms, demyelination is associated with an inflammatory response manifested by the accumulation of perivascular lymphocytes that is most intense in the parietooccipital region. In the slowly progressive adult form, **adrenomyeloneuropathy**, the main finding is a distal axonopathy that affects the long tracts in the spinal cord. The inflammatory response is mild or absent.

Pathogenesis

The adrenal dysfunction is probably a direct consequence of the accumulation of VLCFAs. The cells in the zona fasciculata are distended with abnormal lipids. Cholesterol esterified with VLCFA is relatively resistant to adrenocorticotropic hormone (ACTH)-stimulated cholesterol ester hydrolases, and this limits the capacity to convert cholesterol to active steroids. In addition, $C_{26:0}$ excess increases the viscosity of the plasma membrane and this may interfere with receptor and other cellular functions.

There is no correlation between the neurologic phenotype and the nature of the mutation or the severity of the biochemical defect as assessed by plasma levels of VLCFAs or between the degree of adrenal involvement and nervous system involvement. The severity of the illness and rate of progression correlate with the intensity of the inflammatory response. The inflammatory response may be cytokine mediated and may involve an autoimmune response triggered in an unknown way by the excess of VLCFAs. Mitochondrial damage and oxidative stress also contribute. Approximately half of the patients do not experience the inflammatory response; this difference is not understood.

Clinical Manifestations

There are 5 relatively distinct phenotypes, 3 of which are present in childhood with symptoms and signs. In all the phenotypes, development is usually normal in the first 3-4 yr of life.

In the **childhood cerebral form** of ALD, symptoms are first noted most commonly between the ages of 4 and 8 yr. The most common initial manifestations are hyperactivity, which is often mistaken for an attention deficit disorder, and worsening school performance in a child who had previously been a good student. **Auditory discrimination** is often impaired, although tone perception is preserved. This may be evidenced by difficulty in using the telephone and greatly impaired performance on intelligence tests in items that are presented verbally. Spatial orientation is often impaired. Other initial symptoms are disturbances of vision, ataxia, poor handwriting, seizures, and strabismus. Visual disturbances are often caused by involvement of the cerebral cortex, which leads to variable and seemingly inconsistent visual capacity. **Seizures** occur in nearly all patients and may represent the first manifestation of the disease. Some patients present with increased intracranial pressure or with unilateral mass lesions. Impaired cortisol response to ACTH stimulation is present in 85% of patients, and mild hyperpigmentation is noted. In most patients with this phenotype, adrenal dysfunction is recognized only after the condition is diagnosed because of the cerebral symptoms. Cerebral childhood ALD tends to progress rapidly with increasing spasticity and paralysis, visual and hearing loss, and loss of ability to speak or swallow. The mean interval between the first neurologic symptom and an apparently vegetative state is 1.9 yr. Patients may continue in this apparently vegetative state for 10 yr or more.

Adolescent ALD designates patients who experience neurologic symptoms between the ages of 10 and 21 yr. The manifestations resemble those of childhood cerebral ALD except that progression is slower. Approximately 10% of patients present acutely with status epilepticus, adrenal crisis, acute encephalopathy, or coma.

Adrenomyeloneuropathy first manifests in late adolescence or adulthood as a progressive paraparesis caused by long tract degeneration in the spinal cord. Approximately half of the patients also have involvement of the cerebral white matter.

The **"Addison only"** phenotype is an important condition. Of male patients with Addison disease, 25% may have the biochemical defect of ALD. Many of these patients have intact neurologic systems, whereas others have subtle neurologic signs. Many acquire adrenomyeloneuropathy in adulthood.

The term "asymptomatic ALD" is applied to persons who have the biochemical defect of ALD but are free of neurologic or endocrinal disturbances. Nearly all persons with the gene defect eventually become neurologically symptomatic.

Approximately 50% of female heterozygotes acquire a syndrome that resembles adrenomyeloneuropathy but is milder and of later onset. Adrenal insufficiency and cerebral disease are rare.

Cases of typical ALD have occurred in relatives of those with adrenomyeloneuropathy. One of the most difficult problems in the management of X-linked ALD is the common observation that affected individuals in the same family may have quite different clinical courses. For example, in 1 family, 1 affected boy had severe classic ALD culminating in death by age 10 yr; another affected male (a brother) had late-onset adrenomyeloneuropathy, and a third had no symptoms at all.

Laboratory and Radiographic Findings

The most specific and important laboratory finding is the demonstration of abnormally high levels of VLCFA in plasma, red blood cells, or cultured skin fibroblasts. The test should be performed in a laboratory that has experience with this specialized procedure. Positive results are obtained in all male patients with ALD and in approximately 85% of female carriers of ALD. Mutation analysis is the most reliable method for the identification of carriers.

Neuroimaging

Patients with childhood cerebral or adolescent ALD show cerebral white matter lesions that are characteristic with respect to location and attenuation patterns on MRI. In 80% of patients, the lesions are symmetric and involve the periventricular white matter in the posterior parietal and occipital lobes. Approximately 50% show a garland of accumulated contrast material adjacent and anterior to the posterior hypodense lesions (Fig. 86-5*A*). This zone corresponds to the zones of intense perivascular lymphocytic infiltration where the blood–brain barrier breaks down. In 12% of patients, the initial lesions are frontal. Unilateral lesions that produce a mass effect suggestive of a brain tumor may occur. MRI provides a clearer delineation of normal and abnormal white matter than does CT (Fig. 86-5*B*).

Impaired Adrenal Function

More than 85% of patients with the childhood form of ALD have elevated levels of ACTH in plasma and a subnormal rise of cortisol levels in plasma following intravenous injection of 250 µg of ACTH (Cortrosyn).

Diagnosis and Differential Diagnosis

The earliest manifestations of childhood cerebral ALD are difficult to distinguish from the more common attention-deficit disorders or

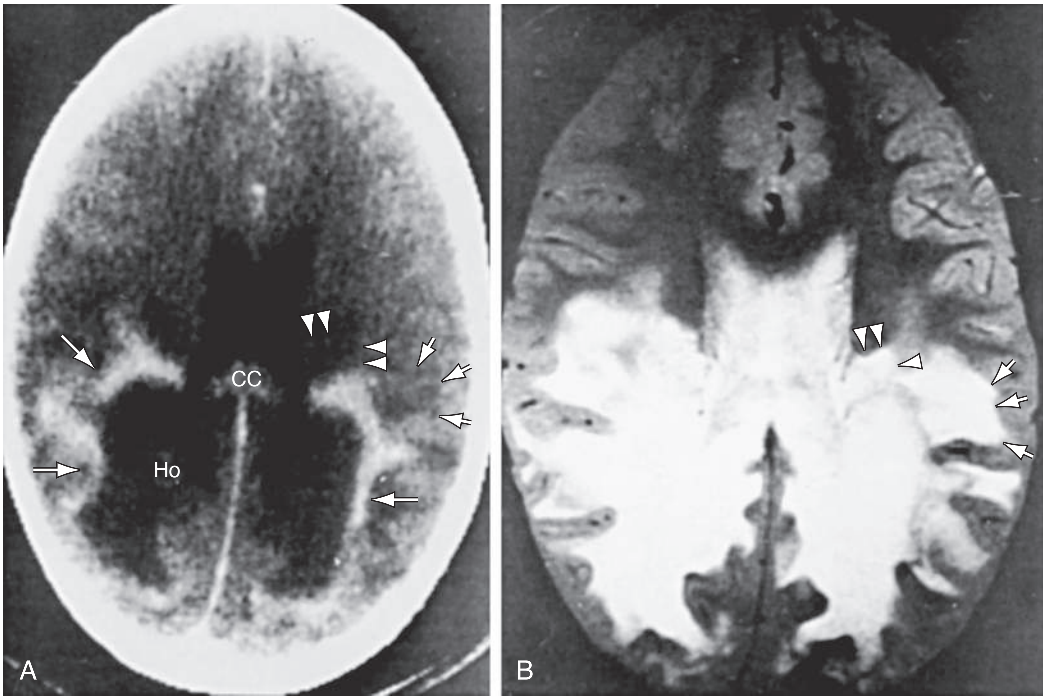

Figure 86-5 **A,** Contrast-enhanced CT abnormalities in adrenoleukodystrophy with typical parietooccipital location, showing symmetric bilateral hypodense inactive zones (Ho). The enhancing active periphery zone of hypodensity is demarcated by *arrows*. Compare the anterior zone of hypodensity *(arrowheads)* with that on the MRI in **B.** CC, corpus callosum. **B,** MRI of the same pattern and area shown by CT. MRI T2-weighted image shows a high-intensity signal of the abnormally bright parietooccipital white matter. Subcortical involvement is better identified on MRI. Separation of active zones may be better appreciated by CT, because both inactive and active zones are seen at high-signal areas on MRI. It is assumed, however, that such major distinctions afforded by CT will also be demonstrable when IV enhancement (paramagnetic enhancement) becomes readily available. Note the hypodense involvement of CT (*arrowheads* and *arrows* in **A**) compared with the well-resolved lesions on MRI in **B.** *(From Kumar AJ, Rosenbaum WE, Naidu S, et al: Adrenoleukodystrophy: corresponding MR imaging with CT,* Radiology *165:497–504, 1987.)*

learning disabilities. Rapid progression, signs of dementia, or difficulty in auditory discrimination suggest ALD. Even in early stages, CT or MRI may show strikingly abnormal changes. Other leukodystrophies or multiple sclerosis may mimic these radiographic findings, although early ALD has more of a predilection for the posterior brain than its mimics. Definitive diagnosis depends on demonstration of VLCFA excess, which occurs only in ALD and the other peroxisomal disorders.

Cerebral forms of ALD may present as increased intracranial pressure and unilateral mass lesions. These have been misdiagnosed as gliomas, even after brain biopsy, and several patients have received radiotherapy before the correct diagnosis was made. Measurement of VLCFA in plasma or brain biopsy specimens is the most reliable differentiating test.

Adolescent or adult cerebral ALD can be confused with **psychiatric disorders**, dementing disorders, or epilepsy. The first clue to the diagnosis of ALD may be the demonstration of white matter lesions by neuroimaging; assays of VLCFA are confirmatory.

ALD cannot be distinguished clinically from other forms of Addison disease; it is recommended that assays of VLCFA levels be performed in all male patients with Addison disease. ALD patients do not usually have antibodies to adrenal tissue in their plasma.

Complications

An avoidable complication is the occurrence of adrenal insufficiency. The most difficult neurologic problems are those related to bed rest, contracture, coma, and swallowing disturbances. Other complications involve behavioral disturbances and injuries associated with defects of spatial orientation, impaired vision and hearing, and seizures.

Treatment

Corticosteroid replacement for adrenal insufficiency or adrenocortical hypofunction is effective. It may be lifesaving and increase general strength and well-being, but it does not alter the course of the neurologic disability.

Bone Marrow Transplantation

Bone marrow transplantation (BMT) benefits patients who show early evidence of the inflammatory demyelination that is characteristic of the rapidly progressive neurologic disability in boys and adolescents with the cerebral ALD phenotype. BMT is a high-risk procedure, and patients must be selected with great care. The mechanism of the beneficial effect is incompletely understood. Bone marrow-derived cells do express ALDP, the protein that is deficient in ALD; approximately 50% of brain microglial cells are bone marrow derived. The favorable effect may be caused by modification of the brain inflammatory response. Five to 10 yr follow-up of boys and adolescents who had early cerebral involvement has shown stabilization. On the other hand, BMT has not shown favorable effects in patients who already had severe brain involvement and may accelerate disease progression under these circumstances. The nonverbal IQ has been found to be of predictive value, and transplant is not recommended in patients with performance IQ significantly below 80. Unfortunately, in more than half the patients who are diagnosed because of neurologic symptoms, the illness is so advanced at the time of diagnosis that they are not candidates for transplant.

Consideration of BMT is most relevant in neurologically asymptomatic or mildly involved patients. Screening at-risk relatives of symptomatic patients identifies these patients most frequently. Screening by measurement of plasma VLCFA levels in patients with Addison disease may also identify candidates for BMT. Because of its risk (10-20% mortality) and the fact that up to 50% of untreated patients with ALD do not develop inflammatory brain demyelination, transplant is not recommended in patients who are free of demonstrable brain involvement. The MRI is also of key importance for the crucial decision of whether transplant should be performed. MRI abnormalities precede

clinically evident neurologic or neuropsychologic abnormalities. The brain MRI should be monitored at 6 mo intervals in neurologically asymptomatic boys and adolescents between the ages of 3 and 15 yr. If the MRI is normal, BMT is not indicated. If brain MRI abnormalities develop, the patient should be evaluated at 3 mo intervals to determine if the abnormality is progressive, in combination with careful neurologic and neuropsychologic evaluation; and if early progressive involvement is confirmed, transplant should be considered. Magnetic resonance spectroscopy improves the capacity to determine whether the brain involvement is progressive. It is not known whether BMT has a favorable effect on the noninflammatory spinal cord involvement in adults with the adrenomyeloneuropathy phenotype.

Lorenzo's Oil Therapy

The administration of Lorenzo's oil to asymptomatic boys in an open study reduced the risk of developing the childhood cerebral phenotype by a factor of 2 or more. Lorenzo's oil (4 : 1 mixture of glyceryl trioleate and glyceryl trierucate) combined with a dietary regimen is under investigation for neurologically asymptomatic boys who have a normal brain MRI and are younger than 8 yr old. It has been determined that it must be supervised carefully. Adrenal function and brain MRI must be monitored. Patients who develop progressive MRI abnormalities are evaluated for hematopoietic stem cell transplant when changes are still in an early phase. Lorenzo's oil has not been shown to alter disease progression in patients who already have cerebral involvement.

Supportive Therapy

The progressive behavioral and neurologic disturbances associated with the childhood form of ALD are extremely difficult for the family. ALD patients require the establishment of a comprehensive management program and partnership among the family, physician, visiting nursing staff, school authorities, and counselors. In addition, parent support groups (e.g., United Leukodystrophy Foundation) are often helpful. Communication with school authorities is important because under the provisions of Public Law 94-142, children with ALD qualify for special services as "other health impaired" or "multihandicapped." Depending on the rate of progression of the disease, special needs might range from relatively low-level resource services within a regular school program to home- and hospital-based teaching programs for children who are not mobile.

Management challenges vary with the stage of the illness. The early stages are characterized by subtle changes in affect, behavior, and attention span. Counseling and communication with school authorities are of prime importance. Changes in the sleep–wake cycle can be benefited by the judicious use at night of medications for sleep.

As the leukodystrophy progresses, the modulation of muscle tone and support of bulbar muscular function are major concerns. Baclofen in gradually increasing doses (5 mg twice a day to 25 mg 4 times a day) is an effective pharmacologic agent for the treatment of acute episodic painful muscle spasms. Other agents may also be used, with care being taken to monitor the occurrence of side effects and drug interactions. As the leukodystrophy progresses, bulbar muscular control is lost. Although initially this can be managed by changing the diet to soft and pureed foods, most patients eventually require a gastrostomy tube. At least 30% of patients have focal or generalized seizures that usually readily respond to standard anticonvulsant medications.

Genetic Counseling and Prevention

Genetic counseling and primary and secondary prevention of ALD are of crucial importance. Extended family screening should be offered to all at-risk relatives of symptomatic patients; one program led to the identification of more than 250 asymptomatic affected males and 1,200 women heterozygous for ALD. The plasma assay permits reliable identification of affected males in whom plasma VLCFA levels are increased already on the day of birth. Identification of asymptomatic males permits institution of steroid replacement therapy when appropriate and prevents the occurrence of adrenal crisis, which may be fatal. Monitoring of brain MRI also permits identification of patients who are candidates for BMT at a stage when this procedure has the greatest chance of success. Plasma VLCFA assay is recommended in all male patients with Addison disease. ALD has been shown to be the cause of adrenal insufficiency in more than 25% of boys with Addison disease of unknown cause. Identification of women heterozygous for ALD is more difficult than that of affected males. Plasma VLCFA levels are normal in 15-20% of heterozygous women, and failure to note this has led to serious errors in genetic counseling. DNA analysis permits accurate identification of carriers, provided that the mutation has been defined in a family member, and is the procedure recommended for the identification of heterozygous women.

Prenatal diagnosis of affected male fetuses can be achieved by measurement of VLCFA levels in cultured amniocytes or chorionic villus cells and by mutation analysis. Whenever a new patient with ALD is identified, a detailed pedigree should be constructed and efforts should be made to identify all at-risk female carriers and affected males. These investigations should be accompanied by careful and sympathetic attention to social, emotional, and ethical issues during counseling.

86.3 Disorders of Lipoprotein Metabolism and Transport

William A. Neal and Collin C. John

EPIDEMIOLOGY OF BLOOD LIPIDS AND CARDIOVASCULAR DISEASE

The Seven Countries Study of geographic, social class, and ethnic differences in coronary heart disease (CHD) around the world found strong associations between average intake of saturated fats, plasma cholesterol, and mortality from CHD. Of all common chronic diseases, none is so clearly influenced by both environmental and genetic factors as CHD. This multifactorial disorder is strongly associated with increasing age and male gender, though it is increasingly apparent that heart disease is underrecognized in women. Tobacco use confers a 2-fold higher lifetime risk. Sedentary activity and high intake of saturated fats leading to adiposity increase risk through differences in the plasma levels of lipoproteins that are atherogenic. Family history is a reflection of the combined influence of lifestyle and genetic predisposition to early heart disease. Risk of premature heart disease associated with positive family history is 1.7 times higher than in families with no such history.

The pathogenesis of atherosclerosis begins during childhood. The Johns Hopkins Precursors Study demonstrated that white male medical students with blood cholesterol levels in the lowest quartile showed only a 10% incidence of CHD 3 decades later, whereas those in the highest quartile had a 40% incidence. The Pathobiological Determinants of Atherosclerosis in Youth Study demonstrated a significant relationship between the weight of the abdominal fat pad and the extent of atherosclerosis found at autopsy on subjects 15-34 yr of age. The Bogalusa Heart Study of more than 3,000 black and white children and adolescents has provided the most comprehensive longitudinal data relating the presence and severity of CHD risk factors with semi-quantifiable severity of atherosclerosis. Coronary atherosclerosis was present in 8.5% of military autopsies performed following combat or unintentional injuries.

The "fetal origins hypothesis" is based on the observation that infants born with low birthweight have a higher incidence of heart disease as adults. Epidemiologic studies support the idea that prenatal and early postnatal conditions may affect adult health status. Children who are large for gestational age at birth and exposed to an intrauterine environment of either diabetes or maternal obesity are at increased risk of eventually developing the "metabolic syndrome" (insulin resistance, type II diabetes, obesity, CHD). Breastfeeding preterm infants confers a long-term cardioprotective benefit 13-16 yr later. Those adolescents who were breastfed as infants had lower C-reactive protein

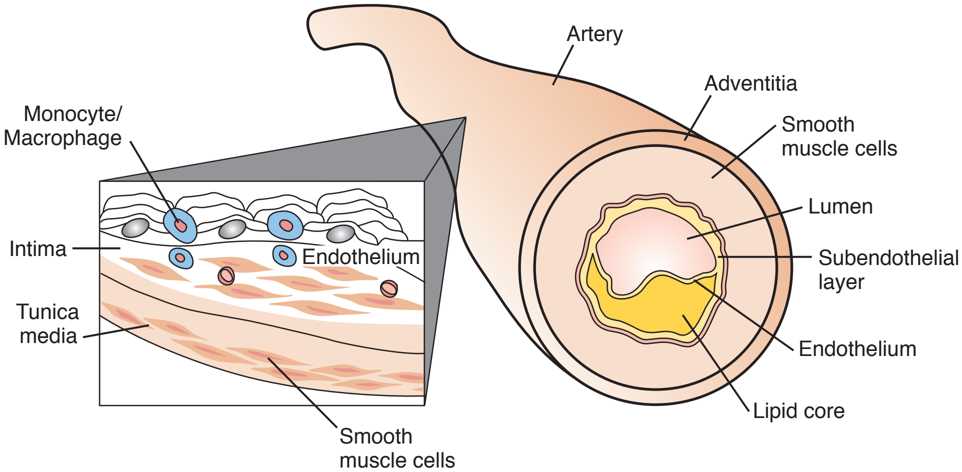

Figure 86-6 The early stage of development of atherosclerosis begins with penetration of the intimal lining of the vessel by inflammatory cells. Deposition of lipid within the subendothelial lining of the arterial wall eventually leads to disruption of smooth muscle cells to form an atheromatous lipid core that impinges on the lumen. Chronic inflammation leads to plaque instability, setting the stage for plaque rupture and complete occlusion of the vessel lumen by clot formation.

concentrations and a 14% lower low-density lipoprotein (LDL):high-density lipoprotein (HDL) ratio compared to those fed infant formulas. The impact of early nutrition and other lifestyle variables on gene expression, known as epigenetics, is an important mechanism by which adult metabolism and body composition may be determined.

In addition, secondary causes of hyperlipidemia may be the result of drugs (cyclosporine, steroids, isotretinoin, protease inhibitors, alcohol, thiazide diuretics, β-blocking agents, valproate) or various diseases (nephrotic syndrome, hypothyroidism, Cushing syndrome, anorexia nervosa, obstructive jaundice).

BLOOD LIPIDS AND ATHEROGENESIS

Numerous epidemiologic studies demonstrate the association of hypercholesterolemia, referring to elevated total blood cholesterol, with atherosclerotic disease. The ability to measure subcomponents within classes of lipid particles, as well as markers of inflammation, have further elucidated the process of atherogenesis and plaque rupture leading to acute coronary syndromes. Atherosclerosis affects primarily the coronary arteries but may also involve the aorta, arteries of the lower extremities, and carotid arteries.

The early stage of development of atherosclerosis is thought to begin with vascular endothelial dysfunction and intima-media thickness, which has been shown to occur in preadolescent children with risk factors such as obesity or familial hypercholesterolemia. The complex process of penetration of the intimal lining of the vessel may be a consequence of a variety of insults, including the presence of highly toxic oxidized LDL particles. Lymphocytes and monocytes penetrate the damaged endothelial lining, where they become macrophages laden with LDL lipids and then become foam cells. Such accumulation is counterbalanced by HDL particles capable of removing lipid deposits from the vessel wall. Fundamental to plaque formation is an inflammatory process (elevated C-reactive protein) involving macrophages and the arterial wall. The deposition of lipid within the subendothelial lining of the arterial wall appears macroscopically as fatty streaks, which may to some degree be reversible. A later stage of plaque development involves disruption of arterial smooth muscle cells stimulated by the release of tissue cytokines and growth factors. The atheroma is composed of a core of fatty substance separated from the lumen by collagen and smooth muscle (Fig. 86-6). Growth of the atherosclerotic plaque may result in ischemia of the tissue supplied by the artery. Chronic inflammation within the atheroma, results in plaque instability and subsequent rupture. Platelet adherence leads to clot formation at the site of rupture, resulting in myocardial infarction or a cerebrovascular event.

PLASMA LIPOPROTEIN METABOLISM AND TRANSPORT

Abnormalities of lipoprotein metabolism are associated with diabetes mellitus and premature atherosclerosis. Lipoproteins are soluble complexes of lipids and proteins that effect transport of fat absorbed from the diet, or synthesis by the liver and adipose tissues, for utilization and storage. Dietary fat is transported from the small intestine as chylomicrons. Lipids synthesized by the liver as very-low-density lipoproteins (VLDLs) are catabolized to intermediate-density lipoproteins (IDLs) and LDLs. HDLs are fundamentally involved in VLDL and chylomicron metabolism and cholesterol transport. Nonesterified free fatty acids are metabolically active lipids derived from lipolysis of triglycerides stored in adipose tissue bound to albumin for circulation in the plasma (Fig. 86-7).

Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins (Fig. 86-8). The density of the several classes of lipoproteins is inversely proportional to the ratio of lipid to protein (Fig. 86-9). Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins.

Constituent proteins are known as apolipoproteins (Table 86-6). They are responsible for a variety of metabolic functions in addition to their structural role, including cofactors or inhibitors of enzymatic pathways, and mediators of lipoprotein binding to cell surface receptors. ApoA is the major apolipoprotein (Apo) of HDL. ApoB is present in LDL, VLDL, IDL, and chylomicrons. ApoB-100 is derived from the liver, whereas apoB-48 comes from the small intestine. ApoC-I, C-II, and C-III are small peptides important in triglyceride metabolism. Loss of function and disruptive mutations of the *APOC3* gene are associated with low levels of triglycerides and a reduced risk of ischemic CHD. Likewise, apoE, which is present in VLDL, HDL, chylomicrons, and chylomicron remnants, plays an important role in the clearance of triglycerides.

Transport of Exogenous (Dietary) Lipids

All dietary fat with the exception of medium-chain triglycerides is efficiently carried into the circulation by way of lymphatic drainage from the intestinal mucosa. Triglyceride and cholesteryl esters combine with apoA and apoB-48 in the intestinal mucosa to form chylomicrons, which are carried into the peripheral circulation via the lymphatic system. HDL particles contribute apoC-II to the chylomicrons, required for the activation of lipoprotein lipase (LPL) within the capillary endothelium of adipose, heart, and skeletal muscle tissue. Free fatty acids are oxidized, esterified for storage as

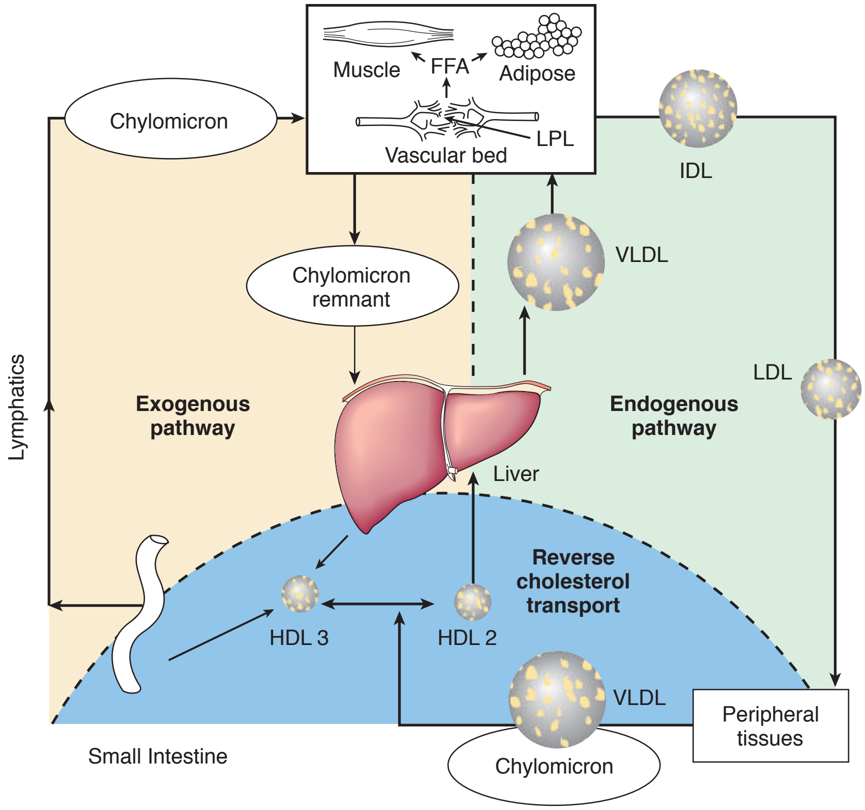

Figure 86-7 The exogenous, endogenous, and reverse cholesterol pathways. The exogenous pathway transports dietary fat from the small intestine as chylomicrons to the periphery and the liver. The endogenous pathway denotes the secretion of very-low-density lipoprotein (VLDL) from the liver and its catabolism to intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL). Triglycerides are hydrolyzed from the VLDL particle by the action of lipoprotein lipase (LPL) in the vascular bed, yielding free fatty acids (FFAs) for utilization and storage in muscle and adipose tissue. High-density lipoprotein (HDL) metabolism is responsible for the transport of excess cholesterol from the peripheral tissues back to the liver for excretion in the bile. Nascent HDL-3 particles derived from the liver and small intestine are esterified to more mature HDL-2 particles by enzyme-mediated movement of chylomicron and VLDL into the HDL core, which is removed from the circulation by endocytosis.

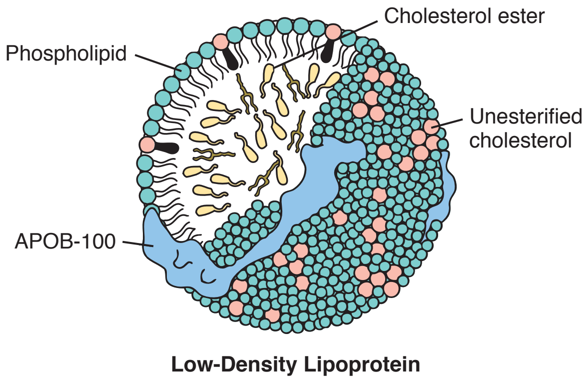

Figure 86-8 Schematic of low-density lipoprotein. Lipoprotein consists of a central core of cholesteryl esters, surrounded by phospholipids, cholesterol, and protein.

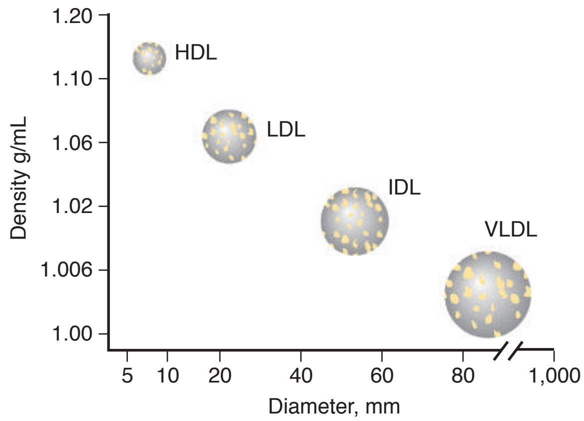

Figure 86-9 The density of the several classes of lipoprotein is inversely proportional to the ratio of lipid to protein. As lipid is less dense than protein, the more lipid contained in the particle increases its size and decreases its density. *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *IDL,* intermediate density lipoprotein; *VLDL,* very-low-density lipoprotein.

triglycerides, or released into the circulation bound to albumin for transport to the liver. After hydrolysis of the triglyceride core from the chylomicron, apoC particles are recirculated back to HDL. The subsequent contribution of apoE from HDL to the remnant chylomicron facilitates binding of the particle to hepatic LDL receptors (LDL-R). Within the hepatocyte, the chylomicron remnant may be incorporated into membranes, resecreted as lipoprotein back into the circulation, or secreted as bile acids. Normally, all dietary fat is disposed of within 8 hr after the last meal, an exception being individuals with a disorder of chylomicron metabolism. Postprandial hyperlipidemia is a risk factor for atherosclerosis. Abnormal transport of chylomicrons and their remnants may result in their absorption into the blood vessel wall as foam cells, caused by the ingestion of cholesteryl esters by macrophages, the earliest stage in the development of fatty streaks.

Transport of Endogenous Lipids from the Liver

The formation and secretion of VLDL from the liver and its catabolism to IDL and LDL particles describe the endogenous lipoprotein pathway. Fatty acids used in the hepatic formation of VLDL are derived primarily by uptake from the circulation. VLDL appears to be transported from the liver as rapidly as it is synthesized, and it consists of triglycerides, cholesteryl esters, phospholipids, and apoB-100. Nascent particles of VLDL secreted into the circulation combine with apoC and apoE. The size of the VLDL particle is determined by the amount of triglyceride present, progressively shrinking in size as triglyceride is hydrolyzed by the action of LPL, yielding free fatty acids for utilization

Table 86-6 Characteristics of the Major Lipoproteins

LIPOPROTEIN	SOURCE	SIZE (nm)	DENSITY (g/mL)	Composition %		
				PROTEIN	LIPID	APOLIPOPROTEINS
Chylomicrons	Intestine	80-1,200	<0.95	1-2	98-99	C-I, C-II, C-III, E, A-I, A-II, A-IV, B-48
Chylomicron remnants	Chylomicrons	40-150	<1.0006	6-8	92-94	B-48, E
VLDL	Liver, intestine	30-80	0.95-1.006	7-10	90-93	B-100, C-I, C-II, C-III
IDL	VLDL	25-35	1.006-1.019	11	89	B-100, E
LDL	VLDL	18-25	1.019-1.063	21	79	B-100
HDL	Liver, intestine VLDL, Chylomicrons	5-20	1.125-1.210	32-57	43-68	A-I, A-II, A-IV C-I, C-II, C-III D, E

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

or storage in muscle and adipose tissue. Hydrolysis of approximately 80% of the triglyceride present in VLDL particles produces IDL particles containing an equal amount of cholesterol and triglyceride. The remaining remnant IDL is converted to LDL for delivery to peripheral tissues or to the liver. ApoE is attached to the remnant IDL particle to allow binding to the cell and subsequent incorporation into the lysosome. Individuals with deficiency of either apoE2 or hepatic triglyceride lipase accumulate IDL in the plasma.

LDL particles account for approximately 70% of the plasma cholesterol in normal individuals. LDL receptors are present on the surfaces of nearly all cells. Most LDL is taken up by the liver, and the rest is transported to peripheral tissues such as the adrenal glands and gonads for steroid synthesis. Dyslipidemia is greatly influenced by LDL-R activity. The efficiency with which VLDL is converted into LDL is also important in lipid homeostasis.

High-Density Lipoprotein and Reverse Cholesterol Transport

As hepatic secretion of lipid particles into the bile is the only mechanism by which cholesterol can be removed from the body, transport of excess cholesterol from the peripheral cells is a vitally important function of HDL. HDL is heavily laden with apoA-I containing lipoproteins, which is nonatherogenic in contrast to B lipoproteins. Cholesterol-poor nascent HDL particles secreted by the liver and small intestine are esterified to more mature HDL-2 particles by the action of the enzyme lecithin-cholesterol acyltransferase (LCAT), which facilitates movement of chylomicrons and VLDL into the HDL core. HDL-2 may transfer cholesteryl esters back to apoB lipoproteins mediated by cholesteryl ester transfer protein (CETP), or the cholesterol-rich particle may be removed from the plasma by endocytosis, completing reverse cholesterol transport. Low HDL may be genetic (deficiency of apoA-I) or secondary to increased plasma triglyceride.

LCAT deficiency results in diminished maturation of HDL particles, affecting their ability to do reverse cholesterol transport. This reduces its protective effect on atherosclerosis. There are rare reports, however, of less-than-expected severity of atherosclerosis despite low HDL secondary to LCAT deficiency, suggesting that the relationship may, for unknown reasons, be variable.

HYPERLIPOPROTEINEMIAS

Hypercholesterolemia

See Table 86-7.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a monogenic autosomal codominant disorder characterized by strikingly elevated LDL cholesterol, premature cardiovascular disease (CVD), and tendon xanthomas. In the past, FH referred to defects of LDL receptor activity. However, genetic studies have broadened our understanding of the etiology of this lipoprotein abnormality to include defects in the genes for ApoB, as well as proprotein convertase subtilisin/kexin type 9. Severe hypercholesterolemia predisposing to premature CHD may be caused by other genetic abnormalities yet to be discovered. Of the nearly 800 mutations described, some result in failure of synthesis of the LDL receptor (receptor negative) and others cause defective binding or release at the lipoprotein-receptor interface. Receptor negative mutations result in more severe phenotypes than receptor defective mutations.

Homozygous Familial Hypercholesterolemia

FH homozygotes inherit 2 abnormal LDL receptor genes, resulting in markedly elevated plasma cholesterol levels ranging between 500 and 1,200 mg/dL. Triglyceride levels are normal to mildly elevated, and HDL levels may be slightly decreased. The condition occurs in 1 in 1,000,000 persons. Receptor-negative patients have <2% normal LDL receptor activity, whereas those who are receptor-defective may have as much as 25% normal activity and a better prognosis.

The prognosis is poor regardless of the specific LDL receptor aberration. Severe atherosclerosis involving the aortic root and coronary arteries is present by early to mid-childhood. These children usually present with xanthomas, which may cause thickening of the Achilles tendon or extensor tendons of the hands, or cutaneous lesions on the hands, elbows, knees, or buttocks (Figs. 86-10, 86-11, and 86-12). Corneal arcus may be present. Family history is informative because premature heart disease is strongly prevalent among relatives of both parents. The diagnosis may be confirmed by measuring LDL receptor activity in cultured skin fibroblasts. Phenotypic expression of the disease may also be assessed by measuring receptor activity on the surface of lymphocytes by using cell sorting techniques.

Untreated homozygous patients rarely survive to adulthood. Symptoms of coronary insufficiency may occur; sudden death is common. LDL apheresis to selectively remove LDL particles from the circulation is recommended for many children as it slows the progression of atherosclerosis. Liver transplantation is also successful in decreasing LDL cholesterol levels, but complications related to immunosuppression are common. HMG-CoA reductase inhibitors may be modestly effective depending on the specific class of LDL receptor defect present. Combination therapy with ezetimibe, selectively blocking cholesterol adsorption in the gut, usually results in further decline in LDL levels; it has largely replaced the use of bile acid sequestrants. Early clinical trials using microsomal triglyceride transfer protein inhibition with lomitapide resulted in a significant reduction in all apoB lipoproteins, including LDL, but hepatic fat deposition as a side effect limits consideration of this pharmacologic approach at this time. Mipomersen, an antisense oligonucleotide that binds to the sequence that encodes apolipoprotein B, reduces the synthesis of apoB and thus also VLDL and LDL; LDL cholesterol levels may decline approximately 25% with this treatment. Adverse effects include flu-like symptoms, hepatic steatosis, and cirrhosis.

Table 86-7 Hyperlipoproteinemias

DISORDER	LIPOPROTEINS ELEVATED	CLINICAL FINDINGS	GENETICS	ESTIMATED INCIDENCE
Familial hypercholesterolemia	LDL	Tendon xanthomas, CHD	AD	1 in 500

Heterozygous Familial Hypercholesterolemia

Heterozygous FH is one of the most common single-gene mutations associated with acute coronary syndromes and atherosclerotic CHD in adults. Its prevalence is approximately 1 in 500 individuals worldwide, but the frequency may be as high as 1 in 250 in selected populations, such as French-Canadians, Afrikaners, and Christian Lebanese, as a result of the founder effect of unique new mutations.

Heart disease accounts for more than half of all deaths in Western society. The pathogenesis of CHD is both environmental and genetic, and the complex interrelationship between the 2 determines the phenotypic expression of disease. Chinese people with heterozygous FH living in China have a mean LDL cholesterol of 168 mg/dL, whereas immigrant Chinese with the disease living in Canada average 288 mg/dL. This dramatic disparity in lipoprotein levels between geographic locations is expected to narrow as dietary and physical activity practices in China approximate those of the industrialized West.

Because heterozygous FH is a codominant condition with nearly full penetrance, 50% of first-degree relatives of affected individuals will have the disease, as will 25% of 2nd-degree relatives. An estimated 10 million people have FH worldwide. Symptoms of CHD usually occur at the mean age of 45-48 yr in males, and a decade later in females. Genetic testing of individuals who fulfill clinical criteria for the diagnosis of heterozygous FH is positive approximately 80% of the time.

The World Health Organization has targeted FH for individualized intervention strategies because of its large effect on morbidity and mortality. A relatively small percentage of the population accounts for a disproportionately high share of the burden of CVD. The clinical expression of the disease is straightforward and treatment is effective.

One cannot overemphasize the importance of family history for suspecting the possibility of FH. Indeed, the whole basis for deciding which children should have blood cholesterol testing is determined by a family history of premature CHD and/or parental hypercholesterolemia. In fact, the risk of CHD in individuals with FH can be as high as 20 times greater than the general population.

Plasma levels of LDL cholesterol do not allow unequivocal diagnosis of FH heterozygotes, but values are generally twice normal for age because of 1 absent or dysfunctional allele. The U.S. MED-PED ("make early diagnosis–prevent early death") Program based in Utah has formulated diagnostic criteria. Similar criteria with minor variations exist in the United Kingdom and Holland. Within well-defined FH families, the diagnosis is reliably made according to LDL cutoff points. More stringent criteria are required to establish the diagnosis in previously undiagnosed families, requiring strong evidence of an autosomal inheritance pattern and higher LDL cutoff points. At a total cholesterol level of 310 mg/dL, only 4% of persons in the general population would have FH, whereas 95% of persons who were first-degree relatives of known cases would have the disease. The mathematical probability of FH, verified by molecular genetics, is derived from a U.S. population cohort and may not be applicable to other countries.

Very high cholesterol levels in children should prompt extensive screening of adult 1st- and 2nd-degree relatives ("reverse" cholesterol screening). A child younger than age 18 yr with total plasma cholesterol of 270 mg/dL and/or low-density lipoprotein-cholesterol (LDL-C) of 200 mg/dL has an 88% chance of having FH. *Formal clinical diagnosis of FH is based upon the presence of 2 or more family members having elevated LDL cholesterol levels greater than 220 mg/dL. It should be noted, however, that LDL-C level cutoff points vary with age* (Table 86-8). Conversely, criteria for diagnosing probable FH in a child whose first-degree relative has known FH require only modest elevation of total cholesterol to 220 mg/dL (LDL-C 155 mg/dL).

Treatment of children with FH should begin with a rather rigorous low-fat diet (see below). Diet alone is rarely sufficient for decreasing blood cholesterol levels to acceptable levels (LDL-C <130 mg/dL).

Ezetimibe blocks cholesterol adsorption in the gastrointestinal tract and has a low risk of side effects. Data suggest that ezetimibe will lower total cholesterol by 20-30 mg/dL. *HMG-CoA reductase inhibitors are the drug of choice for treatment of FH because of their remarkable effectiveness and acceptable risk profile.* There is sufficient clinical experience with this class of drugs in children to document that they are as effective in children as in adults, and the risks of elevated hepatic enzymes and myositis are no greater than in adults.

Familial Defective ApoB-100

Familial defective apoB-100 is an autosomal dominant condition that is indistinguishable from heterozygous FH. LDL cholesterol levels are increased, triglycerides are normal, adults often develop tendon

From Williams RR, Hunt SC, Schumacher MC, et al: Diagnosing heterozygous familial hypercholesterolemia using new practical criteria validated by molecular genetics, Am J Cardiol *72:171–176, 1993.*

xanthomas, and premature CHD occurs. Familial defective apoB-100 is caused by mutation in the receptor binding region of apoB-100, the ligand of the LDL receptor, with an estimated frequency of 1 in 700 people in Western cultures. It is usually caused by substitution of glutamine for arginine in position 3500 in apoB-100, which results in reduced ability of the LDL receptor to bind LDL cholesterol, thus impairing its removal from the circulation. Specialized laboratory testing can distinguish familial defective apoB-100 from FH, but this is not necessary, except in research settings, because treatment is the same.

Autosomal Recessive Hypercholesterolemia

This rare condition, caused by a defect in LDL receptor–mediated endocytosis in the liver, clinically presents with severe hypercholesterolemia at levels intermediate between those found in homozygous and heterozygous FH. It is disproportionately present among Sardinians, and is modestly responsive to treatment with HMG-CoA reductase inhibitors.

Sitosterolemia

A rare autosomal recessive condition characterized by excessive intestinal adsorption of plant sterols, sitosterolemia is caused by mutations in the adenosine triphosphate-binding cassette transporter system, which is responsible for limiting adsorption of plant sterols in the small intestine and promotes biliary excretion of the small amounts adsorbed. Plasma cholesterol levels may be severely elevated, resulting in tendon xanthomas and premature atherosclerosis. Diagnosis can be confirmed by measuring elevated plasma sitosterol levels. Treatment with HMG-CoA reductase inhibitors is not effective, but cholesterol adsorption inhibitors, such as ezetimibe, and bile acid sequestrants are effective.

Polygenic Hypercholesterolemia

Primary elevation in LDL cholesterol among children and adults is most often polygenic; the small effects of many genes are impacted by environmental influences (diet). Plasma cholesterol levels are modestly elevated; triglyceride levels are normal. Polygenic hypercholesterolemia aggregates in families sharing a common lifestyle but does not follow predictable hereditary patterns found in single-gene lipoprotein defects. Treatment of children with polygenic hypercholesterolemia is directed toward adoption of a healthy lifestyle: reduced total and saturated fat consumption and at least 1 hr of physical activity daily. Cholesterol-lowering medication is rarely necessary.

Hypercholesterolemia with Hypertriglyceridemia

Familial Combined Hyperlipidemia

This is an autosomal dominant condition characterized by moderate elevation in plasma LDL cholesterol and triglycerides, and reduced plasma HDL cholesterol. It is the most common primary lipid disorder, occurring in approximately 1/200 people. Family history of premature heart disease is typically positive; the formal diagnosis requires that at least two first-degree relatives have evidence of one of three variants of dyslipidemia: (1) >90th percentile plasma LDL cholesterol; (2) >90th percentile LDL cholesterol and triglycerides; and (3) >90th percentile triglycerides. Individuals switch from one phenotype to another. Xanthomas are not a feature of familial combined hyperlipidemia (FCHL). Elevated plasma apoB levels with increased small dense LDL particles support the diagnosis.

Children and adults with FCHL have coexisting adiposity, hypertension, and hyperinsulinemia, suggesting the presence of the *metabolic syndrome.* Formal diagnosis in adults of this syndrome as defined by the National Cholesterol Education Program (NCEP)'s Adult Treatment Panel III identifies 6 major components: abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance with or without impaired glucose tolerance, evidence of vascular inflammation, and prothrombotic state. It is estimated that 30% of overweight adults fulfill criteria for the diagnosis of metabolic syndrome, including 65% of those with FCHL. Hispanics and South Asians from the Indian subcontinent are especially susceptible. There is no official definition of metabolic syndrome for children. Absolute cutoffs for diagnosis in children do not account for continuous variables in aging, sexual maturation, and race/ethnicity.

FCHL and type II diabetes share many features of the metabolic syndrome, suggesting that they are less distinct entities than originally conceptualized. Genetic association studies reveal evidence for a common genetic background. The resultant metabolic overlap is associated with ectopic fat accumulation and insulin resistance. The mechanisms associating visceral adiposity with the metabolic syndrome and type II diabetes are not fully understood. A plausible unifying principle is that obesity causes endoplasmic reticulum stress, leading to suppression of insulin receptor signaling and thus insulin resistance and heightened inflammatory response. How this relates to atherogenesis is unclear. It is assumed that hypercholesterolemia and, with less certainty, hypertriglyceridemia confer risk for CVD in patients with FCHL. When features of the metabolic syndrome are included in logistic models shared etiologic features such as increased visceral adiposity become apparent. Visceral adiposity increases with age and its importance in children as a risk factor for heart disease and diabetes is limited by the relative paucity of data. Although longitudinal measurement of waist circumference and the presence of intraabdominal fat as determined by MRI is being conducted in the research setting, body mass index (BMI) remains the surrogate for adiposity in the pediatric clinical setting.

The metabolic syndrome is a dramatic illustration of the interaction of genetics and the environment. Genetic susceptibility is essential as an explanation for premature heart disease in individuals with FCHL. Unhealthy lifestyle, poor diet, and physical inactivity contribute to obesity and attendant features of the metabolic syndrome.

The cornerstone of management is lifestyle modification. This includes a diet low in saturated fats, trans fats, and cholesterol, as well as reduced consumption of simple sugars. Increased dietary intake of fruits and vegetables is important, as is 1 hr of moderate physical activity daily. Compliance among children and their parents is often a problem, but small incremental steps are more likely to succeed than aggressive weight-loss strategies. It is very important that the child's caregivers participate in the process. Plasma triglyceride levels are usually quite responsive to dietary restriction, especially reduction in the amount of sweetened drinks consumed. Blood cholesterol levels may decrease by 10-15%, but if LDL cholesterol remains >160 mg/dL, drug therapy should be considered.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)

Familial dysbetalipoproteinemia (FDBL) is caused by mutations in the gene for apoE, which when exposed to environmental influences such as high fat, high caloric diet, or excessive alcohol intake, results in a mixed type of hyperlipidemia. Patients tend to have elevated plasma cholesterol and triglycerides to a relatively similar degree. HDL cholesterol is typically normal in contrast to other causes of hypertriglyceridemia associated with low HDL. This rare disorder affects approximately 1 in 10,000 persons. ApoE mediates removal of chylomicron and VLDL remnants from the circulation by binding to hepatic surface receptors. The polymorphic *apoE* gene expresses in 3 isoforms: *apoE3, apoE2,* and *apoE4. E4* is the "normal" allele present in the majority of the population. The *apoE2* isoform has lower affinity for the LDL receptor and its frequency is approximately 7%. Approximately 1% of the population is homozygous for *apoE2/E2,* the most common mutation associated with FDBL, but only a minority expresses the disease. Expression requires precipitating illnesses such as diabetes, obesity, renal disease, or hypothyroidism. Individuals homozygous for *apoE4/E4* are at risk for late-onset Alzheimer disease and dementia from repeated sports-related head injuries.

Most patients with FDBL present in adulthood with distinctive xanthomas. Tuberoeruptive xanthomas resemble small grape-like clusters on the knees, buttocks, and elbows. Prominent orange-yellow discoloration of the creases of the hands (palmar xanthomas) is also typically present. Atherosclerosis, often presenting with peripheral vascular

disease, usually occurs in the 4th or 5th decade. Children may present with a less-distinctive rash and generally have precipitating illnesses.

The diagnosis of FDBL is established by lipoprotein electrophoresis, which demonstrates a broad beta band containing remnant lipoproteins. Direct measurement of VLDL by ultracentrifugation can be performed in specialized lipid laboratories. A VLDL : total triglyceride ratio >0.30 supports the diagnosis. *ApoE* genotyping for *apoE2* homozygosity can be performed, confirming the diagnosis in the presence of the distinctive physical findings. A negative result does not necessarily rule out the disease as other mutations in *apoE* may cause even more serious manifestations.

Pharmacologic treatment of FDBL is necessary to decrease the likelihood of symptomatic atherosclerosis in adults. HMG-CoA reductase inhibitors, nicotinic acid, and fibrates are all effective. FDBL is quite responsive to recommended dietary restriction.

Hypertriglyceridemias

The familial disorders of triglyceride-rich lipoproteins include both common and rare variants of the Frederickson classification system. These include chylomicronemia (type I), familial hypertriglyceridemia (type IV), and the more severe combined hypertriglyceridemia and chylomicronemia (type V). Hepatic lipase deficiency also results in a similar combined hyperlipidemia.

Familial Chylomicronemia (Type I Hyperlipidemia)

This rare single-gene defect, like FH, is caused by mutations affecting clearance of apoB-containing lipoproteins. Deficiency or absence of LPL or its cofactor apoC-II, which facilitates lipolysis by LPL, causes severe elevation of triglyceride rich plasma chylomicrons. HDL cholesterol levels are decreased. As clearance of these particles is markedly delayed, the plasma is noted to have a turbid appearance even after prolonged fasting (Fig. 86-13). Chylomicronemia caused by LPL deficiency is associated with modest elevation in triglycerides, whereas this is not the case when the cause is deficient or absent apoC-II. Both are autosomal recessive conditions with a frequency of approximately 1 in 1,000,000. The disease usually presents during childhood with acute pancreatitis. Eruptive xanthomas on the arms, knees, and buttocks may be present, and there may be hepatosplenomegaly. The diagnosis is established by assaying triglyceride lipolytic activity. Treatment of chylomicronemia is by vigorous dietary fat restriction supplemented by fat-soluble vitamins. Medium-chain triglycerides that are adsorbed into the portal venous system may augment total fat intake, and administration of fish oils may also be beneficial.

Figure 86-13 Milky plasma from patient with acute abdominal pain. *(From Durrington P: Dyslipidaemia,* Lancet *362:717–731, 2003.)*

Familial Hypertriglyceridemia (Type IV Hyperlipidemia)

Familial hypertriglyceridemia (FHTG) is an autosomal dominant disorder of unknown etiology that occurs in approximately 1 in 500 individuals. It is characterized by elevation of plasma triglycerides >90th percentile (250-1,000 mg/dL range), often accompanied by slight elevation in plasma cholesterol and low HDL. FHTG does not usually manifest until adulthood, although it is expressed in approximately 20% of affected children. In contrast to FCHL, FHTG is not thought to be highly atherogenic. It is most likely caused by defective breakdown of VLDL, or less often by overproduction of this class of lipoproteins.

The diagnosis should include the presence of at least one first-degree relative with hypertriglyceridemia. FHTG should be distinguished from FCHL and FDBL, as the latter require more vigorous treatment to prevent coronary or peripheral vascular disease. The differentiation is usually possible on clinical grounds, in that lower LDL cholesterol levels accompany FHTG, but measurement of normal apoB levels in FHTG may be helpful in ambiguous situations.

A more severe hypertriglyceridemia characterized by increased levels of chylomicrons as well as VLDL particles (Frederickson type V) may occasionally be encountered. Triglyceride levels are often >1,000 mg/dL. The disease is rarely seen in children. In contrast to chylomicronemia (Frederickson type I), LPL or apoC-II deficiency is not present. These patients often develop eruptive xanthomas in adulthood, whereas type IV hypertriglyceridemia individuals do not. Acute pancreatitis may be the presenting illness. As with other hypertriglyceridemias, excessive alcohol consumption and estrogen therapy can exacerbate the disease.

Secondary causes of transient hypertriglyceridemia should be ruled out before making a diagnosis of FHTG. A diet high in simple sugars and carbohydrates, or excessive alcohol consumption as well as estrogen therapy may exacerbate hypertriglyceridemia. Adolescents and adults should be questioned about excessive consumption of soda and other sweetened drinks, as it is common to encounter people who drink supersized drinks or multiple 12 oz cans of sweetened drinks daily. Cessation of this practice often results in dramatic fall in triglyceride levels as well as weight among those who are obese. HDL cholesterol levels will tend to rise as BMI stabilizes.

Pediatric diseases associated with hyperlipidemia include hypothyroidism, nephrotic syndrome, biliary atresia, glycogen storage disease, Niemann-Pick disease, Tay-Sachs disease, systemic lupus erythematosus, hepatitis, and anorexia nervosa (Table 86-9). Certain medications exacerbate hyperlipidemia, including isotretinoin (Accutane), thiazide diuretics, oral contraceptives, steroids, β blockers, immunosuppressants, and protease inhibitors used in the treatment of HIV.

Treatment of hypertriglyceridemia in children rarely requires medication unless levels >1,000 mg/dL persist after dietary restriction of fats, sugars, and carbohydrates, accompanied by increased physical activity. In such cases, the aim is to prevent episodes of pancreatitis. The common use of fibrates (fenofibric acid) and niacin in adults with hypertriglyceridemia is not recommended in children. HMG-CoA reductase inhibitors are reasonably effective in lowering triglyceride levels, and there is considerably more experience documenting the safety and efficacy of this class of lipid-lowering medications in children. In adults, prescription (Lovaza, Vascepa) and nonprescription fish oils have been approved by the FDA as adjuncts to diet in the treatment of severe hypertriglyceridemias.

Hepatic Lipase Deficiency

Hepatic lipase deficiency is a very rare autosomal recessive condition causing elevation in both plasma cholesterol and triglycerides. Hepatic lipase hydrolyzes triglycerides and phospholipids in VLDL remnants and IDL, preventing their conversion to LDL. HDL cholesterol levels tend to be increased rather than decreased, suggesting the diagnosis. Laboratory confirmation is established by measuring hepatic lipase activity in heparinized plasma.

Disorders of High-Density Lipoprotein Metabolism

Primary Hypoalphalipoproteinemia

Isolated low HDL cholesterol is a familial condition that often follows a pattern suggestive of autosomal dominant inheritance but may occur independent of family history. It is the most common disorder of HDL metabolism. It is defined as HDL cholesterol <10th percentile for gender and age with normal plasma triglycerides and LDL cholesterol. Whether it is associated with more rapid atherosclerosis is uncertain. It appears to be related to a reduction in apoA-I synthesis and increased catabolism of HDL. Secondary causes of low HDL cholesterol, such as the metabolic syndrome, and rare diseases such as LCAT deficiency and Tangier disease must be ruled out.

Familial Hyperalphalipoproteinemia

This is an unusual condition conferring deceased risk for CHD among family members. Plasma levels of HDL cholesterol exceed 80 mg/dL.

Familial Apolipoprotein A-I Deficiency

Mutations in the *apoA-I* gene may result in complete absence of plasma HDL. Nascent HDL is produced in the liver and small intestine. Free cholesterol from peripheral cells is esterified by LCAT, enabling formation of mature HDL particles. ApoA-I is required for normal enzymatic functioning of LCAT. The resultant accumulation of free cholesterol in the circulation eventually leads to corneal opacities, planar xanthomas, and premature atherosclerosis. Some patients, however, may have mutations of *apoA-I* that result in very rapid catabolism of the protein not associated with atherogenesis, despite HDL cholesterol levels in the 15-30 mg/dL range.

Tangier Disease

This is an autosomal codominant disease associated with levels of HDL cholesterol <5 mg/dL. It is caused by mutations in ABCA1, a protein that facilitates the binding of cellular cholesterol to apoA-I. This results in free cholesterol accumulation in the reticuloendothelial system manifested by tonsillar hypertrophy of a distinctive orange color and hepatosplenomegaly. Intermittent peripheral neuropathy may occur from cholesterol accumulation in Schwann cells. Diagnosis should be suspected in children with enlarged orange tonsils and extremely low HDL cholesterol levels.

Familial Lecithin–Cholesterol Acyltransferase Deficiency

Mutations affecting LCAT interfere with the esterification of cholesterol, thereby preventing formation of mature HDL particles. This is associated with rapid catabolism of apoA-I. Free circulating cholesterol in the plasma is greatly increased, which leads to corneal opacities and HDL cholesterol levels <10 mg/dL. Partial LCAT deficiency is known as “fish-eye” disease. Complete deficiency causes hemolytic anemia and progressive renal insufficiency early in adulthood. This rare disease is not thought to cause premature atherosclerosis. Laboratory confirmation is based on demonstration of decreased cholesterol esterification in the plasma.

Cholesteryl Ester Transfer Protein Deficiency

Mutations involving the *CETP* gene are localized to chromosome 16y21. CETP facilitates the transfer of lipoproteins from mature HDL to and from VLDL and chylomicron particles, thus ultimately regulating the rate of cholesterol transport to the liver for excretion in the bile. About half of mature HDL-2 particles are directly removed from the circulation by HDL receptors on the surface of the liver. The other half of cholesteryl esters in the core of HDL exchange with triglycerides in the core of apoB lipoproteins (VLDL, IDL, LDL) for transport to the liver. Homozygous deficiency of CETP has been observed in subsets of the Japanese population with extremely high HDL cholesterol levels (>150 mg/dL).

Conditions Associated with Low Cholesterol

Disorders of apoB-containing lipoproteins and intracellular cholesterol metabolism are associated with low plasma cholesterol.

Abetalipoproteinemia

This rare autosomal recessive disease is caused by mutations in the gene encoding microsomal triglyceride transfer protein necessary for the transfer of lipids to nascent chylomicrons in the small intestine and VLDL in the liver. This results in absence of chylomicrons, VLDL, LDL, and apoB, and very low levels of plasma cholesterol and triglycerides. Fat malabsorption, diarrhea, and failure to thrive present in early childhood. Spinocerebellar degeneration, secondary to vitamin E deficiency, manifests in loss of deep tendon reflexes progressing to ataxia and lower extremity spasticity by adulthood. Patients with abetalipoproteinemia also acquire a progressive pigmented retinopathy associated with decreased night and color vision and eventual blindness. The neurologic symptoms and retinopathy may be mistaken for Friedreich ataxia. Differentiation from Friedreich ataxia is suggested by the presence of malabsorption and acanthocytosis on peripheral blood smear in abetalipoproteinemia. Many of the clinical manifestations of the disease are a result of malabsorption of fat-soluble vitamins, such as vitamins E, A, and K. Early treatment with supplemental vitamins, especially E, may significantly slow the development of neurologic sequelae. Vitamin E is normally transported from the small intestine to the liver by chylomicrons, where it is dependent on the endogenous VLDL pathway for delivery into the circulation and peripheral tissues. Parents of children with abetalipoproteinemia have normal blood lipid and apoB levels.

Familial Hypobetalipoproteinemia

Familial homozygous hypobetalipoproteinemia is associated with symptoms very similar to those of abetalipoproteinemia, but the inheritance pattern is autosomal codominant. The disease is caused by mutations in the gene encoding apoB-100 synthesis. It is distinguishable from abetalipoproteinemia in that heterozygous parents of probands

have plasma LDL cholesterol and apoB levels less than half normal. There are no symptoms or sequelae associated with the heterozygous condition.

The selective inability to secrete apoB-48 from the small intestine results in a condition resembling abetalipoproteinemia or homozygous hypobetalipoproteinemia. Sometimes referred to as Anderson disease, the failure of chylomicron absorption causes steatorrhea and fat-soluble vitamin deficiency. The blood level of apoB-100, derived from normal hepatocyte secretion, is normal in this condition.

Smith-Lemli-Opitz Syndrome

Patients with Smith-Lemli-Opitz syndrome (SLOS) often have multiple congenital anomalies and developmental delay caused by low plasma cholesterol and accumulated precursors (Tables 86-10 and 86-11). Family pedigree analysis has revealed its autosomal recessive inheritance pattern. Mutations in the *DHCR7* (7-dehydrocholesterol-Δ7 reductase) gene result in deficiency of the microsomal enzyme DHCR7, which is necessary to complete the final step in cholesterol synthesis. It is not known why defects in cholesterol synthesis result in congenital malformations, but as cholesterol is a major component of myelin and a contributor to signal transduction in the developing nervous system, neurodevelopment is severely impaired. The incidence of SLOS is estimated to be 1 in 20,000-60,000 births among whites, with a somewhat higher frequency in Hispanics and lower incidence in individuals of African descent.

Spontaneous abortion of SLOS fetuses may occur. Type II SLOS often leads to death by the end of the neonatal period. Survival is unlikely when the plasma cholesterol level is <20 mg/dL. Laboratory measurement should be performed by gas chromatography, as standard techniques for lipoprotein assay include measurement of cholesterol precursors, which may yield a false-positive result. Milder cases may not present until late childhood. Phenotypic variance ranges from microcephaly, cardiac and brain malformation, and multiorgan system failure to only subtle dysmorphic features and mild developmental delay. Treatment includes supplemental dietary cholesterol (egg yolk) and HMG-CoA reductase inhibition to prevent the synthesis of toxic precursors proximal to the enzymatic block.

Disorders of Intracellular Cholesterol Metabolism

Cerebrotendinous Xanthomatosis

This autosomal recessive disorder presents clinically in late adolescence with tendon xanthomas, cataracts, and progressive neurodegeneration. It is caused by tissue accumulation of bile acid intermediates shunted into cholestanol resulting from mutations in the gene for sterol 27-hydroxylase. This enzyme is necessary for normal mitochondrial synthesis of bile acids in the liver. Early treatment with chenodeoxycholic acid reduces cholesterol levels and prevents the development of symptoms.

Wolman Disease and Cholesterol Ester Storage Disease

These autosomal recessive disorders are caused by lack of lysosomal acid lipase. After LDL cholesterol is incorporated into the cell by endocytosis, it is delivered to lysosomes where it is hydrolyzed by lysosomal lipase. Failure of hydrolysis because of complete absence of the enzyme causes accumulation of cholesteryl esters within the cells. Hepatosplenomegaly, steatorrhea, and failure to thrive occur during early infancy, leading to death by the age of 1 yr. In cholesterol ester storage disease, a less-severe form than Wolman disease, there is low but detectable acid lipase activity.

Niemann-Pick Disease Type C

This is a disorder of intracellular cholesterol transport characterized by accumulation of cholesterol and sphingomyelin in the central nervous and reticuloendothelial systems. Death from this autosomal recessive neurologic disease usually occurs by adolescence.

Lipoprotein Patterns in Children and Adolescents

Table 86-12, derived primarily from the Lipid Research Clinics Population Studies, shows the distribution of lipoprotein levels in American

youth at various ages. Total plasma cholesterol rises rapidly from a mean of 68 mg/dL at birth to a level approximately twice that by the end of the neonatal period. A very gradual rise in total cholesterol level occurs until puberty, at which time the mean level reaches 160 mg/dL. Total cholesterol falls transiently during puberty, in males because of a small decrease in HDL cholesterol, and in females secondary to a slight fall in LDL cholesterol. Blood cholesterol levels track reasonably well as individuals age.

High blood cholesterol tends to aggregate in families, a reflection of genetic and environmental influences.

Acceptable total cholesterol among children and adolescents is <170 mg/dL; borderline is 170-199 mg/dL; and high >200 mg/dL. Acceptable LDL cholesterol is <110 mg/dL; borderline 110-129 mg/dL; and high >130 mg/dL. HDL cholesterol should be >40 mg/dL.

Blood Cholesterol Screening

Previous guidelines for cholesterol measurement in children utilized a *targeted approach*. This meant obtaining a fasting lipid panel in a select group of children between the ages of 2 and 10 yr who met at least 1 of the following criteria:

- Parents or grandparents have documented premature coronary artery disease (before the age of 55 yr if male and 65 yr if female)
- Parents have been found to have high blood concentration of cholesterol (>240 mg/dL)
- Family history is unobtainable, particularly those with other risk factors such as obesity, hypertension, smoking, and/or diabetes mellitus.

Reliance on family history of premature heart disease or known parental heart disease, or known parental hypercholesterolemia was considered by some to be too insensitive and difficult to apply. Data from a large cohort of 5th grade school children who had comprehensive screening of CVD risk factors conducted by the Coronary Artery Risk Detection in Appalachian Communities (CARDIAC) Project, which utilized a *universal screening* approach, found 36% of children with severe dyslipidemia did not fulfill criteria for the selective screening approach.

The American Academy of Pediatrics began recommending a universal screening approach for cholesterol screening to all children in 2011. They recommend a lipid profile to be checked for all children between the ages of 9 and 11 yr and then another between ages 17 and 21 yr as cholesterol levels may vary after puberty. However, if a child would have met the selective criteria from the previous guidelines, then screening can occur as early as age 2 yr. Of note, new data suggest that obtaining a nonfasting lipid profile can be just as useful in detecting severe genetic dyslipidemias as a fasting lipid profile, and thus, can be used as the first line of screening in children. Fasting lipid profiles may also be used depending on parental, child, and clinician preference, especially if there is concern for hypertriglyceridemia, as triglycerides are more affected by fasting status.

If a nonfasting lipid profile is used and reveals a non-HDL cholesterol (total cholesterol − HDL cholesterol) >145 mg/dL, then 2 separate **fasting** lipid profiles should be obtained at least 2 wk apart but within 3 mo of each other and the results averaged together to confirm the abnormality. If a fasting lipid profile is initially used and reveals an LDL-C ≥130 mg/dL, then another fasting lipid profile at least 2 wk apart but within 3 mo should be obtained and the results averaged together. In summary, children with suspected dyslipidemias should have results confirmed with 2 separate **fasting** lipid profiles.

Risk Assessment and Treatment of Hyperlipidemia

The NCEP recommends a population-based approach toward healthy lifestyle applicable to all children, and an individualized approach directed at those children at high risk (Fig. 86-14). The important focus on maintenance of a healthy lifestyle rather than aggressive weight reduction is recommended by the American Academy of Pediatrics.

All children with dyslipidemias are stratified according to the presence of "high-level" or "moderate-level" risk factors to determine their ultimate treatment. High-level risk factors are defined as the following: hypertension requiring drug therapy (blood pressure ≥99th percentile + 5 mm Hg), current cigarette smoker, BMI at the ≥ 97th percentile, presence of type I or type II diabetes mellitus, chronic kidney disease, postorthoptic heart transplant, and/or Kawasaki disease with current aneurysms. Moderate-level risk factors are defined as the following: hypertension that does not require drug therapy, BMI at the ≥95th percentile but <97th percentile, HDL cholesterol <40 mg/dL, Kawasaki disease with regressed coronary aneurysms, chronic inflammatory disease, HIV infection, and/or presence of nephrotic syndrome.

The initial treatment for dyslipidemia in a child always begins with a 6-mo trial of lifestyle modification, namely, changes in dietary and physical activity patterns. Being overweight confers special risk of CVD because of the strong association with the insulin resistance syndrome (metabolic syndrome). Although there is no standardized definition of metabolic syndrome defined for youth, it is likely that half of all severely obese children are insulin resistant. Data from the CARDIAC project noted that 49% of 5th grade children with the hyperpigmented rash, acanthosis nigricans, had 3 or more factors for the insulin resistance syndrome when using the definition classically used for adults, including evidence of insulin resistance, hypertension, HDL cholesterol <40 mg/dL, triglycerides >150 mg/dL, in addition to obesity.

The Cardiovascular Health Integrated Lifestyle Diet-1 (CHILD-1) diet is the first level of dietary change to be recommended for all children with dyslipidemias. The CHILD-1 diet is specially designed for children with risk factors for coronary artery disease and focuses on such things as limitation of dietary cholesterol to no more than 300 mg/day, limitation of sugary drink consumption, use of reduced fat/skim milk, avoiding foods high in *trans*-type fats, limitation of foods high in sodium, and encouraging consumption of foods high in fiber. Specific recommendations are dependent on the child's age.

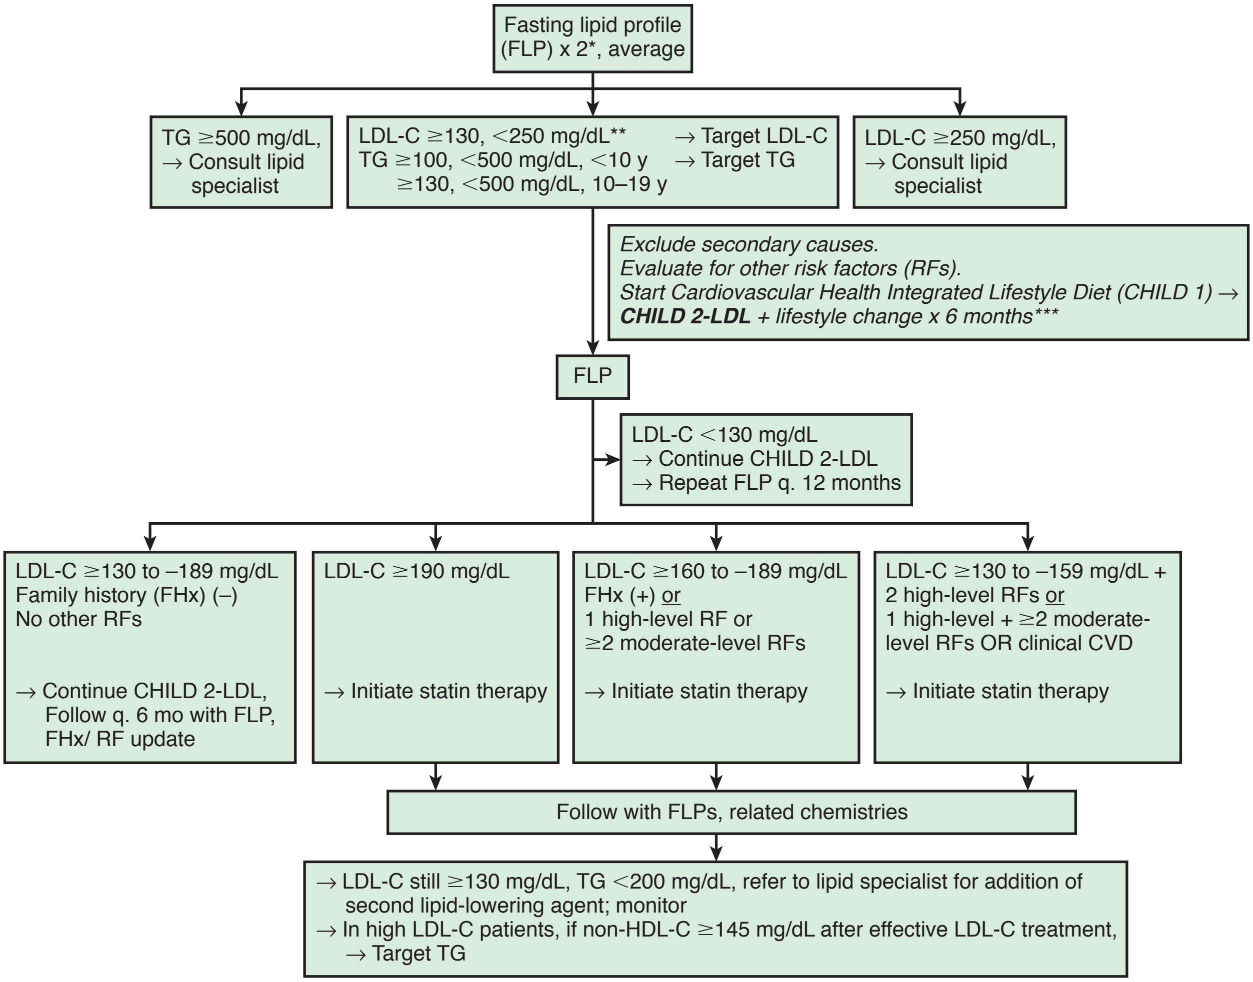
The use of the Cardiovascular Health Integrated Lifestyle Diet-2 (CHILD-2) diet is recommended if the CHILD-1 diet alone is unsuccessful. Although similar in many aspects to the CHILD-1 diet, the CHILD-2 diet is geared toward a specific dyslipidemia type, where the CHILD-2 LDL diet is recommended for those children with elevated LDL levels and the CHILD-2 TG diet is recommended for those children presenting with elevated triglycerides. The basic recommendations of calorie consumption for the CHILD-2 diet are as follows: only 25% to 30% of calories from fat, less than or equal to 7% of calories from saturated fat about 10% of calories from monounsaturated fat, less than 200 mg/d of cholesterol. If the CHILD-2 LDL diet is recommended, the use of plant sterols and water-soluble fiber is emphasized. If the CHILD-2 TG diet is recommended, the increasing consumption of complex carbohydrates and omega-3 fatty acids is emphasized.

If followed, these dietary recommendations will provide adequate calories for optimal growth and development without promoting obesity. Compliance on the part of children and their caregivers is challenging in today's society. Children learn eating habits from their parents. Successful adoption of a healthier lifestyle is far more likely to occur if meals and snacks in the home are applicable to the entire family rather than an individual child. A regular time for meals together as a family is desirable. Grandparents and other nonparental caregivers sometimes need to be reminded not to indulge the child who is on a restricted diet. Additionally, the rise in obesity is prompting some school districts to restrict sweetened drink availability, and offer more nutritious cafeteria selections.

As mentioned, changes in physical activity habits are also an important part of the initial lifestyle modification. The National Association for Sport and Physical Education recommends that children should accumulate at least 60 minutes of age-appropriate physical activity on most days of the week. Extended periods (2 hr or more) of daytime inactivity are discouraged, as is more than 2 hr of television and other forms of screen time. Unfortunately, the continued rise in sedentary activity among our youth contributes to the increase in obesity nationwide, which in turn, leads to the increasing prevalence of other risk factors such as hypertension.

Pharmacologic Therapy. See Tables 86-13 and 86-14.

The use of pharmacotherapy to treat dyslipidemias in children has been advocated by the American Academy of Pediatrics since the



* Obtain FLPs at least 2 weeks but no more than 3 months apart.
** Use of drug therapy is limited to children ≥10 y with defined risk profiles.
*** In a child with LDL-C >190 mg/dL and other RFs, trial of CHILD 2 LDL diet may be abbreviated.

Table 86-13 Drugs Used for the Treatment of Hyperlipidemia

DRUG	MECHANISM OF ACTION	INDICATION	STARTING DOSE
HMG-CoA reductase inhibitors (statins)	↓ Cholesterol and VLDL synthesis ↑ Hepatic LDL receptors	Elevated LDL	5-80 mg qhs
Bile acid sequestrants: Cholestyramine Colestipol	↑ Bile and excretion	Elevated LDL	 4-32 g daily 5-40 g daily
Nicotinic acid	↓ Hepatic VLDL synthesis	Elevated LDL Elevated TG	100-2,000 mg tid
Fibric acid derivatives: Gemfibrozil	↑ LPL ↓ VLDL	Elevated TG	600 mg bid
Fish oils	↓ VLDL production	Elevated TG	3-10 g daily
Cholesterol absorption inhibitors: Ezetimibe	↓ Intestinal absorption cholesterol	Elevated LDL	10 mg daily

LDL, low-density lipoprotein; LPL, lipoprotein lipase; TG, triglyceride; VLDL, very-low-density lipoprotein.

Table 86-14 Side Effects of Lipid-Lowering Drugs

DRUG AND SITE OR TYPE OF EFFECT	EFFECT
STATINS	
Skin	Rash
Nervous system	Loss of concentration, sleep disturbance, headache, peripheral neuropathy
Liver	Hepatitis, loss of appetite, weight loss, and increases in serum aminotransferases to 2-3 times the upper limit of the normal range
Gastrointestinal tract	Abdominal pain, nausea, diarrhea
Muscles	Muscle pain or weakness, myositis (usually with serum creatine kinase >1,000U/L), rhabdomyolysis with renal failure
Immune system	Lupus-like syndrome (lovastatin, simvastatin, or fluvastatin)
Protein binding	Diminished binding of warfarin (lovastatin, simvastatin, fluvastatin)
BILE ACID-BINDING RESINS	
Gastrointestinal tract	Abdominal fullness, nausea, gas, constipation, hemorrhoids, anal fissure, activation of diverticulitis, diminished absorption of vitamin D in children
Liver	Mild serum aminotransferase elevations, which can be exacerbated by concomitant treatment with a statin
Metabolic system	Increases in serum triglycerides of ≈10% (greater increases in patients with hypertriglyceridemia)
Electrolytes	Hyperchloremic acidosis in children and patients with renal failure (cholestyramine)
Drug interactions	Binding of warfarin, digoxin, thiazide diuretics, thyroxine, statins
NICOTINIC ACID	
Skin	Flushing, dry skin, pruritus, ichthyosis, acanthosis nigricans
Eyes	Conjunctivitis, cystoid macular edema, retinal detachment
Respiratory tract	Nasal stuffiness
Heart	Supraventricular arrhythmias
Gastrointestinal tract	Heartburn, loose bowel movements or diarrhea
Liver	Mild increase in serum aminotransferases, hepatitis with nausea and fatigue
Muscles	Myositis
Metabolic system	Hyperglycemia (incidence: ≈5% higher in patients with diabetes), increase of 10% in serum uric acid
FIBRATES	
Skin	Rash
Gastrointestinal tract	Stomach upset, abdominal pain (mainly gemfibrozil), cholesterol-saturated bile, increase of 1-2% in gallstone incidence
Genitourinary tract	Erectile dysfunction (mainly clofibrate)
Muscles	Myositis with impaired renal function
Plasma proteins	Interference with binding of warfarin, requiring reduction in the dose of warfarin by ≈30%
Liver	Increased serum aminotransferases

From Knopp RH: Drug treatment of lipid disorders, N Engl J Med *341:498–512, 1999.*

inception of screening and treatment guidelines from the NCEP in 1992. Although the treatment guidelines have been slightly modified by the American Academy of Pediatrics since that time, pharmacologic therapy with cholesterol-lowering medication still remains a cornerstone of therapy for children who fail to respond to a 6 mo period of rigorous lifestyle modification. Drug therapy should be considered when one of the following conditions are met, which are also shown in Figure 86-14:

- LDL cholesterol remains >190 mg/dL
- LDL cholesterol remains >160 mg/dL with presence of 1 high-level risk factor and/or at least 2 moderate-level risk factors
- LDL cholesterol remains >130 mg/dL with presence of at least 2 high-level risk factors, 1 high-level risk factor, **and** at least 2 moderate-level risk factors, or evidence of coronary artery disease

Considerable experience with drug therapy in children and adolescents with hyperlipidemia over the past 20 yr has expanded therapeutic options, improved compliance, and enhanced efficacy. In the past, the mainstay of drug therapy was bile acid sequestrants such as cholestyramine and colestipol because they were not systemically absorbed. Interruption of the enterohepatic circulation of bile acids promotes synthesis in the liver of new bile acids from cholesterol. Gastrointestinal side effects and taste resulted in less than desirable compliance, even when there were few viable options.

HMG-CoA reductase inhibitors, also known as "statins" are remarkably effective in lowering LDL cholesterol levels and reducing plaque inflammation, thereby reducing the likelihood of a sudden coronary event in an at-risk adult within weeks of starting the medication. As a class, they work by blocking the intrahepatic biosynthesis of cholesterol, thereby stimulating the production of more LDL receptors on the cell surface and facilitating the uptake of LDL cholesterol from the bloodstream. The NCEP Adult Treatment Panel advocates aggressive lowering of LDL to below 70 mg/dL in individuals with known coronary artery disease. This information is relevant because a child who fulfills criteria for consideration of cholesterol-lowering medication will almost always have inherited the condition from one of the child's parents. Not infrequently, when providing care for the child, questions come up about screening and treatment of parents or grandparents. Statins are equally effective in children, capable of lowering LDL-C levels by 50% when necessary. They are considered first-line therapy for children who meet criteria for pharmacologic therapy. They also will effect a modest reduction in triglycerides and an inconsistent increase in HDL cholesterol. Their side–effect profile, mainly liver dysfunction and rarely rhabdomyolysis with secondary renal failure, should be taken into consideration before prescribing the drug. However, there has been no evidence to date that complications are any more frequent in children than adults, and skeletal muscle discomfort seems to be somewhat less of a problem. Drug interactions may occur as well, so careful attention should be paid to a child's active prescriptions to avoid potentiation of the aforementioned side effects. Children should have liver enzymes monitored regularly, and creatine phosphokinase measured if muscle aches or weakness occurs. Liver enzymes may be allowed to rise 3-fold before discontinuing the drug. There is a suggested link between the use of statins and increased risk of developing type II diabetes mellitus in

adults, but these results have not been replicated in children. It should be reemphasized that children with modest elevations in cholesterol, such as that seen in polygenic hypercholesterolemia, are not, as a rule, candidates for statins because of their side–effect profile. Statins should be started at the lowest effective dose and allowed at least 8 wk to achieve their peak effect. If LDL levels are not at goal, which in children who are treated is generally established to be <130 mg, then the medication may be titrated upwards with careful monitoring of side effects.

Other cholesterol-lowering medications such as nicotinic acid and fibrates have been used far less often in children than bile acid sequestrants and statins. Nicotinic acid and fibrates have been used selectively in children with marked hypertriglyceridemia (>500 mg/dL) at risk for acute pancreatitis, though dietary restriction of complex sugars and carbohydrates will usually result in significant lowering of triglyceride levels. Current guidelines recommend treatment of LDL cholesterol as the initial priority and after LDL levels are at goal, then if triglycerides remain between 200 and 499 mg/dL and non-HDL cholesterol remains ≥145 mg/dL treatment, pharmacologic treatment to reduce triglyceride levels is indicated. Omega-3 fatty acid supplementation, available both over the counter and in prescription form, is a safe and useful treatment thought to reduce triglyceride levels by decreasing the hepatic synthesis of triglycerides.

Ezetimibe has proven to be useful in the pediatric population because of its efficacy and low side–effect profile. Ezetimibe reduces plasma LDL cholesterol by blocking sterol absorption in enterocytes. The drug is marketed as an adjunct to statins when adult subjects are not achieving sufficient blood lipid lowering with statins alone. Not surprisingly, large clinical trials of ezetimibe used as monotherapy in children have not been conducted because the potential market in the pediatric age group is small. Nevertheless, there are sufficient reports in the literature documenting the effectiveness of this medication without worrisome side effects that one can feel on relatively safe grounds recommending it instead of a statin when moderate hypercholesterolemia is encountered, or apprehension from parents makes using a statin difficult.

Bibliography is available at Expert Consult.

86.4 Lipidoses (Lysosomal Storage Disorders)

Margaret M. McGovern and Robert J. Desnick

The lysosomal lipid storage diseases are diverse disorders, each caused by an inherited deficiency of a specific lysosomal hydrolase leading to the intralysosomal accumulation of the enzyme's particular substrate (Tables 86-15 and 86-16). With the exception of Wolman disease and cholesterol ester storage disease, the lipid substrates share a common structure that includes a ceramide backbone (2-*N*-acylsphingosine) from which the various sphingolipids are derived by substitution of hexoses, phosphorylcholine, or 1 or more sialic acid residues on the terminal hydroxyl group of the ceramide molecule. The pathway of sphingolipid metabolism in nervous tissue (Fig. 86-15) and in visceral organs (Fig. 86-16) is known; each catabolic step, with the exception of the catabolism of lactosylceramide, has a genetically determined metabolic defect and a resultant disease. Because sphingolipids are essential components of all cell membranes, the inability to degrade these substances and their subsequent accumulation results in the physiologic and morphologic alterations and characteristic clinical manifestations of the lipid storage disorders (see Table 86-15). Progressive lysosomal accumulation of glycosphingolipids in the central nervous system leads to neurodegeneration, whereas storage in visceral cells can lead to organomegaly, skeletal abnormalities, pulmonary infiltration, and other manifestations. The storage of a substrate in a specific tissue is dependent on its normal distribution in the body.

Diagnostic assays for the identification of affected individuals rely on the measurement of the specific enzymatic activity in isolated leukocytes or cultured fibroblasts or lymphoblasts. Figure 86-17 shows an approach to differentiating these disorders. For most disorders, carrier identification and prenatal diagnosis are available; a specific diagnosis is essential to permit genetic counseling. Neonatal screening using dried blood spots and performing enzyme assays and mutational analysis for Gaucher, Pompe, Fabry, and Niemann-Pick diseases are undergoing pilot studies. The characterization of the genes that encode the specific enzymes required for sphingolipid metabolism permit the development of therapeutic options, such as recombinant enzyme replacement therapy, as well as the potential of cell or gene therapy. Identification of specific disease-causing mutations improves diagnosis, prenatal detection, and carrier identification. For several disorders (Gaucher, Fabry, and Niemann-Pick types A and B disease), it has been possible to make genotype–phenotype correlations that predict disease severity and allow more precise genetic counseling. Inheritance is autosomal recessive except for X-linked Fabry disease.

GM_1 GANGLIOSIDOSIS

GM_1 gangliosidosis most frequently presents in early infancy, but has been described in patients with juvenile and adult onset subtypes. Inherited as an autosomal recessive trait, each subtype results from a different gene mutation that leads to the deficient activity of β-galactosidase, a lysosomal enzyme encoded by a gene on chromosome 3 (3p21.33). Although the disorder is characterized by the pathologic accumulation of GM_1 gangliosides in the lysosomes of both neural and visceral cells, GM_1 ganglioside accumulation is most marked in the brain. In addition, keratan sulfate, a mucopolysaccharide, accumulates in liver and is excreted in the urine of patients with GM_1 gangliosidosis. The β-galactosidase gene has been isolated and sequenced; mutations causing the disease subtypes have been identified.

The clinical manifestations of the infantile form of GM_1 gangliosidosis may be evident in the newborn as hepatosplenomegaly, edema, and skin eruptions (**angiokeratoma**). It most frequently presents in the first 6 mo of life with developmental delay followed by progressive psychomotor retardation and the onset of tonic–clonic seizures. A typical facies is characterized by low-set ears, frontal bossing, a depressed nasal bridge, and an abnormally long philtrum. Up to 50% of patients have a **macular cherry-red spot**. Hepatosplenomegaly and skeletal abnormalities similar to those of the mucopolysaccharidoses, including anterior beaking of the vertebrae, enlargement of the sella turcica, and thickening of the calvarium, are present. By the end of the first year of life, most patients are blind and deaf, with severe neurologic impairment characterized by decerebrate rigidity. Death usually occurs by 3-4 yr of age. The juvenile-onset form of GM_1 gangliosidosis is clinically distinct, with a variable age at onset. Affected patients present primarily with neurologic symptoms including ataxia, dysarthria, intellectual disability, and spasticity. Deterioration is slow; patients may survive through the 4th decade of life. These patients lack the visceral involvement, facial abnormalities, and skeletal features seen in type 1 disease. Adult-onset patients have been described who present with gait and speech abnormalities, dystonia and mild skeletal abnormalities. There is no specific treatment for either form of GM_1 gangliosidosis.

The diagnosis of GM_1 gangliosidosis should be suspected in infants with typical clinical features and is confirmed by the demonstration of the deficiency of β-galactosidase activity in peripheral leukocytes. Other disorders that share some of the features of the GM_1 gangliosidoses include Hurler disease (mucopolysaccharidosis type I), I-cell disease, and Niemann-Pick disease (NPD) type A, which can each be distinguished by the demonstration of their specific enzymatic deficiencies. Carriers of the disorder are detected by the measurement of the enzymatic activity in peripheral leukocytes or by identifying the specific gene mutations; prenatal diagnosis is accomplished by determination of the enzymatic activity in cultured amniocytes or chorionic villi or identification of the specific disease-causing mutations. Currently only supportive therapy is available for patients with GM_1 gangliosidosis. However studies in mice with GM_1-gangliosidosis have demonstrated that orally administered *N*-octyl-4-epi-β-valienamine

(NOEV),which stabilizes the mutant enzyme protein produced by affected animals, crossed the brain and improved neurologic deterioration suggesting that this approach may be useful to study in humans.

THE GM_2 GANGLIOSIDOSES

The GM_2 gangliosidoses include Tay-Sachs disease and Sandhoff disease; each results from the deficiency of β-hexosaminidase activity and the lysosomal accumulation of GM_2 gangliosides, particularly in the central nervous system. Both disorders have been classified into infantile-, juvenile-, and adult-onset forms based on the age at onset and clinical features. β-Hexosaminidase occurs as 2 isozymes: β-hexosaminidase A, which is composed of 1 α and 1 β subunit, and β-hexosaminidase B, which has 2 β subunits. β-Hexosaminidase A deficiency results from mutations in the α subunit and causes Tay-Sachs disease, whereas mutations in the β-subunit gene result in the deficiency of both β-hexosaminidases A and B and cause Sandhoff

disease. Both are autosomal recessive traits, with Tay-Sachs disease being more frequent in the Ashkenazi Jewish population, where the carrier frequency is approximately 1 in 25.

More than 50 mutations have been identified; most are associated with the infantile forms of disease. Three mutations account for >98% of mutant alleles among Ashkenazi Jewish carriers of Tay-Sachs disease, including 1 allele associated with the adult-onset form. Mutations that cause the subacute or adult-onset forms result in enzyme proteins with residual enzymatic activities, the levels of which correlate with the severity of the disease.

Patients with the infantile form of Tay-Sachs disease have clinical manifestations in infancy including loss of motor skills, increased startle reaction, and macular pallor and **retinal cherry-red spots** (see Table 86-15). Affected infants usually develop normally until 4-5 mo of age when decreased eye contact and an exaggerated startle response to noise (**hyperacusis**) are noted. **Macrocephaly**, not associated with

hydrocephalus, may develop. In the 2nd yr of life, seizures develop which may be refractory to anticonvulsant therapy. Neurodegeneration is relentless, with death occurring by the age of 4 or 5 yr. The juvenile and later-onset forms initially present with ataxia and dysarthria and may not be associated with a macular cherry-red spot.

The clinical manifestations of **Sandhoff** disease are similar to those of Tay-Sachs disease. Infants with Sandhoff disease have hepatosplenomegaly, cardiac involvement, and mild bony abnormalities. The juvenile form of this disorder presents as ataxia, dysarthria, and mental deterioration, but without visceral enlargement or a macular cherry red spot. There is no treatment available for Tay-Sachs disease or Sandhoff disease, although experimental approaches are being evaluated.

The diagnosis of infantile Tay-Sachs disease and Sandhoff disease is usually suspected in an infant with neurologic features and a cherry-red spot. Definitive diagnosis is made by determination of β-hexosaminidase A and B activities in peripheral leukocytes. The 2 disorders are distinguished by the enzymatic assay, because in Tay-Sachs disease only the β-hexosaminidase A isozyme is deficient, whereas in Sandhoff disease both of the β-hexosaminidase A and B isozymes are deficient. At-risk pregnancies for both disorders can be prenatally diagnosed by determining the enzyme levels in fetal cells obtained by amniocentesis or chorionic villus sampling. Identification of carriers in families is also possible by β-hexosaminidases A and B determination. Indeed, for Tay-Sachs disease, carrier screening of all couples in which at least 1 member is of Ashkenazi Jewish descent is recommended before the initiation of pregnancy to identify couples at risk. These studies can be conducted by the determination of the level of β-hexosaminidase A activity in peripheral leukocytes or plasma. Molecular studies to identify the exact molecular defect in enzymatically identified carriers should also be performed to permit more specific identification of carriers in the family and to allow prenatal diagnosis in at-risk couples by both enzymatic and genotype determinations. The incidence of Tay-Sachs disease has been markedly reduced since the introduction of carrier screening programs in the Ashkenazi Jewish population. Newborn screening may be possible by measuring specific glycosphingolipid markers, or the relevant enzymatic activities in dried blood spots.

GAUCHER DISEASE

This disease is a multisystemic lipidosis characterized by hematologic abnormalities, organomegaly, and skeletal involvement, the latter usually manifesting as bone pain and pathologic fractures (see Table 86-15). It is one of the most common lysosomal storage diseases and the most prevalent genetic defect among Ashkenazi Jews. There are 3 clinical subtypes delineated by the absence or presence and progression of neurologic manifestations: type 1 or the adult, nonneuronopathic form; type 2, the infantile or acute neuronopathic form; and type 3, the juvenile or subacute neuronopathic form. All are autosomal recessive traits. Type 1, which accounts for 99% of cases, has a striking predilection for Ashkenazi Jews, with an incidence of approximately 1 in 1,000 live births and a carrier frequency of approximately 1 in 18 adults.

Gaucher disease results from the deficient activity of the lysosomal hydrolase, acid β-glucosidase, which is encoded by a gene located on chromosome 1q21-q31. The enzymatic defect results in the

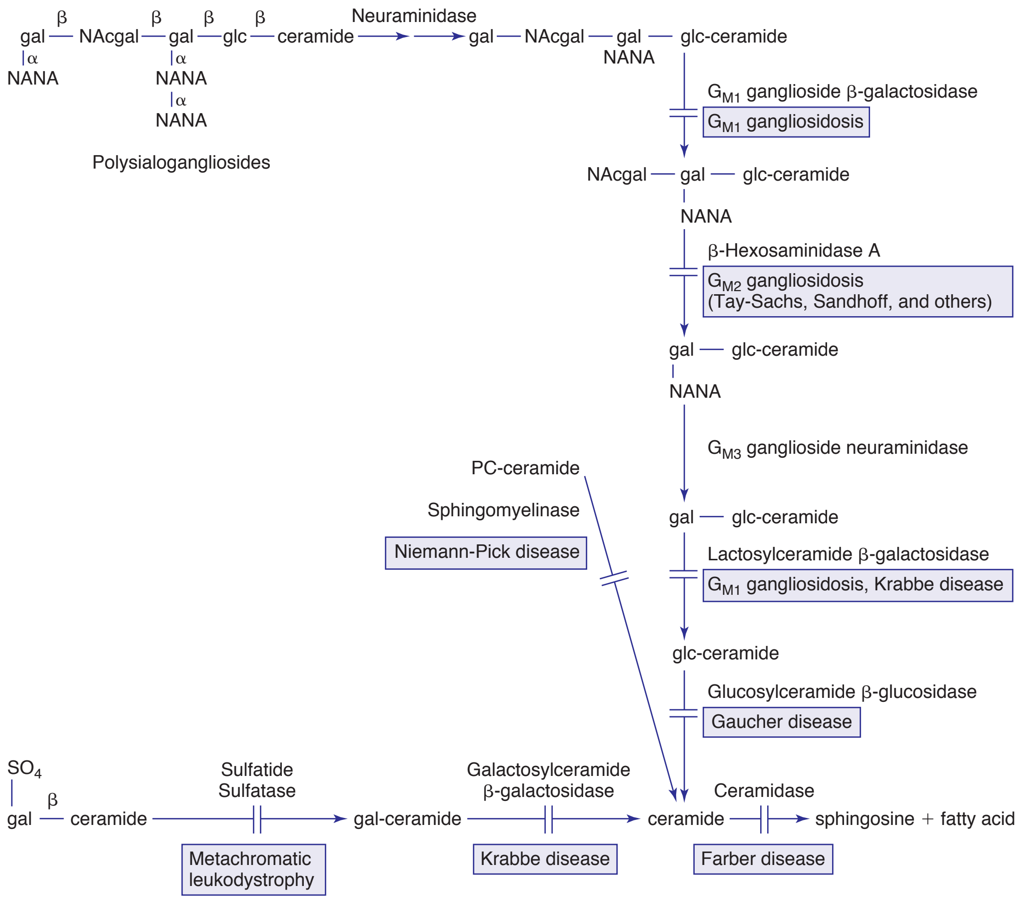

Figure 86-15 Pathways in the metabolism of sphingolipids found in nervous tissues. The name of the enzyme catalyzing each reaction is given with the name of the substrate that it hydrolyzes. Inborn errors are depicted as *bars* crossing the reaction *arrows,* and the name of the associated defect or defects is given in the nearest *box.* The gangliosides are named according to the nomenclature of Svennerholm. Anomeric configurations are given only at the largest starting compound. *Gal,* galactose; *glc,* glucose; *NAcgal, N*-acetylgalactosamine; *NANA, N*-acetylneuraminic acid; *PC,* phosphorylcholine.

accumulation of undegraded glycolipid substrates, particularly glucosylceramide, in cells of the reticuloendothelial system. This progressive deposition results in infiltration of the bone marrow, progressive hepatosplenomegaly, and skeletal complications. Four mutations—N370S, L444P, 84insG, and IVS2+2—account for approximately 95% of mutant alleles among Ashkenazi Jewish patients, permitting screening for this disorder in this population. Genotype–phenotype correlations have been noted, providing the molecular basis for the clinical heterogeneity seen in Gaucher disease type 1. Patients who are homozygous for the N370S mutation tend to have later onset, with a more indolent course than patients with 1 copy of N370S and another common allele.

Clinical manifestations of type 1 Gaucher disease have a variable age at onset, from early childhood to late adulthood, with most symptomatic patients presenting by adolescence. At presentation, patients may have bruising from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated liver function test results, splenomegaly, and bone pain. Occasional patients have pulmonary involvement at the time of presentation. Patients presenting in the 1st decade frequently are not Jewish and have growth retardation and a more malignant course. Other patients may be discovered fortuitously during evaluation for other conditions or as part of routine examinations; these patients may have a milder or even a benign course. In symptomatic patients, splenomegaly is progressive and can become massive. Most patients develop radiologic evidence of skeletal involvement, including an Erlenmeyer flask deformity of the distal femur. Clinically apparent bony involvement, which occurs in most patients, can present as bone pain, a pseudoosteomyelitis pattern or pathologic fractures. Lytic lesions can develop in the long bones, including the femur, ribs, and pelvis; osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis or bruising and is frequently overlooked until other symptoms become apparent. With the exception of the severely growth-retarded child, who may experience developmental delay secondary to the effects of chronic disease, development and intelligence are normal.

The pathologic hallmark of Gaucher disease is the Gaucher cell in the reticuloendothelial system, particularly in the bone marrow (Fig. 86-18). These cells, which are 20-100 µm in diameter, have a characteristic wrinkled paper appearance resulting from the presence of intracytoplasmic substrate inclusions. The cytoplasm of the Gaucher cell reacts strongly positive with the periodic acid–Schiff stain. The presence of this cell in bone marrow and tissue specimens is highly suggestive of Gaucher disease, although it also may be found in patients with granulocytic leukemia and myeloma.

Gaucher disease type 2 is a rare form and does not have an ethnic predilection. It is characterized by a rapid neurodegenerative course with extensive visceral involvement and death within the first years of life. It presents in infancy with increased tone, strabismus, and organomegaly. Failure to thrive and stridor caused by laryngospasm are typical. After a several-year period of psychomotor regression, death typically occurs secondary to respiratory compromise. **Gaucher disease type 3** presents with clinical manifestations that are intermediate to those seen in types 1 and 2, with presentation in childhood

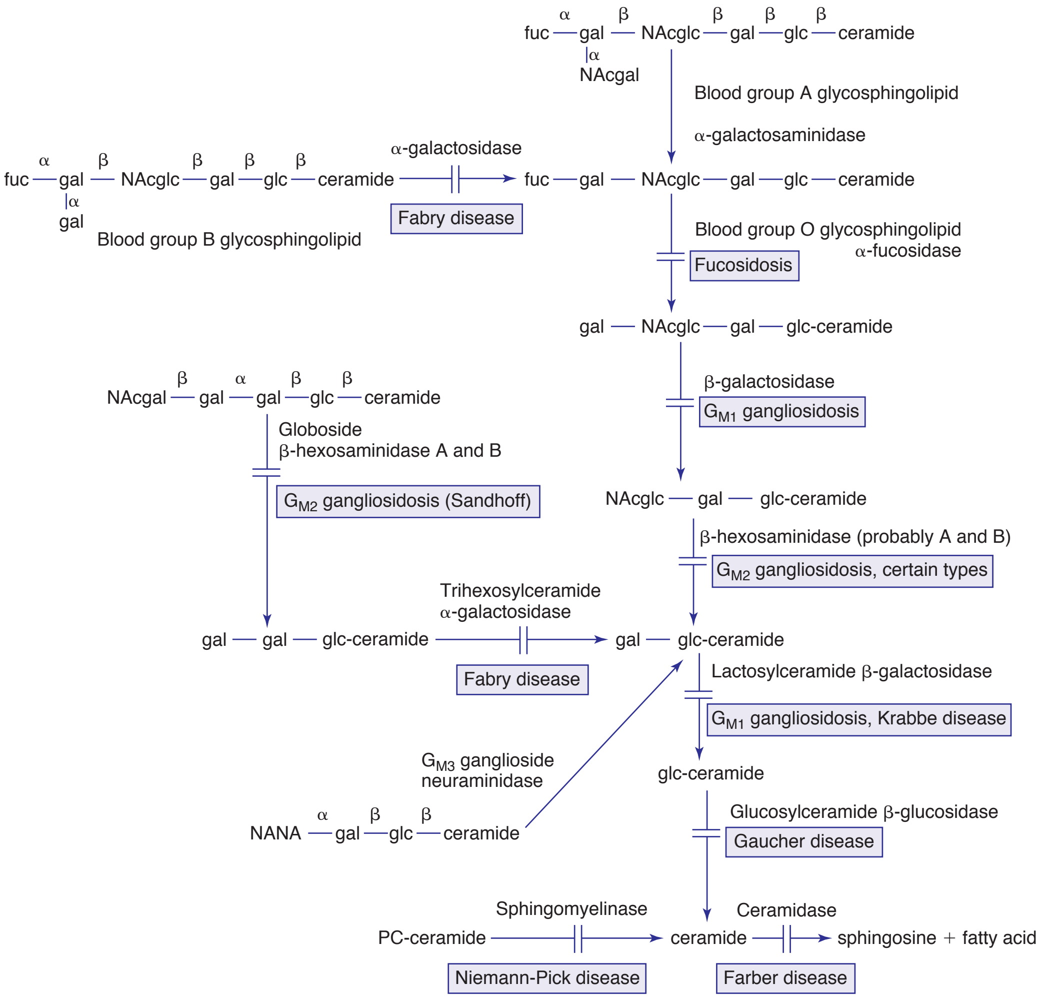

Figure 86-16 Pathways in the degradation of sphingolipids found in visceral organs and red or white blood cells. See also the legend for Figure 86-15. *Fuc,* fucose; *NAcglc, N*-acetylglucosamine.

and death by age 10-15 yr. It has a predilection for the Swedish Norrbottnian population, among whom the incidence is approximately 1 in 50,000. Neurologic involvement is present. Type 3 disease is further classified as types 3a and 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Gaucher disease should be considered in the differential diagnosis of patients with unexplained organomegaly, who bruise easily, have bone pain, or have a combination of these conditions. Bone marrow examination usually reveals the presence of Gaucher cells. All suspected diagnoses should be confirmed by determination of the acid β-glucosidase activity in isolated leukocytes or cultured fibroblasts, and by identification of their specific acid β-glucosidase gene mutations. In Ashkenazi Jewish individuals the identification of carriers can be achieved best by molecular testing for the common Ashkenazi mutations. Testing should be offered to all family members, keeping in mind that heterogeneity, even among members of the same kindred, can be so great that nonsymptomatic affected individuals may be diagnosed. Prenatal diagnosis is available by determination of enzyme activity and/or the specific family mutations in chorionic villi or cultured amniotic fluid cells.

Treatment of patients with Gaucher disease type 1 includes enzyme replacement therapy. The efficacy of enzyme replacement therapy with mannose-terminated recombinant human acid β-glucosidase has definitively been demonstrated. Most symptoms (organomegaly, hematologic indices, bone pain) are reversed by enzyme replacement therapy (60 IU/kg) administered by intravenous infusion every other week and the bone involvement can be stabilized or improved. Two additional enzyme preparations are approved by the FDA for the treatment of type 1 Gaucher disease, including velaglucerase alfa (VPRIV, Shire HGT), which is produced in human fibrosarcoma cells, and taliglucerase alfa (Uplyso, Protalix Biotherapeutics), which is produced in carrot cells.

Although enzyme replacement does not alter the neurologic progression of patients with Gaucher disease types 2 and 3, it has been used in selected patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatments, including the use of oral substrate reduction agents designed to decrease the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase (e.g., miglustat), also are available. A small number of patients have undergone bone marrow transplantation (BMT), which is curative but is associated with significant morbidity and mortality from the procedure, limiting the selection of appropriate candidates.

NIEMANN-PICK DISEASE

The original description of NPD was what is now known as **type A NPD**, a fatal disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by 2-3 yr of age. **Type B** disease is a non-neuronopathic form observed in children and adults. **Type C** disease is a neuronopathic form that results from defective cholesterol transport. All subtypes are inherited as autosomal recessive traits and display variable clinical features (see Table 86-15).

NPD types A and B result from the deficient activity of acid sphingomyelinase, a lysosomal enzyme encoded by a gene on chromosome

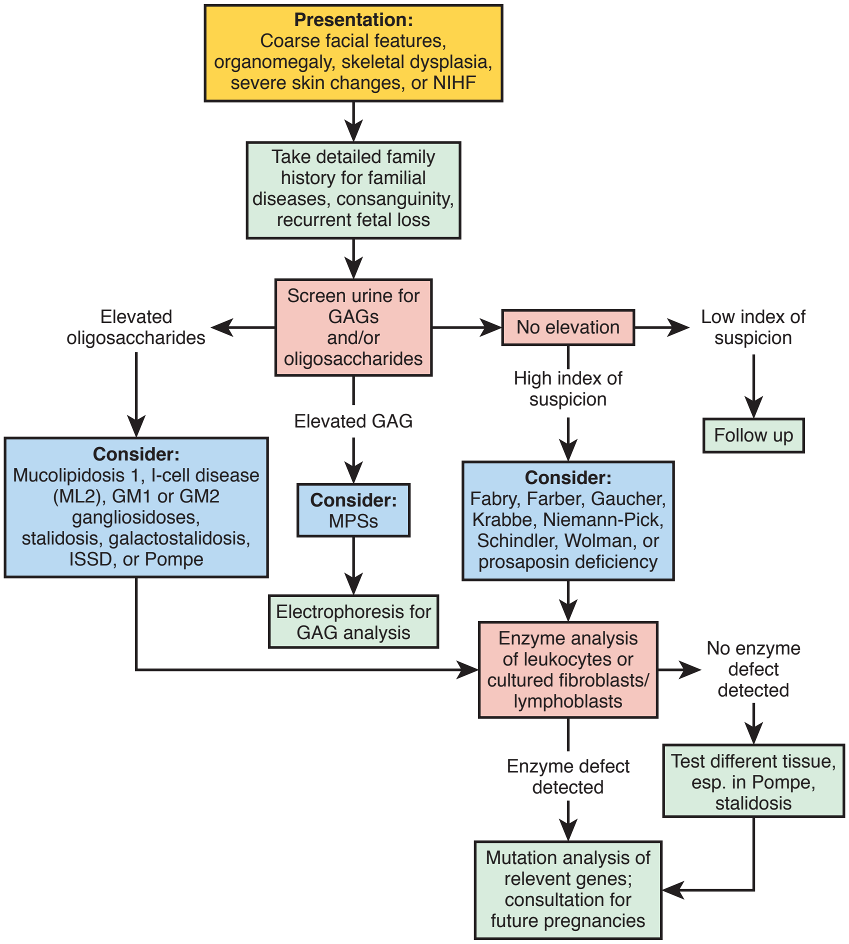

Figure 86-17 Algorithm of the clinical evaluation recommended for an infant with a suspected lysosomal storage disease. *GAGs,* glycosaminoglycans; *NIHF,* nonimmune hydrops fetalis. *(From Staretz-Chacham O, Lang TC, LaMarca ME, et al: Lysosomal storage disorders in the newborn,* Pediatrics *123:1191–1207, 2009.)*

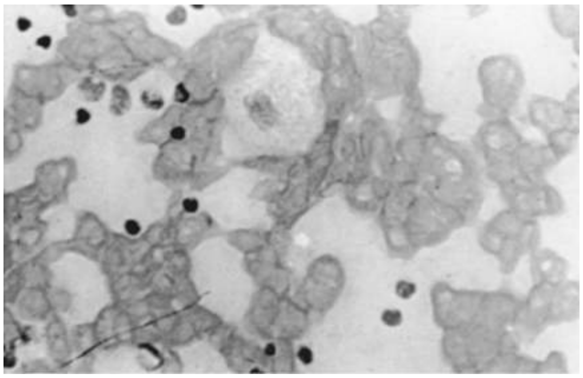

Figure 86-18 Cells from the spleen of a patient with Gaucher disease. A characteristic spleen cell is shown engorged with glucocerebroside.

11 (11p15.1-p15.4). The enzymatic defect results in the pathologic accumulation of sphingomyelin, a ceramide phospholipid, and other lipids in the monocyte–macrophage system, the primary pathologic site. The progressive deposition of sphingomyelin in the central nervous system results in the neurodegenerative course seen in type A, and in nonneural tissue in the systemic disease manifestations of type B, including progressive lung disease in some patients. A variety of mutations in the acid sphingomyelinase gene that cause types A and B NPD have been identified.

The clinical manifestations and course of type A NPD is uniform and is characterized by a normal appearance at birth. Hepatosplenomegaly, moderate lymphadenopathy, and psychomotor retardation are evident by 6 mo of age, followed by neurodevelopmental regression and death by 3 yr. With advancing age, the loss of motor function and the deterioration of intellectual capabilities are progressively debilitating; and in later stages, spasticity and rigidity are evident. Affected infants lose contact with their environment. In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most are diagnosed in infancy or childhood when enlargement of the liver or spleen, or both, is detected during a routine physical examination. At diagnosis, type B NPD patients usually have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on the chest radiograph. **Pulmonary symptoms** may present in adults. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth, the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations.

Severely affected patients may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia caused by secondary **hypersplenism** may require partial or complete splenectomy; this should be avoided if possible because splenectomy frequently causes progression of pulmonary disease, which can be life-threatening. In general, type B patients do not have neurologic involvement and have a normal IQ. Some patients with type B disease have cherry-red maculae or haloes and subtle neurologic symptoms (peripheral neuropathy). In some type B patients, decreased pulmonary diffusion caused by alveolar infiltration becomes evident in late childhood or early adulthood and progresses with age.

Severely affected individuals may experience significant pulmonary compromise by 15-20 yr of age. Such patients have low PO_2 values and dyspnea on exertion. Life-threatening bronchopneumonias may occur, and cor pulmonale has been described.

Type C NPD patients often present with prolonged neonatal jaundice, appear normal for 1-2 yr, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that of patients with types A or B NPD, and they may survive into adulthood. The underlying biochemical defect in type C patients is an abnormality in cholesterol transport, leading to the accumulation of sphingomyelin and cholesterol in their lysosomes and a secondary partial reduction in acid sphingomyelinase activity (see Chapter 86.3).

In type B NPD patients, splenomegaly is usually the first manifestation detected. The splenic enlargement is noted in early childhood; in very mild disease, the enlargement may be subtle and detection may be delayed until adolescence or adulthood. The presence of the characteristic NPD cells in bone marrow aspirates supports the diagnosis of type B NPD. Patients with type C NPD, however, also have extensive infiltration of NPD cells in the bone marrow and, thus, all suspected cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity level in peripheral leukocytes, cultured fibroblasts, or lymphoblasts, or a combination of these cells. Patients with types A and B NPD have markedly decreased levels (1-10%), whereas patients with type C NPD have normal or somewhat decreased acid sphingomyelinase activities. The enzymatic identification of NPD carriers is problematic. In families in which the specific molecular lesion has been identified, however, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B NPD can be made reliably by the measurement of acid sphingomyelinase activity in cultured amniocytes or chorionic villi; molecular analysis of fetal cells to identify the specific acid sphingomyelinase mutations can provide the specific diagnosis or serve as a confirmatory test. The clinical diagnosis of type C NPD can be supported by the demonstration of filipin stain positivity in cultured fibroblasts and/or by identifying a specific mutation in the *NPC 1* or *2* gene.

Currently there is no specific treatment for NPD. Orthotopic liver transplantation in an infant with type A disease and cord blood transplantation in several type B NPD patients have been attempted with little or no success. BMT in a small number of type B NPD patients has been successful in reducing the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and radiologically detected infiltration of the lungs. In 1 patient, liver biopsies taken up to 33 mo posttransplantation showed only a moderate reduction in stored sphingomyelin. A phase I trial of enzyme replacement therapy for type B NPD has been completed which demonstrated elevated cytokine and bilirubin levels at the higher doses administered (0.6 and 1.0 mg/kg). The observed toxicity is presumably a result of the catabolism of the accumulated sphingomyelin to ceramide. Further clinical studies to evaluate effectiveness of this approach are planned. Clinical trials of miglustat (Actelion, Basel, Switzerland) have been performed and the drug has been approved in Europe for the treatment of type C disease. Treatment of type A disease by BMT has not been successful presumably because of the severe neurologic involvement.

FABRY DISEASE

This disease is an X-linked inborn error of glycosphingolipid metabolism caused by the absent or markedly deficient activity of α-galactosidase A (α-gal A). There are 2 major phenotypes. Affected males with the classic phenotype present in childhood with angiokeratomas (telangiectatic skin lesions), hypohidrosis, corneal and lenticular opacities, acroparesthesias, and with advancing age develop vascular disease of the kidney, heart, and/or brain (see Table 86-15). This classic phenotype is caused by the absent activity of the α-gal A and has an estimated prevalence of approximately 1 in 50,000 males. The later-onset phenotype occurs in affected males with residual α-gal A activity and presents in the 4th to 8th decades with cardiac disease and/or renal failure. This phenotype is more prevalent than the classic phenotype.

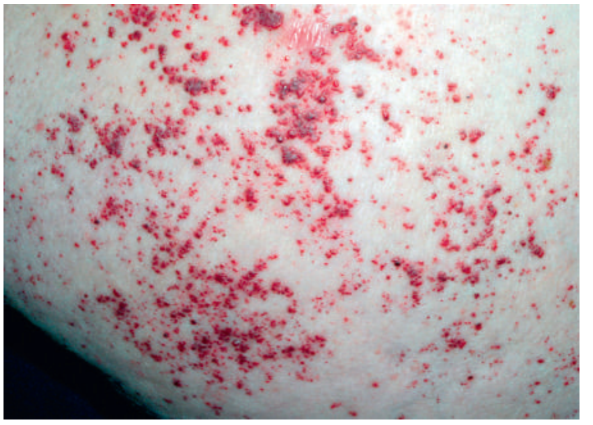

Figure 86-19 Typical angiokeratomas. Angiokeratomas are quite large and easily recognizable, but if only a few lesions exist or they are restricted only to the genitalia or umbilical regions, they can be easily missed. *(From Zarate VA, Hopkin RJ: Fabry's disease,* Lancet *372:1427, 2008.)*

Heterozygous females for the classic phenotype can be asymptomatic or as severely affected as the males, the variability a result of random X-inactivation. The enzyme deficiency results from mutations in the α-gal A gene located on the long arm of the X chromosome (Xq22). The enzymatic defect leads to the systemic accumulation of neutral glycosphingolipids, primarily globotriaosylceramide, particularly in the plasma and lysosomes of vascular endothelial and smooth muscle cells, cardiac myocytes, and renal podocytes. The progressive vascular glycosphingolipid deposition in classically affected males results in small vessel occlusion and ischemia, leading to the major disease manifestations. The complementary DNA and genomic sequences encoding α-gal A have been characterized and more than 500 different mutations in the α-gal A gene are responsible for this lysosomal storage disease.

The **angiokeratomas** usually occur in childhood and may lead to early diagnosis (Fig. 86-19). They increase in size and number with age and range from barely visible to several millimeters in diameter. The lesions are punctate, dark red to blue-black, and flat or slightly raised. They do not blanch with pressure, and the larger ones may show slight hyperkeratosis. Characteristically, the lesions are most dense between the umbilicus and knees, in the "bathing trunk area," but may occur anywhere, including the oral mucosa. The hips, thighs, buttocks, umbilicus, lower abdomen, scrotum, and glans penis are common sites, and there is a tendency toward symmetry. Variants without skin lesions have been described. Sweating is usually decreased or absent. Corneal opacities and characteristic lenticular lesions, observed under slit-lamp examination, are present in affected males, as well as in approximately 90% of heterozygotes from families with the classic phenotype. Conjunctival and retinal vascular tortuosity is common and results from the systemic vascular involvement.

Pain is the most debilitating symptom in childhood and adolescence. **Fabry crises,** lasting from minutes to several days, consist of agonizing, burning pain in the hands, feet, and proximal extremities and are usually associated with exercise, fatigue, fever, or a combination of these factors. These painful acroparesthesias usually become less frequent in the 3rd and 4th decades of life, although in some men, they may become more frequent and severe. Attacks of abdominal or flank pain may simulate appendicitis or renal colic.

The major morbid symptoms result from the progressive involvement of the vascular system. Early in the course of the classic phenotype, casts, red cells, and lipid inclusions with characteristic birefringent "Maltese crosses" appear in the urinary sediment. Proteinuria, isosthenuria, and gradual deterioration of renal function and development of azotemia occur in the 2nd through 4th decades in the classic phenotype and in the 4th to 8th decades in the later-onset form. Cardiovascular findings may include arrhythmias, left ventricular hypertrophy, angina, myocardial ischemia or infarction, and heart failure. Mitral insufficiency is the most common valvular lesion. Cerebrovascular

manifestations, including transient ischemic attacks and strokes, result from multifocal small vessel involvement. Other features may include chronic bronchitis and dyspnea, lymphedema of the legs without hypoproteinemia, episodic diarrhea, osteoporosis, retarded growth, and delayed puberty. Death most often results from renal failure or vascular disease of the heart or brain. Before hemodialysis or renal transplantation, the mean age at death for affected men was 40 yr. Patients with the later-onset phenotype with residual α-gal A activity have cardiac and/or renal disease. The cardiac manifestations include hypertrophy of the left ventricular wall and interventricular septum, and electrocardiographic abnormalities consistent with cardiomyopathy. Patients may progress to hypertrophic cardiomyopathy or myocardial infarction, or both.

The diagnosis in classically affected males is most readily made from the history of painful acroparesthesias, hypohidrosis, the presence of the characteristic skin lesions, and the observation of the corneal opacities and lenticular lesions. The disorder is often misdiagnosed as rheumatic fever, erythromelalgia, or neurosis. The skin lesions must be differentiated from the benign angiokeratomas of the scrotum (Fordyce disease) or from angiokeratoma circumscriptum. **Angiokeratomas** identical to those of Fabry disease have been reported in fucosidosis, aspartylglycosaminuria, late-onset GM_1 gangliosidosis, galactosialidosis, α-*N*-acetylgalactosaminidase deficiency, and sialidosis. Later-onset patients have been identified among patients on hemodialysis and among patients with hypertrophic cardiomyopathy or who have suffered cryptogenic strokes. Later-onset patients lack the early classic manifestations such as the angiokeratomas, acroparesthesias, hypohidrosis, and corneal opacities. The diagnosis of classic and later-onset patients is confirmed biochemically by the demonstration of markedly decreased α-gal A activity in plasma, isolated leukocytes, or cultured fibroblasts or lymphoblasts. The specific α-gal A mutation can be determined by gene sequencing.

Heterozygous females may have corneal opacities, isolated skin lesions, and intermediate activities of α-gal A in plasma or cells. Rare female heterozygotes may have manifestations as severe as those in affected males. Asymptomatic at-risk females in families affected by Fabry disease, however, should be optimally diagnosed by the direct analysis of their family's specific mutation. Prenatal detection of affected males can be accomplished by the demonstration of deficient α-gal A activity and/or the family's specific gene mutation in chorionic villi obtained in the 1st trimester or in cultured amniocytes obtained by amniocentesis in the 2nd trimester of pregnancy. Fabry disease can be detected by newborn screening and pilot studies have been conducted in Italy and Taiwan.

Treatment for Fabry disease may include the use of phenytoin and/or carbamazepine to decrease the frequency and severity of the chronic acroparesthesias and the periodic crises of excruciating pain. Renal transplantation and long-term hemodialysis are lifesaving procedures for patients with renal failure.

Enzyme replacement therapy for Fabry patients using recombinant human α-gal A preparations produced in Chinese hamster ovary cells (agalsidase beta, Fabrazyme, Genzyme Corporation) and in human fibrosarcoma cells (agalsidase alfa, Replagal, Shire HGT) has been developed. Both Fabrazyme and Replagal were approved by the European Medicines Agency in the European Union, but only Fabrazyme is approved by the FDA in the United States. The effectiveness of enzyme replacement therapy with Fabrazyme in stabilization of renal disease, regression of hypertrophic cardiomyopathy, reduction of pain, and improvement in quality of life has been demonstrated. Because most classically affected males produce no enzyme protein, these patients produce immunoglobulin G antibodies in response to the infused enzyme which can impact the effectiveness of substrate clearance. Treatment of classically affected males should begin in childhood.

FUCOSIDOSIS

This is a rare autosomal recessive disorder caused by the deficient activity of α-fucosidase and the accumulation of fucose-containing glycosphingolipids, glycoproteins, and oligosaccharides in the lysosomes of the liver, brain, and other organs (see Table 86-15). The α-fucosidase gene is on chromosome 1 (1p24), and specific mutations are known. Although the disorder is panethnic, most reported patients are from Italy and the United States. There is wide variability in the clinical phenotype, with the most severely affected patients presenting in the first year of life with developmental delay and somatic features similar to those of the mucopolysaccharidoses. These features include frontal bossing, hepatosplenomegaly, coarse facial features, and macroglossia. The central nervous system storage results in a relentless neurodegenerative course, with death in childhood. Patients with milder disease have angiokeratomas and longer survival. No specific therapy exists for the disorder, which can be diagnosed by the demonstration of deficient α-fucosidase activity in peripheral leukocytes or cultured fibroblasts. Carrier identification and prenatal diagnosis are possible by determination of the enzymatic activity or the specific family mutations.

SCHINDLER DISEASE

This is an autosomal recessive neurodegenerative disorder that results from the deficient activity of α-*N*-acetylgalactosaminidase and the accumulation of sialylated and asialoglycopeptides and oligosaccharides (see Table 86-15). The gene for the enzyme is located on chromosome 22 (22q11). The disease is clinically heterogeneous, and 2 major phenotypes have been identified. Type I disease is an infantile-onset neuroaxonal dystrophy. Affected infants have normal development for the first 9-15 mo of life followed by a rapid neurodegenerative course that results in severe psychomotor retardation, cortical blindness, and frequent myoclonic seizures. Type II disease is characterized by a variable age at onset, mild intellectual disability, and angiokeratomas. There is no specific therapy for either form of the disorder. The diagnosis is by demonstration of the enzymatic deficiency in leukocytes or cultured skin fibroblasts or specific gene mutations.

METACHROMATIC LEUKODYSTROPHY

This is an autosomal recessive white matter disease caused by a deficiency of arylsulfatase A (ASA), which is required for the hydrolysis of sulfated glycosphingolipids. Another form of metachromatic leukodystrophy (MLD) is caused by a deficiency of a sphingolipid activator protein (SAP1), which is required for the formation of the substrate–enzyme complex. The deficiency of this enzymatic activity results in the white matter storage of sulfated glycosphingolipids, which leads to demyelination and a neurodegenerative course. The *ASA* gene is on chromosome 22 (22q13.31qter); specific mutations tend to fall into 2 groups that correlate with disease severity.

The clinical manifestations of the late **infantile** form of MLD, which is most common, usually present between 12 and 18 mo of age as irritability, inability to walk, and hyperextension of the knee, causing genu recurvatum. The clinical progression of the disease relates to the pathologic involvement of both central and peripheral nervous system, giving a mixture of upper and lower motor neuron and cognitive and psychiatric signs. Deep tendon reflexes are diminished or absent. Gradual muscle wasting, weakness, and hypotonia become evident and lead to a debilitated state. As the disease progresses, nystagmus, myoclonic seizures, optic atrophy, and quadriparesis appear, with death in the 1st decade of life (see Table 86-15). The **juvenile** form of the disorder has a more indolent course with onset that may occur as late as 20 yr of age. This form of the disease presents with gait disturbances, mental deterioration, urinary incontinence, and emotional difficulties. The **adult** form, which presents after the 2nd decade, is similar to the juvenile form in its clinical manifestations, although emotional difficulties and psychosis are more prominent features. Dementia, seizures, diminished reflexes, and optic atrophy also occur in both the juvenile and adult forms. The pathologic hallmark of MLD is the deposition of metachromatic bodies, which stain strongly positive with periodic acid–Schiff and Alcian blue, in the white matter of the brain. Neuronal inclusions may be seen in the midbrain, pons, medulla, retina, and spinal cord; demyelination occurs in the peripheral nervous system. The diagnosis of MLD should be suspected in patients with the clinical features of leukodystrophy. Decreased nerve conduction velocities, increased cerebrospinal fluid protein, metachromatic deposits in sampled segments of sural nerve, and metachromatic granules in urinary

sediment are all suggestive of MLD. Confirmation of the diagnosis is based on the demonstration of the reduced activity of ASA in leukocytes or cultured skin fibroblasts. SAP deficiency is diagnosed by measuring the concentration of SAP1 in cultured fibroblasts using a specific antibody to the protein. The diagnosis, identification of carriers and prenatal diagnosis are available for both forms of the disorder by detection of the causative mutations in the ASA or SAP genes.

Unrelated donor umbilical cord blood transplantation has been undertaken in some pediatric patients with MLD. A longitudinal study of 6 patients with late-infantile onset and 14 with juvenile onset revealed that motor deficits present at the time of transplant did not improve and that neurologic symptoms continued to progress in those with late-infantile presentation. In contrast, in juvenile patients the brainstem auditory evoked responses, visual evoked potentials, electroencephalogram, and/or peripheral nerve conduction velocities stabilized or improved. Therefore consideration of umbilical cord blood transplantation for children with presymptomatic late-infantile MLD or minimally symptomatic juvenile MLD may be indicated.

MULTIPLE SULFATASE DEFICIENCY

This is an autosomal recessive disorder that results from the enzymatic deficiency of at least 9 sulfatases including arylsulfatases A, B, and C, and iduronate-2-sulfatase. The specific defect is an enzyme in the C-α-formylglycine generating system (the gene for which is located at 3p26), which introduces a common posttranslational modification in all of the affected sulfatases and explains the occurrence of these multiple enzyme defects. Because of the deficiency of these enzymes, sulfatides, mucopolysaccharides, steroid sulfates, and gangliosides accumulate in the cerebral cortex and visceral tissues, resulting in a clinical phenotype with features of a **leukodystrophy** as well as those of the **mucopolysaccharidoses**. Severe ichthyosis may also occur. Carrier testing and prenatal diagnosis by measurement of the enzymatic activities or the specific gene defects can be performed. There is no specific treatment for multiple sulfatase deficiency other than supportive care.

KRABBE DISEASE

This condition, also called globoid cell leukodystrophy, is an autosomal recessive fatal disorder of infancy. It results from the deficient activity of galactocerebrosidase and the white matter accumulation of galactosylceramide, which is normally found almost exclusively in the myelin sheath. Both peripheral and central myelin are affected, resulting in spasticity and cognitive impairment coupled with deceptively normal or even absent deep tendon reflexes. The galactocerebrosidase gene is on chromosome 14 (14q31), and specific disease-causing mutations are known. The **infantile** form of Krabbe disease is rapidly progressive and patients present in early infancy with irritability, seizures, and hypertonia (see Table 86-15). Optic atrophy is evident in the 1st yr of life, and mental development is severely impaired. As the disease progresses, optic atrophy and severe developmental delay become apparent; affected children exhibit opisthotonos and die before 3 yr of age. A **late infantile** form of Krabbe presents after the age of 2 yr. Affected individuals have a course similar to that of the early infantile form.

The diagnosis of Krabbe disease relies on the demonstration of the specific enzymatic deficiency in white blood cells or cultured skin fibroblasts. Causative gene mutations have been identified. Carrier identification and prenatal diagnosis are available. The development of methods to measure galactocerebrosidase activity on dried blood spots has led to the inclusion of Krabbe disease in the newborn screening programs of some states. Treatment of infants with Krabbe disease with umbilical cord blood cell transplantation has been reported in prenatally identified asymptomatic newborns and symptomatic infants. Transplanted infants appear to develop neurologic manifestations at a slower rate but succumb to a neurologic demise.

FARBER DISEASE

This is a rare autosomal recessive disorder that results from the deficiency of the lysosomal enzyme acid ceramidase and the accumulation of ceramide in various tissues, especially the joints. Symptoms can begin in the first year of life with painful joint swelling and nodule formation (Fig. 86-20), which is sometimes diagnosed as rheumatoid arthritis. As the disease progresses, nodule or granulomatous formation on the vocal cords can lead to hoarseness and breathing difficulties; failure to thrive is common. In some patients, moderate central nervous system dysfunction is present (see Table 86-15). Patients may die of recurrent pneumonias in their teens; there is currently no specific therapy. The diagnosis of this disorder should be suspected in patients who have nodule formation over the joints but no other findings of rheumatoid arthritis. In such patients, ceramidase activity should be determined in cultured skin fibroblasts or peripheral leukocytes. Various disease causing mutations have been identified in the acid ceramidase gene. Carrier detection and prenatal diagnosis are available.

Figure 86-20 Forearm of an 18 mo old girl with Farber disease. Note the painful joint swelling and the nodule formation. The infant was suspected of having rheumatoid arthritis.

WOLMAN DISEASE AND CHOLESTEROL ESTER STORAGE DISEASE

These are autosomal recessive lysosomal storage diseases that result from the deficiency of acid lipase and the accumulation of cholesterol esters and triglycerides in histiocytic foam cells of most visceral organs. The gene for lysosomal acid lipase is on chromosome 10 (10q24-q25). Wolman disease is the more severe clinical phenotype and is a fatal disorder of infancy. Clinical features become apparent in the first weeks of life and include failure to thrive, relentless vomiting, abdominal distention, steatorrhea, and hepatosplenomegaly (see Table 86-15). There usually is hyperlipidemia. Hepatic dysfunction and fibrosis may occur. **Calcification of the adrenal glands** occurs in about 50% of patients. Death usually occurs within the first 6 mo of life.

Cholesterol ester storage disease is a less-severe disorder that may not be diagnosed until adulthood. Hepatomegaly can be the only detectable abnormality, but affected individuals are at significant risk for premature cirrhosis and atherosclerosis. Adrenal calcification can occur in severe early onset patients.

Diagnosis and carrier identification are based on measuring acid lipase activity in peripheral leukocytes or cultured skin fibroblasts. Disease causing mutations have been identified in the acid ceramide gene. Prenatal diagnosis depends on measuring decreased enzyme levels or identifying specific mutations in cultured chorionic villi or amniocytes. There is no specific therapy available for either disorder. Although pharmacologic agents to suppress cholesterol synthesis, in combination with cholestyramine and diet modification, have been used in patients there is little to no clinical benefit. Enzyme

replacement therapy is currently being evaluated in clinical trials for both diseases (see Chapter 86.3).

Bibliography is available at Expert Consult.

86.5 Mucolipidoses

Margaret M. McGovern and Robert J. Desnick

I-cell disease (mucolipidosis II [ML-II]) and pseudo-Hurler polydystrophy (mucolipidosis III [ML-III]) are rare autosomal recessive disorders that share some clinical features with Hurler syndrome (see Chapter 88). These diseases result from the abnormal targeting of newly synthesized lysosomal enzymes that normally have phosphorylated mannose residues for binding to the mannose-6-phosphate receptors which transport the enzymes to the lysosomes. These mannose-6-phosphate residues are synthesized in a 2-step reaction that occurs in the Golgi apparatus and is mediated by 2 enzymatic activities. The enzyme that catalyzes the first step, the lysosomal enzyme *N*-acetylglucosamine-1-phosphotransferase, is defective in both ML-II and ML-III, which are allelic disorders resulting from mutations in the GlcNAc-phosphotransferase α/β-subunits precursor gene *(GNPTAB)*. This enzyme deficiency results in abnormal targeting of the lysosomal enzymes which are consequently secreted into the extracellular matrix. Because the lysosomal enzymes require the acidic environment of the lysosome to function, patients with this defect accumulate a variety of different substrates because of the intracellular deficiency of most lysosomal enzymes. The diagnosis of ML-II and ML-III can be made by the determination of the serum lysosomal enzymatic activities, which are markedly elevated, or by the demonstration of their reduced enzymatic activity levels in cultured skin fibroblasts. Direct measurement of the phosphotransferase activity is possible as well. Prenatal diagnosis is available for both disorders by measurement of lysosomal enzymatic activities in amniocytes or chorionic villus cells; carrier identification is available for both disorders by measurement of enzymatic activities using cultured skin fibroblasts or by mutation analysis of the causative gene. Neonatal screening by tandem mass spectroscopy may detect I-cell disease.

I-CELL DISEASE

This disorder, ML-II, shares many of the clinical manifestations of Hurler syndrome (see Chapter 88), although there is no mucopolysacchariduria and the presentation is earlier (see Table 86-15). Some patients have clinical features evident at birth, including coarse facial features, craniofacial abnormalities, restricted joint movement, and hypotonia. Nonimmune hydrops may be present in the fetus. The remainder of patients present in the first year with severe psychomotor retardation, coarse facial features, and skeletal manifestations that include kyphoscoliosis and a lumbar gibbus. Patients may also have congenital dislocation of the hips, inguinal hernias, and gingival hypertrophy. Progressive, severe psychomotor retardation leads to death in early childhood. No treatment is available.

PSEUDO-HURLER POLYDYSTROPHY

Pseudo-Hurler polydystrophy (ML-III) is a less-severe disorder than I-cell disease, with later onset and survival to adulthood reported. Affected children may present around the age of 4 or 5 yr with joint stiffness and short stature. Progressive destruction of the hip joints and moderate dysostosis multiplex are evident. Radiographic evidence of low iliac wings, flattening of the proximal femoral epiphyses with valgus deformity of the femoral head, and hypoplasia of the anterior third of the lumbar vertebrae are characteristic findings. Ophthalmic findings include corneal clouding, retinopathy, and astigmatism; visual complaints are uncommon (see Table 86-15). Some patients have learning disabilities or intellectual disability. Treatment, which should include orthopedic care, is symptomatic.

Chapter 87

Defects in Metabolism of Carbohydrates

Priya S. Kishnani and Yuan-Tsong Chen

Carbohydrate synthesis and degradation provide the energy required for most metabolic processes. The important carbohydrates include 3 monosaccharides—glucose, galactose, and fructose—and a polysaccharide, glycogen. Figure 87-1 shows the relevant biochemical pathways of these carbohydrates. Glucose is the principal substrate of energy metabolism. A continuous source of glucose from dietary intake, gluconeogenesis, and glycogenolysis of glycogen maintains normal blood glucose levels. Metabolism of glucose generates adenosine triphosphate (ATP) via glycolysis (conversion of glucose or glycogen to pyruvate), mitochondrial oxidative phosphorylation (conversion of pyruvate to carbon dioxide and water), or both. Dietary sources of glucose come from ingesting polysaccharides, primarily starch and disaccharides, including lactose, maltose, and sucrose. Oral intake of glucose is intermittent and unreliable. Glucose made de novo from amino acids, primarily alanine (gluconeogenesis), contributes to maintaining the euglycemic state, but this process requires time. The breakdown of hepatic glycogen provides the rapid release of glucose, which maintains a constant blood glucose concentration. Glycogen is also the primary stored energy source in muscle, providing glucose for muscle activity during exercise. Galactose and fructose are monosaccharides that provide fuel for cellular metabolism; their role is less significant than that of glucose. Galactose is derived from lactose (galactose + glucose), which is found in milk and milk products. Galactose is an important energy source in infants, but it is first metabolized to glucose. Galactose (exogenous or endogenously synthesized from glucose) is also an important component of certain glycolipids, glycoproteins, and glycosaminoglycans. The dietary sources of fructose are sucrose (fructose + glucose, sorbitol) and fructose itself, which is found in fruits, vegetables, and honey.

Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues, hence the name **glycogen storage disease** (Table 87-1). Defects in gluconeogenesis or the glycolytic pathway, including galactose and fructose metabolism, do not result in an accumulation of glycogen (Table 87-1). The defects in pyruvate metabolism in the pathway of the conversion of pyruvate to carbon dioxide and water via mitochondrial oxidative phosphorylation are more often associated with **lactic acidosis** and some tissue glycogen accumulation.

87.1 Glycogen Storage Diseases

Priya S. Kishnani and Yuan-Tsong Chen

The disorders of glycogen metabolism, the glycogen storage diseases (GSDs), result from deficiencies of various enzymes or transport proteins in the pathways of glycogen metabolism (see Fig. 87-1). The glycogen found in these disorders is abnormal in quantity, quality, or both. GSDs are categorized by numeric type in accordance with the chronological order in which these enzymatic defects were identified. This numeric classification is still widely used, at least up to number VII. The GSDs can also be classified by organ involvement and clinical manifestations into liver and muscle glycogenoses (see Table 87-1).

There are more than 12 forms of glycogenoses. Glucose-6-phosphatase deficiency (type I), lysosomal acid α-glucosidase deficiency (type II), debrancher deficiency (type III), and liver phosphorylase kinase

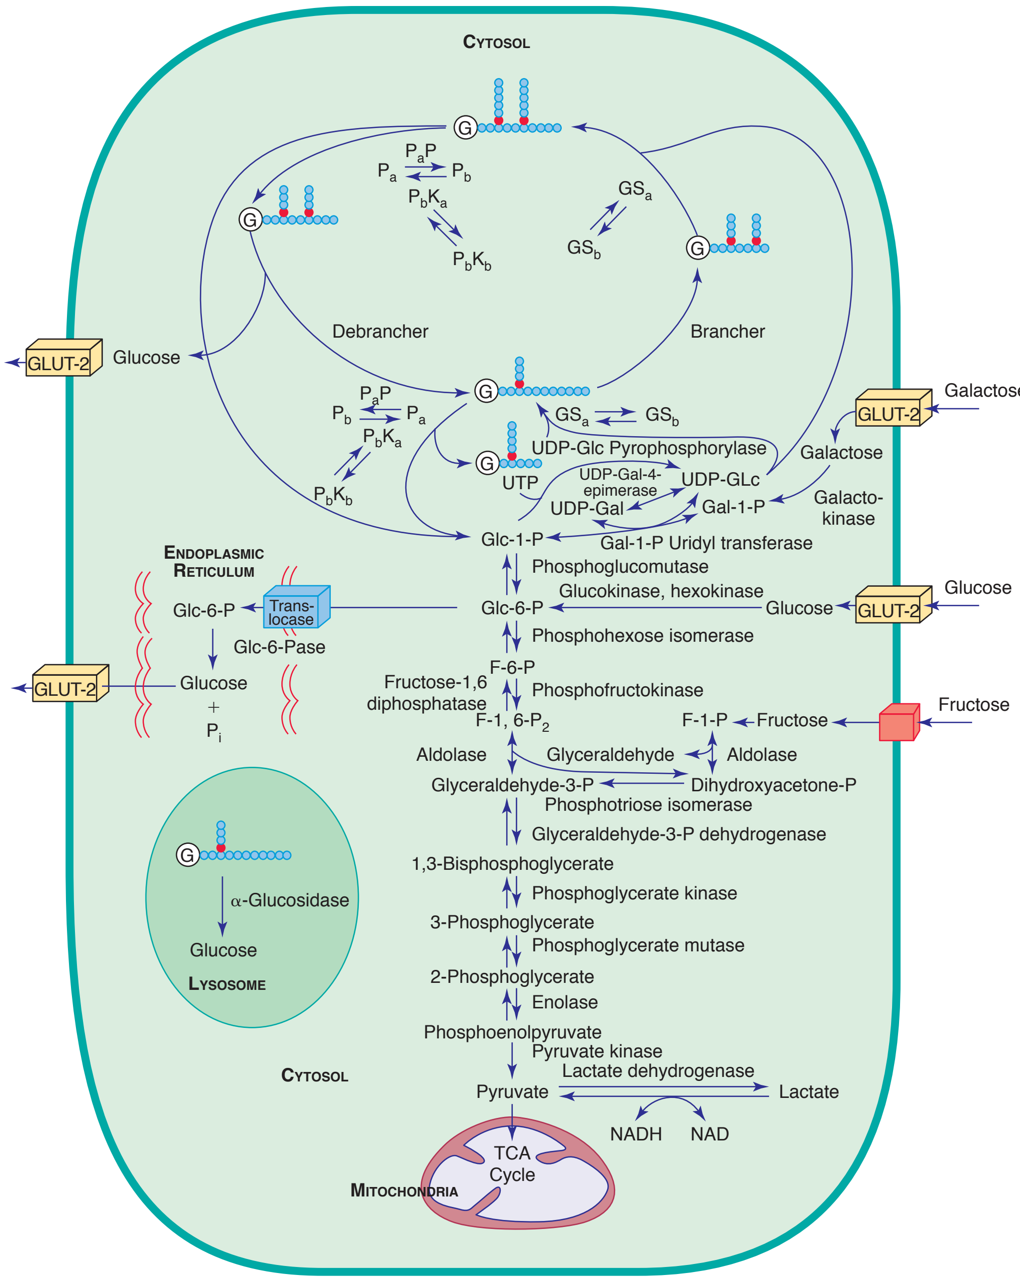

Figure 87-1 **Pathway related to glycogen storage diseases and galactose and fructose disorders.** *G*, glycogen, the primer for glycogen synthesis; *GLUT-2*, glucose transporter 2; *GSa*, active glycogen synthase; *GSb*, inactive glycogen synthase; *NAD/NADH*, nicotinamide-adenine dinucleotide; *Pa*, active phosphorylase; *PaP*, phosphorylase a phosphatase; *Pb*, inactive phosphorylase; *PbKa*, active phosphorylase b kinase; *PbKb*, inactive phosphorylase b kinase; *UDP*, uridine diphosphate. *(Modified from Beaudet AR: Glycogen storage disease. In Harrison TR, Isselbacher KJ, editors:* Harrison's principles of internal medicine, *ed 13, New York, 1994, McGraw-Hill. Reproduced with permission of The McGraw-Hill Companies.)*

deficiency (type IX) are the most common of those that typically present in early childhood; myophosphorylase deficiency (type V, McArdle disease) is the most common in adolescents and adults. The frequency of all forms of GSD is approximately 1 in 20,000 live births.

LIVER GLYCOGENOSES

The GSDs that principally affect the liver include glucose-6-phosphatase deficiency (type I), debranching enzyme deficiency (type III), branching enzyme deficiency (type IV), liver phosphorylase deficiency (type VI), phosphorylase kinase deficiency (type IX, formerly termed GSD VIa), glycogen synthase deficiency (type 0), and glucose transporter-2 defect. Because hepatic carbohydrate metabolism is responsible for plasma glucose homeostasis, this group of disorders typically causes fasting hypoglycemia and hepatomegaly. Some (types III, IV, IX) can be associated with liver cirrhosis. Other organs can also be involved and may manifest as renal dysfunction in type I, myopathy (skeletal and/or cardiomyopathy) in types III and IV, as well as in some rare forms of phosphorylase kinase deficiency, and neurologic involvement in types II (the brain, anterior horns cells), III (peripheral nerves), and IV (some patients can present with diffuse central and peripheral nervous system dysfunction).

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, Von Gierke Disease)

Type I GSD is caused by the absence or deficiency of glucose-6-phosphatase activity in the liver, kidney, and intestinal mucosa. It can be divided into 2 subtypes: type Ia, in which the glucose-6-phosphatase

Table 87-1 Features of the Disorders of Carbohydrate Metabolism

DISORDERS	BASIC DEFECTS	CLINICAL PRESENTATION	COMMENTS
LIVER GLYCOGENOSES			
Type/Common Name			
Ia/Von Gierke	Glucose-6-phosphatase	Growth retardation, hepatomegaly, hypoglycemia; elevated blood lactate, cholesterol, triglyceride, and uric acid levels	Common, severe hypoglycemia
Ib	Glucose-6-phosphate translocase	Same as type Ia, with additional findings of neutropenia and impaired neutrophil function	10% of type Ia
IIIa/Cori or Forbes	Liver and muscle debrancher deficiency (amylo-1,6-glucosidase)	Childhood: hepatomegaly, growth retardation, muscle weakness, hypoglycemia, hyperlipidemia, elevated transaminase levels; liver symptoms can progress to liver failure later in life	Common, intermediate severity of hypoglycemia
IIIb	Liver debrancher deficiency; normal muscle enzyme activity	Liver symptoms same as in type IIIa; no muscle symptoms	15% of type III
IV/Andersen	Branching enzyme	Failure to thrive, hypotonia, hepatomegaly, splenomegaly, progressive cirrhosis (death usually before 5th yr), elevated transaminase levels	Rare neuromuscular variants exist
VI/Hers	Liver phosphorylase	Hepatomegaly, typically mild hypoglycemia, hyperlipidemia, and ketosis	Rare, typically benign glycogenosis; severe presentation also known
Phosphorylase kinase deficiency	Phosphorylase kinase	Hepatomegaly, mild hypoglycemia, hyperlipidemia, and ketosis	Common, typically a benign glycogenosis, severe progressive forms also present
Glycogen synthase deficiency	Glycogen synthase	Early morning drowsiness and fatigue, fasting hypoglycemia, and ketosis, no hepatomegaly	Decreased liver glycogen store
Fanconi-Bickel syndrome	Glucose transporter 2 (GLUT-2)	Failure to thrive, rickets, hepatorenomegaly, proximal renal tubular dysfunction, impaired glucose and galactose utilization	GLUT-2 expressed in liver, kidney, pancreas, and intestine
MUSCLE GLYCOGENOSES			
Type/Common Name			
II/Pompe infantile	Acid α-glucosidase (acid maltase)	Cardiomegaly, hypotonia, hepatomegaly; onset: birth to 6 mo	Common, cardiorespiratory failure leading to death by age 1-2 yr; minimal to no residual enzyme activity
II/Late-onset Pompe (juvenile and adult)	Acid α-glucosidase (acid maltase)	Myopathy, variable cardiomyopathy, respiratory insufficiency; onset: childhood to adulthood	Residual enzyme activity
Danon disease	Lysosome-associated membrane protein 2 (LAMP2)	Hypertrophic cardiomyopathy	Rare, X-linked
PRKAG2 deficiency	Adenosine monophosphate (AMP)-activated protein kinase γ	Hypertrophic cardiomyopathy	Autosomal dominant
V/McArdle	Myophosphorylase	Exercise intolerance, muscle cramps, increased fatigability	Common, male predominance
VII/Tarui	Phosphofructokinase	Exercise intolerance, muscle cramps, hemolytic anemia, myoglobinuria	Prevalent in Japanese and Ashkenazi Jews
Phosphoglycerate kinase deficiency	Phosphoglycerate kinase	As with type V	Rare, X-linked
Phosphoglycerate mutase deficiency	M subunit of phosphoglycerate mutase	As with type V	Rare, majority of patients are African-American
Lactate dehydrogenase deficiency	M subunit of lactate dehydrogenase	As with type V	Rare
GALACTOSE DISORDERS			
Galactosemia with transferase deficiency	Galactose-1-phosphate uridyltransferase	Vomiting, hepatomegaly, cataracts, aminoaciduria, failure to thrive	African-American patients tend to have milder symptoms
Galactokinase deficiency	Galactokinase	Cataracts	Benign
Generalized uridine diphosphate galactose-4-epimerase deficiency	Uridine diphosphate galactose-4-epimerase	Similar to transferase deficiency with additional findings of hypotonia and nerve deafness	A benign variant also exists
FRUCTOSE DISORDERS			
Essential fructosuria	Fructokinase	Urine reducing substance	Benign
	Fructose-1-phosphate aldolase	Acute: vomiting, sweating, lethargy	
Hereditary fructose intolerance		Chronic: failure to thrive, hepatic failure	Prognosis good with fructose restriction

Continued

Table 87-1 Features of the Disorders of Carbohydrate Metabolism—cont'd

DISORDERS	BASIC DEFECTS	CLINICAL PRESENTATION	COMMENTS
DISORDERS OF GLUCONEOGENESIS			
Fructose-1,6-diphosphatase deficiency	Fructose-1,6-diphosphatase	Episodic hypoglycemia, apnea, acidosis	Good prognosis, avoid fasting
Phosphoenolpyruvate carboxykinase deficiency	Phosphoenolpyruvate carboxykinase	Hypoglycemia, hepatomegaly, hypotonia, failure to thrive	Rare
DISORDERS OF PYRUVATE METABOLISM			
Pyruvate dehydrogenase complex defect	Pyruvate dehydrogenase	Severe fatal neonatal to mild late onset, lactic acidosis, psychomotor retardation, and failure to thrive	Most commonly caused by $E_{1\alpha}$ subunit, defect X-linked
Pyruvate carboxylase deficiency	Pyruvate carboxylase	Same as above	Rare, autosomal recessive
Respiratory chain defects (oxidative phosphorylation disease)	Complexes I-V, many mitochondrial DNA mutations	Heterogeneous with multisystem involvement	Mitochondrial inheritance
DISORDERS IN PENTOSE METABOLISM			
Pentosuria	L-Xylulose reductase	Urine-reducing substance	Benign
Transaldolase deficiency	Transaldolase	Liver cirrhosis and failure, cardiomyopathy	Autosomal recessive
Ribose-5-phosphate isomerase deficiency	Ribose-5-phosphate isomerase	Progressive leukoencephalopathy and peripheral neuropathy	

enzyme is defective; and type Ib, in which a translocase that transports glucose-6-phosphate across the microsomal membrane is defective. The defects in both type Ia and type Ib lead to inadequate hepatic conversion of glucose-6-phosphate to glucose through normal glycogenolysis and gluconeogenesis and make affected individuals susceptible to fasting hypoglycemia.

Type I GSD is an autosomal recessive disorder. The structural gene for glucose-6-phosphatase is located on chromosome 17q21; the gene for translocase is on chromosome 11q23. Common mutations responsible for the disease are known. Carrier detection and prenatal diagnosis are possible with the DNA-based diagnosis.

Clinical Manifestations

Patients with type I GSD may present in the neonatal period with hypoglycemia and lactic acidosis; they more commonly present at 3-4 mo of age with hepatomegaly, hypoglycemic seizures, or both. These children often have **doll-like faces** with fat cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is a consequence of massive hepatomegaly; the kidneys are also enlarged, whereas the spleen and heart are normal.

The biochemical hallmarks of the disease are hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Hypoglycemia and lactic acidosis can develop after a short fast. Hyperuricemia is present in young children; gout rarely develops before puberty. Despite marked hepatomegaly, the liver transaminase levels are usually normal or only slightly elevated. Intermittent diarrhea may occur in GSD I. In patients with GSD Ib, the loss of mucosal barrier function as a result of inflammation, which is likely related to the disturbed neutrophil function, seems to be the main cause of diarrhea. Easy bruising and epistaxis are common and are associated with a prolonged bleeding time as a result of impaired platelet aggregation and adhesion.

The plasma may be "milky" in appearance as a result of a striking elevation of triglyceride levels. Cholesterol and phospholipids are also elevated, but less prominently. The lipid abnormality resembles type IV hyperlipidemia and is characterized by increased levels of very-low-density lipoprotein, low-density lipoprotein, and a unique apolipoprotein profile consisting of increased levels of apolipoproteins B, C, and E, with relatively normal or reduced levels of apolipoproteins A and D. The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and fat. The lipid vacuoles are particularly large and prominent. There is little associated fibrosis.

All these findings apply to both type Ia and type Ib GSD, but **type Ib** has additional features of recurrent bacterial infections from **neutropenia** and impaired neutrophil function. Gut mucosa ulceration culminating in GSD enterocolitis is also common. Exceptional cases of type Ib without neutropenia and type Ia with neutropenia have been reported.

Although type I GSD affects mainly the liver, multiple organ systems are involved. Puberty is often delayed. Females can have ultrasound findings consistent with **polycystic ovaries;** other features of polycystic ovary syndrome (acne, hirsutism) are not seen. Nonetheless, fertility appears to be normal, as evidenced in several reports of successful pregnancy in women with GSD I. Increased bleeding during menstrual cycles, including life-threatening menorrhagia, has been noted and could be related to the impaired platelet aggregation. Symptoms of gout usually start around puberty from long-term hyperuricemia. Secondary to the lipid abnormalities, there is an increased risk of **pancreatitis.** The dyslipidemia, together with elevated erythrocyte aggregation, predisposes these patients to atherosclerosis. Premature atherosclerosis has not yet been clearly documented except for rare cases. Impaired platelet aggregation and increased antioxidative defense to prevent lipid peroxidation may function as a protective mechanism to help reduce the risk of atherosclerosis. Frequent fractures and radiographic evidence of **osteopenia** are common; bone mineral content is reduced even in prepubertal patients.

By the 2nd or 3rd decade of life, most patients with type I GSD exhibit **hepatic adenomas** that can hemorrhage and, in some cases, become malignant. **Pulmonary hypertension** has been seen in some long-term survivors of the disease. Iron refractory anemia and an increased prevalence of thyroid autoimmunity are also being recognized.

Renal disease is another complication, and most patients with type I GSD who are older than 20 yr of age have proteinuria. Many also have hypertension, renal stones, nephrocalcinosis, and altered creatinine clearance. Glomerular hyperfiltration, increased renal plasma flow, and microalbuminuria are often found in the early stages of renal dysfunction and can occur before the onset of proteinuria. In younger patients, hyperfiltration and hyperperfusion may be the only signs of renal abnormalities. With the advancement of renal disease, focal segmental glomerulosclerosis and interstitial fibrosis become evident. In some patients, renal function has deteriorated and progressed to failure, requiring dialysis and transplantation. Other renal

abnormalities include amyloidosis, a Fanconi-like syndrome, hypocitraturia, hypercalciuria, and a distal renal tubular acidification defect.

Diagnosis

The diagnosis of type I GSD is suspected on the basis of clinical presentation and the laboratory findings of hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Neutropenia is noted in GSD Ib patients, typically before 1 yr of age. It has also been noted in some cases of GSD Ia, especially those with the mutation p.G188A. Administration of glucagon or epinephrine results in little or no rise in blood glucose level, but the lactate level rises significantly. Before the glucose-6-phosphatase and glucose-6-phosphate translocase genes were cloned, a definitive diagnosis required a liver biopsy. Gene-based mutation analysis provides a noninvasive way to diagnose most patients with types Ia and Ib disease.

Treatment

Treatment is designed to maintain normal blood glucose levels and is achieved by continuous nasogastric infusion of glucose or oral administration of uncooked cornstarch. Nasogastric drip feeding can be introduced in early infancy from the time of diagnosis. It can consist of an elemental enteral formula or contain only glucose or a glucose polymer to provide sufficient glucose to maintain euglycemia during the night. Frequent feedings with high-carbohydrate content are given during the day.

Uncooked cornstarch acts as a slow-release form of glucose and can be introduced at a dose of 1.6 g/kg every 4 hr for children younger than 2 yr of age. The response of young children is variable. As the child grows older, the cornstarch regimen can be changed to every 6 hr at a dose of 1.6-2.5 g/kg of body weight. New starch products, which are currently being developed, are thought to be longer acting, better tolerated, and more palatable. A short-term double-blind crossover pilot study comparing uncooked, physically modified cornstarch to traditional cornstarch showed that the majority of GSD I patients treated with the new starch had better short-term metabolic control and longer duration of euglycemia, especially at night. However, more extensive studies replicating these results are necessary. Because fructose and galactose cannot be converted directly to glucose in GSD type I, these sugars are restricted in the diet. Sucrose (table sugar, cane sugar, other ingredients), fructose (fruit, juice, high fructose corn syrup), lactose (dairy foods), and sorbitol should be avoided or limited. As a result of these dietary restrictions, vitamins and minerals such as calcium and vitamin D may be deficient and supplementation is required to prevent nutritional deficiencies. Dietary therapy improves hyperuricemia, hyperlipidemia, and renal function, slowing the development of renal failure. This therapy fails, however, to normalize blood uric acid and lipid levels completely in some individuals, despite good metabolic control, especially after puberty. The control of hyperuricemia can be further augmented by the use of allopurinol, a xanthine oxidase inhibitor. The hyperlipidemia can be reduced with lipid-lowering drugs such as beta-hydroxy-beta-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors and fibrate (see Chapter 86). Microalbuminuria, an early indicator of renal dysfunction in type I disease, is treated with angiotensin-converting enzyme inhibitors. Citrate supplements can be beneficial for patients with hypocitraturia by preventing or ameliorating nephrocalcinosis and development of urinary calculi. Growth hormone should be used with extreme caution and limited to only those with a documented growth hormone deficiency. Even in those cases, there should be close monitoring of metabolic parameters and presence of adenomas.

In patients with type Ib GSD, granulocyte and granulocyte-macrophage colony-stimulating factors are successful in correcting the neutropenia, decreasing the number and severity of bacterial infections, and improving the chronic inflammatory bowel disease. The minimum effective dose should be used, as side effects are noted on these agents, including splenomegaly, hypersplenism, and bone pain.

Orthotopic liver transplantation is a potential cure of type I GSD. However, the inherent short- and long-term complications leave this as a treatment of last resort, usually for patients with liver malignancy, multiple liver adenomas, metabolic derangements refractory to medical management, and/or liver failure. Large adenomas (>2 cm) that are rapidly increasing in size and/or number may require partial hepatic resection. Smaller adenomas (<2 cm) can be treated with percutaneous ethanol injection or transcatheter arterial embolization. A challenge is the recurrence of liver adenomas with potential for malignant transformation in these patients, ultimately requiring a liver transplant.

Bone marrow transplantation has been reported to correct the neutropenia of type Ib GSD.

Before any surgical procedure, the bleeding status must be evaluated and good metabolic control established. Prolonged bleeding times can be normalized by the use of intensive intravenous glucose infusion for 24-48 hr before surgery. Use of 1-deamino-8-D-arginine vasopressin (DDAVP) can reduce bleeding complications. Lactated Ringer solution should be avoided because it contains lactate and no glucose. Glucose levels should be maintained in the normal range throughout surgery with the use of 10% dextrose. Overall, metabolic control is assessed by growth, improvement, and correction of the metabolic abnormalities such as elevated lactate, glucose, triglyceride, cholesterol, and uric acid levels.

Prognosis

Previously, many patients with type I GSD died at a young age, and the prognosis was guarded for those who survived. Long-term complications occur mostly in adults whose disease was not adequately treated during childhood. Early diagnosis and effective treatment have improved the outcome, although renal disease and formation of hepatic adenomas with potential risk for malignant transformation remain serious complications. The ability to identify transformation to hepatocellular carcinoma in the liver adenomas remains a challenge: α-fetoprotein and carcinoembryonic antigen levels often remain normal in the setting of hepatocellular carcinoma.

Type III Glycogen Storage Disease (Debrancher Deficiency, Limit Dextrinosis)

Type III GSD is caused by a deficiency of glycogen debranching enzyme activity. Debranching enzyme, together with phosphorylase, is responsible for complete degradation of glycogen. When debranching enzyme is defective, glycogen breakdown is incomplete and an abnormal glycogen with short outer branch chains and resembling limit dextrin accumulates. Deficiency of glycogen debranching enzyme causes hepatomegaly, hypoglycemia, short stature, variable skeletal myopathy, and variable cardiomyopathy. The disorder usually involves both liver and muscle and is termed type IIIa GSD. In approximately 15% of patients, the disease appears to involve only liver and is classified as type IIIb.

Type III glycogenosis is an autosomal recessive disease that has been reported in many different ethnic groups; the frequency is relatively high in Sephardic Jews from North Africa. The gene for debranching enzyme is located on chromosome 1p21. More than 40 different mutations are identified; 2 exon 3 mutations c.18_19delGA (previously described as c.17_18delAG) and p.Gln6X are specifically associated with glycogenosis IIIb. Carrier detection and prenatal diagnosis are possible using DNA-based linkage or mutation analysis.

Clinical Manifestations

During infancy and childhood, the disease may be indistinguishable from type I GSD, because hepatomegaly, hypoglycemia, hyperlipidemia, and growth retardation are common (Fig. 87-2). Splenomegaly may be present, but the kidneys are not enlarged. Hepatomegaly and hepatic symptoms in most patients with type III GSD improve with age; however, progressive liver cirrhosis and failure can occur. Hepatocellular carcinoma has also been reported, more typically in patients with progressive liver cirrhosis. The frequency of adenomas in individuals with GSD III is far less than in individuals with GSD I. Furthermore, the relationship of hepatic adenomas and malignancy in GSD III is unclear. α-Fetoprotein and carcinoembryonic antigen levels are not good predictors of the presence of hepatocellular adenomas or malignant transformation. A single case of malignant transformation

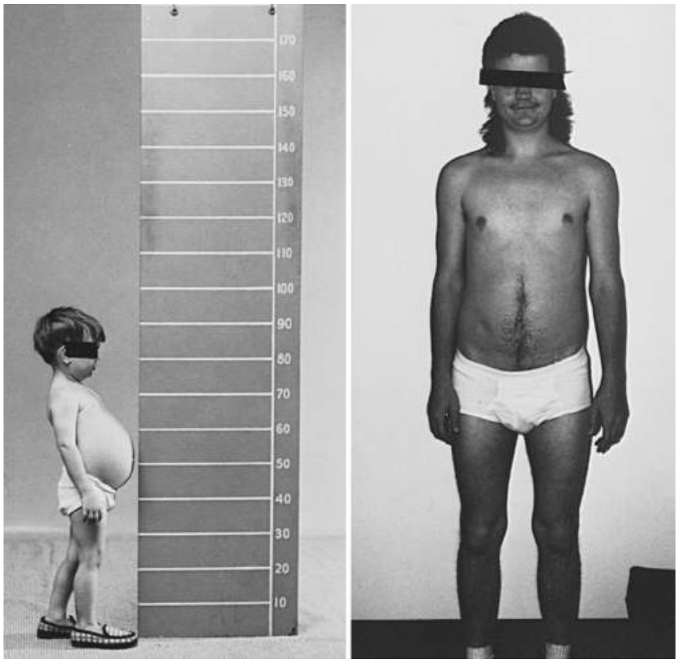

Figure 87-2 Growth and development in a patient with type IIIb glycogen storage disease. The patient has debrancher deficiency in liver but normal activity in muscle. As a child, he had hepatomegaly, hypoglycemia, and growth retardation. After puberty, he no longer had hepatomegaly or hypoglycemia, and his final adult height is normal. He had no muscle weakness or atrophy; this is in contrast to type IIIa patients, in whom a progressive myopathy is seen in adulthood.

at the site of adenomas has been noted. In patients with muscular involvement (type IIIa), muscle weakness can present in childhood but can become severe after the 3rd or 4th decade of life, as evidenced by slowly progressive weakness and wasting. Because patients with GSD III can have decreased bone density, they are at an increased risk of potential fracture. Myopathy does not follow any particular pattern of involvement; both proximal and distal muscles are involved. Electromyography reveals a widespread myopathy; nerve conduction studies are often abnormal. Ventricular hypertrophy is a frequent finding, but overt cardiac dysfunction is rare. Cardiac pathology has shown diffuse involvement of various cardiac structures including vacuolation of myocytes, atrioventricular conduction, and hyperplasia of smooth muscles. There have been some reports of life-threatening arrhythmia and need for heart transplant in some GSD III patients. Hepatic symptoms in some patients may be so mild that the diagnosis is not made until adulthood, when the patients show symptoms and signs of neuromuscular disease. The initial diagnosis has been confused with Charcot-Marie-Tooth disease. Polycystic ovaries are common; some patients can develop hirsutism, irregular menstrual cycles, and other features of polycystic ovarian syndrome. Fertility does not appear to be reduced; successful pregnancies in patients with GSD III have been reported.

Hypoglycemia and hyperlipidemia are common. In contrast to type I GSD, elevation of liver transaminase levels and fasting ketosis are prominent, but blood lactate and uric acid concentrations are usually normal. Serum creatine kinase levels can be useful to identify patients with muscle involvement; normal levels do not rule out muscle enzyme deficiency. The administration of glucagon 2 hr after a carbohydrate meal provokes a normal increase in blood glucose; after an overnight fast, glucagon may provoke no change in blood glucose level.

Diagnosis

The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III glycogenosis from type I. The fibrosis, which ranges from minimal periportal fibrosis to micronodular cirrhosis, appears in most cases to be nonprogressive. Overt cirrhosis has been seen in some patients with GSD III.

Patients with myopathy and liver symptoms have a generalized enzyme defect (type IIIa). The deficient enzyme activity can be demonstrated not only in liver and muscle, but also in other tissues such as heart, erythrocytes, and cultured fibroblasts. Patients with hepatic symptoms without clinical or laboratory evidence of myopathy have debranching enzyme deficiency only in the liver, with enzyme activity retained in the muscle (type IIIb). Definite diagnosis requires enzyme assay in liver, muscle, or both. Mutation analysis can provide a noninvasive method for diagnosis and subtype assignment in the majority of patients.

Treatment

Dietary management is less demanding than in type I GSD. Patients do not need to restrict dietary intake of fructose and galactose. If hypoglycemia is present, frequent meals high in carbohydrates with cornstarch supplements or nocturnal gastric drip feedings are usually effective. A high-protein diet during the daytime plus overnight protein enteral infusion is also effective in preventing hypoglycemia and preventing endogenous protein breakdown because protein can be used as a substrate for gluconeogenesis, a pathway that is intact in type III GSD. There is no satisfactory treatment for the progressive myopathy other than recommending a high-protein diet and an exercise program. Liver transplantation has been performed in GSD III patients with progressive cirrhosis and/or hepatic carcinoma. There are reports of cardiac transplant in GSD III patients with end stage cardiac disease.

Type IV Glycogen Storage Disease (Branching Enzyme Deficiency, Amylopectinosis, or Andersen Disease)

Deficiency of branching enzyme activity results in accumulation of an abnormal glycogen with poor solubility. The disease is referred to as type IV GSD or amylopectinosis because the abnormal glycogen has fewer branch points, more α 1-4 linked glucose units, and longer outer chains, resulting in a structure resembling amylopectin. Type IV GSD is an autosomal recessive disorder. The glycogen branching enzyme *(GBE)* gene is located on chromosome 3p21. More than 20 mutations responsible for type IV GSD have been identified, and their characterization in individual patients can be useful in predicting the clinical outcome. The nearly complete absence of GBE activity with null mutations has been associated with perinatal death and fatal neonatal hypotonia. Residual GBE enzyme activity of greater than 5% and at least 1 missense mutation are associated with a nonlethal phenotype and, in some situations, a lack of progressive liver disease.

Clinical Manifestations

This disorder is clinically variable. The most common and classic form is characterized by progressive cirrhosis of the liver and is manifested in the first 18 mo of life as hepatosplenomegaly and failure to thrive. The cirrhosis progresses to portal hypertension, ascites, esophageal varices, and liver failure that usually lead to death by 5 yr of age. Rare patients survive without progression of liver disease; these patients have a milder hepatic form and do not require a liver transplant.

A **neuromuscular** form of the disease has been reported with 4 main variants recognized based on age of presentation. The perinatal form presents as a fetal akinesia deformation sequence and death in the perinatal period. The congenital form presents at birth with severe hypotonia, muscle atrophy, and neuronal involvement with death in the neonatal period; some patients have cardiomyopathy. The childhood form presents primarily with myopathy or cardiomyopathy. The adult form presents with diffuse central and peripheral nervous system dysfunction accompanied by accumulation of polyglucosan material in the nervous system (**adult polyglucosan body disease**). For adult polyglucosan disease, a leukocyte or nerve biopsy is needed to establish the diagnosis as branching enzyme deficiency is limited to those tissues.

Diagnosis

Tissue deposition of amylopectin-like materials can be demonstrated in liver, heart, muscle, skin, intestine, brain, spinal cord, and peripheral nerve. The hepatic histologic findings are characterized by micronodular cirrhosis and faintly stained basophilic inclusions in the hepatocytes. The inclusions consist of coarsely clumped, stored material that is periodic acid–Schiff positive and partially resistant to diastase digestion. Electron microscopy shows, in addition to the conventional α and β glycogen particles, accumulation of the fibrillar aggregations that are typical of amylopectin. The distinct staining properties of the cytoplasmic inclusions, as well as electron microscopic findings, could be diagnostic. However, polysaccharides with histologic features reminiscent of type IV disease, but without enzymatic correlation, have been observed. The definitive diagnosis rests on the demonstration of the deficient branching enzyme activity in liver, muscle, cultured skin fibroblasts, or leukocytes, or on the identification of disease-causing mutations in the *GBE* gene. Prenatal diagnosis is possible by measuring the enzyme activity in cultured amniocytes, chorionic villi, or mutation analysis.

Treatment

There is no specific treatment for type IV GSD. Unlike patients with the other liver GSDs (I, III, VI, IX), those with GSD IV do not have hypoglycemia, which is only seen when there is overt liver cirrhosis. Liver transplantation has been performed for patients with progressive hepatic failure, but because it is a multisystem disorder involving many organ systems, the long-term success of liver transplantation is unknown. Individuals with significant diffuse reticuloendothelial involvement may have greater risk for morbidity and mortality, which may impact the success rate for liver transplants. Caution should be taken in selecting type IV patients for liver transplantation because these patients have variable phenotypes, which include a nonprogressive form of the liver disease and in some cases, extrahepatic manifestations of the disease.

Type VI Glycogen Storage Disease (Liver Phosphorylase Deficiency, Hers Disease)

There are few patients with documented liver phosphorylase deficiency. Such patients usually have a benign course and present with hepatomegaly and growth retardation in early childhood; however, some cases are more severe. Hypoglycemia, hyperlipidemia, and hyperketosis are of variable severity. Lactic acid and uric acid levels are normal. The heart and skeletal muscles are not involved. The hepatomegaly and growth retardation improve with age and usually disappear around puberty. Some patients with severe hepatomegaly, recurrent severe hypoglycemia, hyperketosis, and postprandial lactic acidosis have recently been reported. Treatment is symptomatic, as some patients require no specific treatment. A high-carbohydrate, high-protein diet and frequent feeding are effective in preventing hypoglycemia. Blood glucose and ketones should be monitored routinely, especially during periods of increased activity/illness.

GSD VI is an autosomal recessive disease. Diagnosis can be confirmed through molecular testing of the liver phosphorylase gene *(PYGL),* which is found on chromosome 14q21-22 and has 20 exons. Many mutations are known in this gene; a splice-site mutation in intron 13 has been identified in the Mennonite population. A liver biopsy showing elevated glycogen content and decreased hepatic phosphorylase enzyme activity can also be used to make a diagnosis.

Type IX Glycogen Storage Disease (Phosphorylase Kinase Deficiency)

This disorder represents a heterogeneous group of glycogenoses. Phosphorylase, the rate-limiting enzyme of glycogenolysis, is activated by a cascade of enzymatic reactions involving adenylate cyclase, cyclic adenosine monophosphate–dependent protein kinase (protein kinase A), and phosphorylase kinase. The latter enzyme has 4 subunits (α, β, γ, δ), each encoded by different genes on different chromosomes and differentially expressed in various tissues. This cascade of reactions is stimulated primarily by glucagon. Glycogenosis could be the result of any enzyme deficiency along this pathway; the most common is the deficiency of phosphorylase kinase. Phosphorylase kinase (PhK) deficiency varies clinically as a result of defects in the various genes encoding the four subunits of the protein. Mutations in the *PHKA1* gene causes muscle PhK deficiency; mutations in the *PHKA2* and *PHKG2* genes cause liver PhK deficiency; mutations in the *PHKB* gene cause PhK deficiency in liver and muscle. Mutations in the *PHKG1* gene have not been identified. Defects in subunits α, β, and γ are responsible for liver presentation. Liver PhK deficiency's physical features are usually recognizable within the first 2 yr of life and include short stature and abdominal distention from moderate to marked hepatomegaly. The clinical severity of liver PhK deficiency varies considerably. Hyperketotic hypoglycemia, if present, is usually mild but can be severe in some cases. Ketosis may occur even when glucose levels are normal. In some children, there may be mild delays in gross motor development and hypotonia. Liver fibrosis can occur and progress to cirrhosis in rare cases, particularly in patients with *PHKG2* mutations. Liver adenoma appears to be very rare. Cognitive and speech delays have been reported in a few individuals, but it is not clear whether these delays are caused by PhK deficiency or whether they are coincidental. Polycystic ovaries are common in females with liver PhK deficiency. Renal tubular acidosis has been reported in rare cases. Cardiac manifestations have not been reported. Unlike in GSD I, lactic acidosis, bleeding tendency, and loose bowel movements are not characteristic. Although growth is retarded during childhood, normal height and complete sexual development are eventually achieved. As with debrancher deficiency, abdominal distention and hepatomegaly usually decrease with age and may disappear by adolescence. Most adults with liver PhK deficiency are asymptomatic, although further long-term studies are needed to fully assess the impact of this disorder in adults. Phenotypic variability within each subtype is being uncovered with the availability of molecular testing. The incidence of all subtypes of PhK deficiency is approximately 1 : 100,000 live births.

X-Linked Liver Phosphorylase Kinase Deficiency

X-linked liver PhK deficiency is the most common form of liver glycogenoses. In addition to liver, enzyme activity can also be deficient in erythrocytes, leukocytes, and fibroblasts; it is normal in muscle. Typically, a 1-5 yr old male presents with growth retardation, an incidental finding of hepatomegaly, and a slight delay in motor development. Cholesterol, triglycerides, and liver enzymes are mildly elevated. Ketosis may occur after fasting. Lactate and uric acid levels are normal. Hypoglycemia is typically mild, if present, but can be severe. The response in blood glucose to glucagon is normal. Hepatomegaly and abnormal blood chemistries gradually improve and can normalize with age. Most adults achieve a normal final height and are usually asymptomatic despite a persistent PhK deficiency. In rare cases, liver fibrosis can occur and progress to cirrhosis. Liver histology shows glycogen-distended hepatocytes, steatosis, and potentially mild periportal fibrosis. The accumulated glycogen (β particles, rosette form) has a frayed or burst appearance and is less compact than the glycogen seen in type I or type III GSD. Fibrous septal formation and low-grade inflammatory changes may be present.

The structural gene for the common liver isoform of the PhK α subunit, *PHKA2,* is located on the X chromosome (αL at Xp22.2). Mutations in the *PHKA2* gene account for 75% of all PhK cases. X-linked liver PhK deficiency is further subdivided into 2 biochemical subtypes: XLG1, with measurable deficiency of PhK activity in both blood cells and liver, and XLG2, with normal in vitro PhK activity in blood cells and variable activity in liver. It is suspected that XLG2 may be caused by missense mutations that affect enzyme regulation, while nonsense mutations affecting the amount of protein result in XLG1.

Autosomal Liver and Muscle Phosphorylase Kinase Deficiency

PhK deficiency in liver and blood cells with an autosomal mode of inheritance has been reported. As with the X-linked form, hepatomegaly and growth retardation are the predominant symptoms in early

childhood. Some patients also exhibit muscle hypotonia. In a few cases where enzyme activity has been measured, reduced PhK activity has been demonstrated in muscle. Mutations causing milder autosomally transmitted liver and muscle PhK deficiency are found in the *PHKB* gene (chromosome 16q12-q13), which encodes the β subunit. Several nonsense mutations, a single-base insertion, a splice-site mutation, and a large intragenic mutation have been identified. In addition, a missense mutation was discovered in an atypical patient with normal blood cell PhK activity.

Autosomal Liver Phosphorylase Kinase Deficiency

This form of PhK deficiency is caused by mutations in the testis/liver isoform of the γ subunit gene (TL, *PHKG2*). In contrast to X-linked PhK deficiency, patients with mutations in the *PHKG2* gene typically have more severe phenotypes with recurrent hypoglycemia and often develop progressive liver cirrhosis. *PHKG2* maps to chromosome 16p12.1- p11.2; many disease-causing mutations are known for this gene.

Muscle-Specific Phosphorylase Kinase Deficiency

A few cases of PhK deficiency restricted to muscle are known. Patients, both male and female, present either with muscle cramps and myoglobinuria with exercise or with progressive muscle weakness and atrophy. PhK activity is decreased in muscle but normal in liver and blood cells. There is no hepatomegaly or cardiomegaly. The structural gene for the muscle-specific form α subunit (αM) is located at Xq12. Mutations of the gene have been found in some male patients with this disorder. The gene for muscle γ subunit (γM, *PHKG1*) is on chromosome 7p12. No mutations in this gene have been reported so far.

Phosphorylase Kinase Deficiency Limited to Heart

These patients present with **cardiomyopathy** in infancy and rapidly progress to heart failure and death. PhK deficiency is demonstrated in the heart with normal enzyme activity in skeletal muscle and liver. Studies have questioned the existence of cardiac-specific primary PhK deficiency. However, the disease presentation has now been linked to the γ2 subunit of adenosine monophosphate–activated protein kinase (see “Glycogen Storage Diseases Mimicking Hypertrophic Cardiomyopathy” below). The γ2 subunit is encoded by the *PRKAG2* gene.

Diagnosis

Definitive diagnosis of PhK deficiency requires demonstration of the enzymatic defect in affected tissues. PhK can be measured in leukocytes and erythrocytes, but because the enzyme has many isozymes, the diagnosis can be easily missed without studies of liver, muscle, or heart. Mutation analysis is necessary in many cases to determine the disease's subtype. Individuals with liver PhK deficiency also usually have elevated transaminases, mildly elevated triglycerides and cholesterol, normal uric acid and lactic acid concentrations, and normal glucagon responses.

The *PHKA2* gene encoding the α subunit is most commonly involved, followed by the *PHKB* gene encoding the β subunit, regardless of the presence of deficiency in erythrocytes. Mutations in the *PHKG2* gene underlying γ-subunit deficiency are typically associated with severe liver involvement with recurrent hypoglycemia and liver fibrosis.

Treatment

The treatment for liver PhK deficiency is symptomatic. It includes a high-carbohydrate, high-protein diet and frequent feedings to prevent hypoglycemia, although many patients require no specific treatment. Cornstarch can be administered with symptom-dependent dosage and timing (0.6-2.5 g/kg every 6 hr). Oral intake of glucose, if tolerated, should be used to treat hypoglycemia. If not, intravenous glucose should be given. Prognosis for the X-linked and certain autosomal forms is typically good, however, patients with mutations in the γ subunit typically have a more severe clinical course with progressive liver disease. There is no treatment for the fatal form of isolated cardiac PhK deficiency other than heart transplantation.

Glycogen Synthase Deficiency

Deficiency of hepatic glycogen synthase *(GYS2)* activity leads to a marked decrease of glycogen stored in the liver. The gene for GYS2 is located at 12p12.2. Several mutations of this gene have been identified in patients with GSD 0. The disease appears to be rare in humans, and in the true sense, this is not a type of GSD because the deficiency of the enzyme leads to decreased glycogen stores. Patients present in infancy with early morning (prebreakfast) drowsiness, pallor, emesis, and fatigue, and sometimes convulsions associated with hypoglycemia and hyperketonemia. Blood lactate and alanine levels are low, and there is no hyperlipidemia or hepatomegaly. Prolonged hyperglycemia, glycosuria, and elevation of lactate with normal insulin levels after administration of glucose or a meal suggest a possible diagnosis of deficiency of glycogen synthase. Definitive diagnosis requires a liver biopsy to measure the enzyme activity or identification of mutations in the liver glycogen synthase gene, located on chromosome 12p12.2. Treatment consists of frequent meals, rich in protein, and nighttime supplementation with uncooked cornstarch to prevent hypoglycemia and hyperketonemia. Most children with GSD 0 are cognitively and developmentally normal. Short stature and osteopenia are common features. The prognosis seems good for patients who survive to adulthood, including resolution of hypoglycemia, except during pregnancy.

Muscle Glycogen Synthase Deficiency

This GSD results from muscle glycogen synthase (glycogen synthase I, *GYS1*) deficiency. The gene for GYS1 has been localized to chromosome 19q13.3. The disease is extremely rare and was reported in 3 children of consanguineous parents of Syrian origin. Muscle biopsies showed lack of glycogen, predominantly oxidative fibers, and mitochondrial proliferation. Glucose tolerance was normal. Molecular study revealed a homozygous stop mutation (R462→ter) in the muscle glycogen synthase gene. The phenotype was variable in the 3 siblings and ranged from sudden cardiac arrest, muscle fatigability, hypertrophic cardiomyopathy, an abnormal heart rate, and hypotension while exercising, to mildly impaired cardiac function at rest.

Hepatic Glycogenosis with Renal Fanconi Syndrome (Fanconi-Bickel Syndrome)

This rare autosomal recessive disorder is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports glucose in and out of hepatocytes, pancreatic β cells, and the basolateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney.

The affected child typically presents in the first year of life with failure to thrive, rickets, and a protuberant abdomen from hepatomegaly and nephromegaly. The disease may be confused with GSD type I because a Fanconi-like syndrome can also develop in type I disease patients. Adults commonly present with short stature, dwarfism, and excess fat in the abdomen and shoulders. Patients are more susceptible to fractures owing to early-onset generalized osteopenia. In addition, intestinal malabsorption and diarrhea may occur.

Laboratory findings include glucosuria, phosphaturia, generalized aminoaciduria, bicarbonate wasting, hypophosphatemia, increased serum alkaline phosphatase levels, and radiologic findings of rickets. Mild fasting hypoglycemia and hyperlipidemia may be present. Liver transaminase, plasma lactate, and uric acid levels are usually normal. Oral galactose or glucose tolerance tests show intolerance, which could be explained by the functional loss of GLUT-2 preventing liver uptake of these sugars. Tissue biopsy results show marked accumulation of glycogen in hepatocytes and proximal renal tubular cells, presumably owing to the altered glucose transport out of these organs. Diffuse glomerular mesangial expansion along with glomerular hyperfiltration and microalbuminuria similar to nephropathy in GSD Ia and diabetes have been reported.

Fanconi-Bickel syndrome is rare. Seventy percent of patients with a detectable GLUT-2 mutation have consanguineous parents. Most patients are homozygous for the disease-related mutations; some patients are compound heterozygotes. The majority of mutations detected thus far predict a premature termination of translation. The resulting loss of the C-terminal end of the GLUT-2 protein predicts a nonfunctioning glucose transporter with an inward-facing substrate-binding site.

There is no specific treatment. Symptom-dependent treatment with phosphate and bicarbonate can result in growth improvement. Symptomatic replacement of water, electrolytes, and vitamin D; restriction of galactose intake; and a diet similar to that used for diabetes mellitus presented in frequent and small meals with an adequate caloric intake may also improve growth.

MUSCLE GLYCOGENOSES

The role of glycogen in muscle is to provide substrates for the generation of ATP for muscle contraction. The muscle GSDs are broadly divided into 2 groups. The first group is characterized by hypertrophic cardiomyopathy, progressive skeletal muscle weakness and atrophy, or both, and includes deficiencies of acid α-glucosidase, a lysosomal glycogen degrading enzyme (type II GSD), lysosomal-associated membrane protein 2 (LAMP2), and adenosine monophosphate–activated protein kinase γ2 (PRKAG2). The second group comprises muscle energy disorders characterized by muscle pain, exercise intolerance, myoglobinuria, and susceptibility to fatigue. This group includes myophosphorylase deficiency (McArdle disease, type V) and deficiencies of phosphofructokinase (type VII), phosphoglycerate kinase, phosphoglycerate mutase, and lactate dehydrogenase. Some of these latter enzyme deficiencies can also be associated with compensated hemolysis, suggesting a more generalized defect in glucose metabolism.

Type II Glycogen Storage Disease (Lysosomal Acid α-1,4-Glucosidase Deficiency, Pompe Disease)

Pompe disease, also referred to as GSD type II or acid maltase deficiency, is caused by a deficiency of acid α-1,4-glucosidase (acid maltase), an enzyme responsible for the degradation of glycogen in lysosomes. This enzyme defect results in lysosomal glycogen accumulation in multiple tissues and cell types, with cardiac, skeletal, and smooth muscle cells being the most seriously affected. The disease is characterized by accumulation of glycogen in lysosomes, as opposed to its accumulation in cytoplasm in the other glycogenoses.

Pompe disease is an autosomal recessive disorder with an incidence of approximately 1 in 40,000 live births in whites and 1 in 18,000 live births in Han Chinese. The gene for acid α-glucosidase is on chromosome 17q25.2. Multiple pathogenic mutations have been identified that could be helpful in delineating the phenotypes. An example is a splice-site mutation (IVS1-13T→G; c.-32-13T>G), commonly seen in late-onset patients of white race.

Clinical Manifestations

The disorder encompasses a range of phenotypes, each including myopathy but differing in age at onset, organ involvement, and clinical severity. **Infantile Pompe disease** was uniformly lethal without enzyme replacement therapy with alglucosidase alfa. Affected infants present in the first few weeks to months of life with hypotonia, a generalized muscle weakness with a "floppy infant" appearance, neuropathic bulbar weakness, feeding difficulties, macroglossia, hepatomegaly, and a hypertrophic cardiomyopathy followed by death from cardiorespiratory failure or respiratory infection usually by 1 yr of age. **Late-onset Pompe disease (juvenile and adult-onset disease)** is characterized by a lack or absence of severe cardiac involvement and a less-severe short-term prognosis. Symptoms related to progressive dysfunction of skeletal muscles can start as early as 1 yr of age to as late as the 6th decade of life. The clinical picture is dominated by slowly progressive proximal muscle weakness with truncal involvement and greater involvement of the lower limbs than the upper limbs. The pelvic girdle, paraspinal muscles, and diaphragm are the muscle groups most seriously affected. Other symptoms may include lingual weakness, ptosis, and dilation of blood vessels such as the basilar artery and the ascending aorta. These patients often present with proximal or limb girdle muscle weakness. With disease progression, patients become confined to wheelchairs and require artificial ventilation. The initial symptoms in some patients may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea, which eventually lead to sleep-disordered breathing and respiratory failure. Respiratory failure is the cause of significant morbidity and mortality in this form of the disease. Basilar artery aneurysms with rupture also contribute to mortality in some cases. The age of death varies from early childhood to late adulthood, depending on the rate of disease progression and the extent of respiratory muscle involvement. With the advent of enzyme replacement therapy, a new picture of the natural history is emerging for both infantile and late onset patients with Pompe disease.

Laboratory Findings

These include elevated levels of serum creatine kinase, aspartate aminotransferase, and lactate dehydrogenase. In the infantile form a chest x-ray showing massive cardiomegaly is frequently the first symptom detected. Electrocardiographic findings include a high-voltage QRS complex and a shortened PR interval. Echocardiography reveals thickening of both ventricles and/or the intraventricular septum and/or left ventricular outflow tract obstruction. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen; acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. Electron microscopy reveals glycogen accumulation within the membranous sac and in the cytoplasm. Electromyography reveals myopathic features with excessive electrical irritability of muscle fibers and pseudomyotonic discharges. Serum creatine kinase is not always elevated in adult patients. Depending on the muscle sampled or tested, the muscle histologic appearance and electromyography may not be abnormal.

Some patients with infantile Pompe disease who had peripheral nerve biopsies demonstrated glycogen accumulation in the neurons and Schwann cells, too. Infantile Pompe disease may manifest both myopathic and neuropathic clinical signs. Generally, the former predominate.

Diagnosis

The confirmatory step for a diagnosis of Pompe disease is enzyme assay demonstrating deficient acid α-glucosidase or gene sequencing showing 2 pathogenic mutations in the *GAA* gene. The enzyme assay is usually done in dried blood spots, leukocytes, blood mononuclear cells, muscle, and cultured skin fibroblasts, using maltose, glycogen, or 4-methylumbelliferyl-α-D-glucopyranoside (4MUG) as a substrate. Deficiency is usually more severe in the infantile form than in the late-onset forms. The skin fibroblast assay is usually preferred to muscle biopsy because it is a less-invasive procedure with the advantage of maintaining a cell line for future use and providing information on residual enzyme activity. Blood-based assays, especially dried blood spots, have the advantage of a rapid turnaround time. A muscle biopsy can yield faster results and provide additional information about glycogen content and site of glycogen storage within and outside the lysosomes of muscle cells. A major limitation of a muscle biopsy in late-onset patients is the variable pathology and glycogen accumulation in different muscles and within muscle fibers; muscle histology and glycogen content can vary depending on the site of muscle biopsy. There is also a high risk from anesthesia in infantile patients. An electrocardiogram can be helpful in making the diagnosis in suspected cases of the infantile form and should be done for patients suspected of having Pompe disease before any procedure requiring anesthesia, including muscle biopsy, is performed. Urinary glucose tetrasaccharides are elevated in the urine of affected patients, and levels are extremely high in infantile patients. This biomarker is valuable for diagnosis and monitoring response to therapy in Pompe disease. Prenatal diagnosis using amniocytes or chorionic villi is available for the infantile form of the disease.

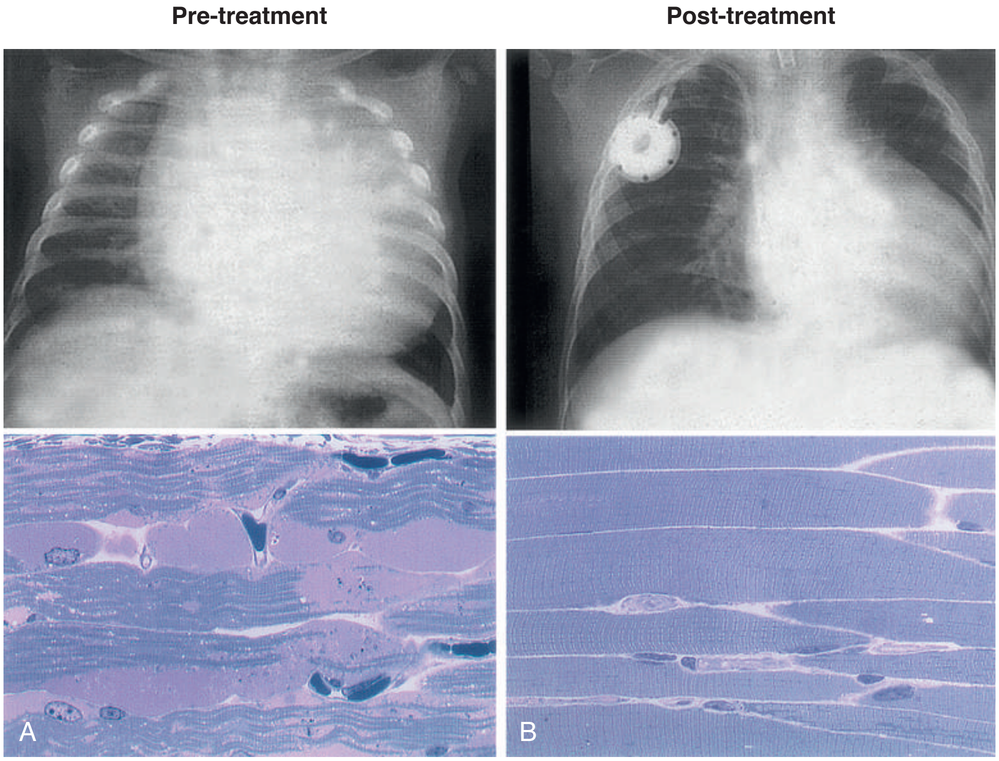

Figure 87-3 Chest x-ray and muscle histology findings of an infantile-onset Pompe disease patient before **(A)** and after **(B)** enzyme replacement therapy. Note the decrease in heart size and muscle glycogen with the therapy. *(Modified from Amalfitano A, Bengur AR, Morse RP, et al: Recombinant human acid alpha-glucosidase enzyme therapy for infantile glycogen storage disease type II: results of a phase I/II clinical trial,* Genet Med *3:132–138, 2001.)*

Treatment

Treatment options were once limited to supportive or palliative care. Specific enzyme replacement therapy (ERT) with recombinant human acid α-glucosidase (alglucosidase alfa, [Myozyme or Lumizyme]) is available for treatment of Pompe disease. Recombinant acid α-glucosidase is capable of preventing deterioration or reversing abnormal cardiac and skeletal muscle functions (Fig. 87-3). ERT should be initiated as soon as possible across the disease spectrum, especially for babies with the infantile form who are diagnosed via newborn screening, as the disease is very rapidly progressive. The dosage is 20 mg/kg given every 2 wk. A high-protein diet and exercise therapy may also be beneficial. Nocturnal ventilatory support, when indicated, should be used. It has been shown to improve the quality of life and is particularly beneficial during a period of respiratory decompensation. Early diagnosis and treatment are necessary for optimal outcomes in Pompe disease. Newborn screening using blood-based assays in Taiwan has resulted in early identification of Pompe cases and, as a result, has improved disease outcomes through the early initiation of ERT.

Glycogen Storage Diseases Mimicking Hypertrophic Cardiomyopathy

Deficiencies of LAMP2 (also called Danon disease) and PRKAG2 result in accumulation of glycogen in the heart and skeletal muscle. Danon disease is transmitted as an X-linked trait and PRKAG2 deficiency as an autosomal dominant trait. These patients present primarily as a hypertrophic cardiomyopathy, but can be distinguished from the usual causes of hypertrophic cardiomyopathy caused by defects in sarcomere protein genes by their electrophysiologic abnormalities, particularly ventricular preexcitation and conduction defects. The onset of cardiac symptoms, including chest pain, palpitation, syncope, and cardiac arrest, can occur between the ages of 8 and 15 yr for LAMP2 deficiency, younger than the average age of 33 yr for patients with PRKAG2 deficiency. However, there are several reports of patients with mutations in the PRKAG2 gene presenting early. These cases present in early infancy with severe hypertrophic cardiomyopathy and a rapidly fatal course. In the past, several of these cases were misdiagnosed as GSD IX as a result of secondary low PhK activity in the heart. The p.Arg531Gln and p.Arg384Thr mutations in the PRKAG2 gene are incompatible with life. Other mutations (p.Arg302Gln, p.Thr400Ans, p.Asn488Ile, and p.His487Tyr) associated with Wolff-Parkinson-White syndrome and adult-onset hypertrophic cardiomyopathy are less disruptive.

The prognosis for LAMP2 deficiency is poor with progressive end-stage heart failure early in adulthood. With the exception of the fatal infantile presentation, cardiomyopathy caused by PRKAG2 mutations is compatible with long-term survival, although some patients may necessitate the implantation of a pacemaker and aggressive control of arrhythmias.

Type V Glycogen Storage Disease (Muscle Phosphorylase Deficiency, McArdle Disease)

GSD V is caused by the deficiency of muscle phosphorylase activity. Lack of this enzyme limits muscle ATP generation by glycogenolysis, resulting in muscle glycogen accumulation, and is the prototype of muscle energy disorders. A deficiency of myophosphorylase impairs the cleavage of glucosyl molecules from the straight chain of glycogen.

Clinical Manifestations

Symptoms usually first develop in late childhood or in the 2nd decade of life. In general, clinical heterogeneity is uncommon, but cases suggesting otherwise have been documented. Studies have shown that McArdle disease can manifest in individuals as old as 74 yr of age, as well as in infancy, in a fatal, early-onset form characterized by hypotonia, generalized muscle weakness, and respiratory complication. Symptoms are generally characterized by exercise intolerance with muscle cramps and pain. Two types of activity tend to cause symptoms: brief exercise of great intensity, such as sprinting or carrying heavy loads; and less intense but sustained activity, such as climbing stairs or walking uphill. Moderate exercise, such as walking on level ground,

can be performed by most patients for long periods. Many patients experience a characteristic "second wind" phenomenon. If they slow down or pause briefly at the first appearance of muscle pain, they can resume exercise with more ease. As a result of the underlying myopathy, these patients may be at risk for statin-induced myopathy and rhabdomyolysis. While patients typically experience episodic muscle pain and cramping from exercise, 35% of patients with McArdle disease report permanent pain that has a serious impact on sleep and other activities. Studies also suggest that there may also be a link between GSD V and levels of cognitive impairment.

Approximately 50% of patients report burgundy-colored urine after exercise, which is the consequence of exercise-induced **myoglobinuria** secondary to **rhabdomyolysis.** Intense myoglobinuria after vigorous exercise may cause acute renal failure. In rare cases, electromyographic findings may suggest an inflammatory myopathy and the diagnosis can be confused with polymyositis.

The level of serum creatine kinase is usually elevated at rest and increases more after exercise. Exercise also increases the levels of blood ammonia, inosine, hypoxanthine, and uric acid. The latter abnormalities are attributed to accelerated recycling of muscle purine nucleotides owing to insufficient ATP production. Type V GSD is an autosomal recessive disorder. The gene for muscle phosphorylase *(PYGM)* has been mapped to chromosome 11q13.

Diagnosis

The standard diagnosis for GSD V includes a muscle biopsy to measure glycogen content as well as enzyme and mutation analysis. An ischemic exercise test offers a rapid diagnostic screening for patients with a metabolic myopathy. Lack of an increase in blood lactate levels and exaggerated blood ammonia elevations indicate muscle glycogenosis and suggest a defect in the conversion of muscle glycogen or glucose to lactate. The abnormal ischemic exercise response is not limited to type V GSD. Other muscle defects in glycogenolysis or glycolysis produce similar results (deficiencies of muscle phosphofructokinase, phosphoglycerate kinase, phosphoglycerate mutase, or lactate dehydrogenase).

Phosphorus MRI allows for the noninvasive evaluation of muscle metabolism. Patients with type V GSD have no decrease in intracellular pH and have excessive reduction in phosphocreatine in response to exercise. The diagnosis should be confirmed by enzymatic evaluation of muscle. A common nonsense mutation p.R49X in exon 1 is found in 90% of white patients, and a deletion of a single codon in exon 17 is found in 61% of Japanese patients. The p.R49X mutation represents 55% of alleles in Spanish patients, whereas the p.W797R mutation represents 14% and the p.G204S represents 9% of mutant alleles in the Spanish population. There seems to be an association between clinical severity of GSD V and the presence of the D allele of the angiotensin-converting enzyme insertion/deletion polymorphism. This may help explain the spectrum of phenotypic variability manifested in this disorder.

Treatment

Avoidance of strenuous exercise prevents the symptoms; however, regular and moderate exercise is recommended to improve exercise capacity. Glucose or sucrose given before exercise or injection of glucagon can markedly improve tolerance in these patients. A high-protein diet may increase muscle endurance and creatine supplement has been shown to improve muscle function in some patients. The clinical response to creatine is dose-dependent: muscle pain may increase on high doses of creatine supplementation. Vitamin B_6 supplementation reduces exercise intolerance and muscle cramps. Longevity is not generally affected.

Type VII Glycogen Storage Disease (Muscle Phosphofructokinase Deficiency, Tarui Disease)

Type VII GSD is caused by a deficiency of muscle phosphofructokinase, which catalyzes the ATP-dependent conversion of fructose-6-phosphate to fructose-1,6-diphosphate and is a key regulatory enzyme of glycolysis. Phosphofructokinase is composed of 3 isoenzyme subunits (M [muscle], L [liver], and P [platelet]) that are encoded by different genes and differentially expressed in tissues. Skeletal muscle contains only the M subunit, and red blood cells contain a hybrid of L and M forms. Type VII disease is caused by a defective M isoenzyme, which causes a complete enzyme defect in muscle and a partial defect in red blood cells.

Type VII GSD is an autosomal recessive disorder and is prevalent among Japanese people and Ashkenazi Jews. The gene for muscle phosphofructokinase is located on chromosome 12q13.3. A splicing defect and a nucleotide deletion in the muscle phosphofructokinase gene account for 95% of mutant alleles in Ashkenazi Jews. Diagnosis based on molecular testing is thus possible in this population.

Clinical Manifestations

Six features of type VII are distinctive: (1) Exercise intolerance, usually evident in childhood, is more severe than in type V disease and may be associated with nausea, vomiting, and severe muscle pain; vigorous exercise causes severe muscle cramps and myoglobinuria. (2) Compensated hemolysis occurs as evidenced by an increased level of serum bilirubin and an elevated reticulocyte count. (3) Hyperuricemia is common and exaggerated by muscle exercise to a greater degree than that observed in type V or III GSD. (4) An abnormal polysaccharide is present in muscle fibers; it is periodic acid–Schiff-positive but resistant to diastase digestion. (5) Exercise intolerance is particularly acute after meals that are rich in carbohydrates because glucose cannot be utilized in muscle and because glucose inhibits lipolysis, thereby depriving muscle of fatty acid and ketone substrates. In contrast, patients with type V disease can metabolize bloodborne glucose derived from either liver glycogenolysis or exogenous glucose; indeed, glucose infusion improves exercise tolerance in type V patients. (6) There is no spontaneous second-wind phenomenon because of the inability to metabolize blood glucose.

Other rare type VII variants occur. One variant presents in infancy with hypotonia and limb weakness and proceeds to a rapidly progressive myopathy that leads to death by 4 yr of age. There is a second variant that occurs in infancy and results in congenital myopathy and arthrogryposis with a fatal outcome. A third variant presents in infancy with hypotonia, mild developmental delay and seizures. An additional presentation is hereditary nonspherocytic hemolytic anemia. Although these patients do not experience muscle symptoms, it remains unclear whether these symptoms will develop later in life. One variant presents in adults and is characterized by a slowly progressive, fixed muscle weakness rather than cramps and myoglobinuria. It may also cause mitral valve thickening from glycogen buildup.

Diagnosis

To establish a diagnosis, a biochemical or histochemical demonstration of the enzymatic defect in the muscle is required. The absence of the M isoenzyme of phosphofructokinase can also be demonstrated in blood cells and fibroblasts.

Treatment

There is no specific treatment. Avoidance of strenuous exercise is advisable to prevent acute attacks of muscle cramps and myoglobinuria. Drugs such as statins should be avoided. Precautionary measures should be taken to avoid hyperthermia while undergoing anesthesia. Carbohydrate meals and glucose infusions have demonstrated worsening symptoms because of the body's inability to utilize glucose. The administered glucose tends to lower the levels of fatty acids in the blood, a primary source of muscle fuel. One case of a child with a severe infantile form of GSD VII, demonstrated that the initiation of a ketogenic diet resulted in significant clinical improvement.

Other Muscle Glycogenoses with Muscle Energy Impairment

Six additional defects in enzymes—phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose-1,6-bisphosphate aldolase A, muscle pyruvate kinase, and β-enolase in the pathway of the terminal glycolysis—cause symptoms and signs of muscle energy

impairment similar to those of types V and VII GSD. The failure of blood lactate to increase in response to exercise is a useful diagnostic test and can be used to differentiate muscle glycogenoses from disorders of lipid metabolism, such as carnitine palmitoyl transferase II deficiency and very long chain acyl-CoA dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels can be normal in the disorders affecting terminal glycolysis and assaying the muscle enzyme activity is needed to make a definite diagnosis. There is no specific treatment. Avoidance of strenuous exercise prevents acute attacks of muscle cramps and myoglobinuria. Avoidance of drugs such as statins, and malignant hyperthermia precautions for patients undergoing anesthesia should be followed.

87.2 Defects in Galactose Metabolism

Priya S. Kishnani and Yuan-Tsong Chen

Milk and dairy products contain lactose, the major dietary source of galactose. The metabolism of galactose produces fuel for cellular metabolism through its conversion to glucose-1-phosphate (see Table 87-1). Galactose also plays an important role in the formation of galactosides, which include glycoproteins, glycolipids, and glycosaminoglycans. Galactosemia denotes the elevated level of galactose in the blood and is found in 3 distinct inborn errors of galactose metabolism in 1 of the following enzymes: galactose-1-phosphate uridyl transferase, galactokinase, and uridine diphosphate galactose-4-epimerase. The term *galactosemia,* although adequate for the deficiencies in any of these disorders, generally designates the transferase deficiency.

GALACTOSE-1-PHOSPHATE URIDYL TRANSFERASE DEFICIENCY GALACTOSEMIA

Two forms of the deficiency exist: infants with complete or near complete deficiency of the enzyme (classic galactosemia) and those with partial transferase deficiency. **Classic galactosemia** is a serious disease with onset of symptoms typically by the second half of the 1st wk of life. The incidence is predicted to be 1 in 60,000 live births. The newborn infant receives high amounts of lactose (up to 40% in breast milk and certain formulas), which consists of equal parts of glucose and galactose. Without the transferase enzyme, the infant is unable to metabolize galactose-1-phosphate, the accumulation of which results in injury to kidney, liver, and brain. This injury may begin prenatally in the affected fetus by transplacental galactose derived from the diet of the heterozygous mother or by endogenous production of galactose in the fetus.

Clinical Manifestations

The diagnosis of uridyl transferase deficiency should be considered in newborn or young infants with any of the following features: jaundice, hepatomegaly, vomiting, hypoglycemia, seizures, lethargy, irritability, feeding difficulties, poor weight gain or failure to regain birth weight, aminoaciduria, nuclear cataracts, vitreous hemorrhage, hepatic failure, liver cirrhosis, ascites, splenomegaly, or intellectual disability. Symptoms are milder and improve when milk is temporarily withdrawn and replaced by intravenous or lactose-free nutrition. Patients with galactosemia are at increased risk for *Escherichia coli* neonatal sepsis; the onset of sepsis often precedes the diagnosis of galactosemia. Pseudotumor cerebri can occur and cause a bulging fontanel. Death from liver and kidney failure and sepsis may follow within days. When the diagnosis is not made at birth, damage to the liver (cirrhosis) and brain (intellectual disability) becomes increasingly severe and irreversible.

Partial transferase deficiency is generally asymptomatic. It is more frequent than classic galactosemia and is diagnosed in newborn screening because of moderately elevated blood galactose and/or low transferase activity. Galactosemia should be considered for the newborn or young infant who is not thriving or who has any of the preceding findings. Light and electron microscopy of hepatic tissue reveals fatty infiltration, the formation of pseudoacini, and eventual macronodular cirrhosis. These changes are consistent with a metabolic disease but do not indicate the precise enzymatic defect.

Diagnosis

The preliminary diagnosis of galactosemia is made by demonstrating a reducing substance in several urine specimens collected while the patient is receiving human milk, cow's milk, or any other formula containing lactose. The reducing substance found in urine by Clinitest (glucose, galactose, and others) can be identified by chromatography or by an enzymatic test specific for galactose. Galactosuria is present, provided the last milk feed does not date back more than a few hours and the child is not vomiting excessively. Clinistix urine test results are usually negative because the test materials rely on the action of glucose oxidase, which is specific for glucose and is nonreactive with galactose. Owing to a proximal renal tubular syndrome, the acutely ill baby may also excrete glucose together with amino acids. Because galactose is injurious to persons with galactosemia, diagnostic challenge tests dependent on administering galactose orally or intravenously should not be used. Direct enzyme assay using erythrocytes establishes the diagnosis. One needs to confirm that the patient did not receive a blood transfusion before the collection of the blood sample, as a diagnosis could be missed. A novel method utilizes nonradioactive UV and high-performance liquid chromatography to accurately detect levels of galactose-1-phosphate uridyl transferase in erythrocytes.

Genetics

Transferase deficiency is an autosomal recessive disorder. Based on newborn screening in the United States, the frequency of the disease is approximately 1 in 47,000 live births. There are several enzymatic variants of galactosemia. The *Duarte variant,* a single amino acid substitution (p.N314D), has diminished red cell enzyme activity (50% of normal), but usually no clinical significance. This variant is the most common, with a carrier frequency of 12% in the general population. Those who are heterozygous for the Duarte variant of galactosemia typically have 25% of normal galactose activity, few symptoms, elevated metabolites, and no need for intervention. Other similar variants expressing little enzyme activity typically require no intervention. Some African-American patients have milder symptoms despite the absence of measurable transferase activity in erythrocytes; these patients retain 10% enzyme activity in liver and intestinal mucosa, whereas most white patients have no detectable activity in any of these tissues. More than 230 identifiable mutations have been associated with transferase deficiency. In African-Americans, 62% of alleles are represented by the p.S135L mutation, a mutation that is responsible for a milder disease course. In the white population, 70% of alleles are represented by the p.Q188R and p.K285N missense mutations and are associated with severe disease. Carrier testing and prenatal diagnosis can be performed by direct enzyme analysis of amniocytes or chorionic villi; testing can also be DNA based.

Treatment and Prognosis

Because of newborn screening for galactosemia, patients are being identified and treated early. Various non–lactose-containing milk substitutes are available (casein hydrolysates, soybean-based formula). Elimination of galactose from the diet along with adequate calcium supplementation reverses growth failure and renal and hepatic dysfunction. Cataracts regress, and most patients have no impairment of vision. Early diagnosis and treatment have improved the prognosis of galactosemia; however, on long-term follow-up, patients still manifest ovarian failure with primary or secondary amenorrhea, decreased bone mineral density, developmental delay, and learning disabilities that increase in severity with age. **Hypergonadotrophic hypogonadism** is reported in 80% to more than 90% of female patients with classic galactosemia. Although most women with classic galactosemia are infertile when they reach childbearing age, a small number have given birth. Most patients manifest speech disorders, whereas a smaller number demonstrate poor growth and impaired motor function and balance (with or without overt ataxia). The relative control of

galactose-1-phosphate levels does not always correlate with long-term outcome, leading to the belief that other factors, such as elevated galactitol, decreased uridine diphosphate galactose (a donor for galactolipids and proteins), and endogenous galactose production may be responsible.

GALACTOKINASE DEFICIENCY

The deficient enzyme is galactokinase, which normally catalyzes the phosphorylation of galactose. The principal metabolites accumulated are galactose and galactitol. Two genes are reported to encode galactokinase: *GK1* on chromosome 17q24 and *GK2* on chromosome 15. Cataracts are usually the sole manifestation of galactokinase deficiency; pseudotumor cerebri is a rare complication. The affected infant is otherwise asymptomatic. Heterozygote carriers may be at risk for presenile cataracts. Affected patients have an increased concentration of blood galactose levels, provided they have been fed a lactose-containing formula. The diagnosis is made by demonstrating an absence of galactokinase activity in erythrocytes or fibroblasts. Transferase activity is normal. Treatment is dietary restriction of galactose.

URIDINE DIPHOSPHATE GALACTOSE-4-EPIMERASE DEFICIENCY

The abnormally accumulated metabolites are similar to those in transferase deficiency; however, there is also an increase in cellular uridine diphosphate galactose. There are 2 distinct forms of epimerase deficiency. The first is a benign form discovered incidentally through neonatal screening programs. Affected persons are healthy and without problems; the enzyme deficiency is limited to leukocytes and erythrocytes. No treatment is required. The second form of epimerase deficiency is severe, and clinical manifestations resemble transferase deficiency, with the additional symptoms of hypotonia and nerve deafness. The enzyme deficiency is generalized, and clinical symptoms respond to restriction of dietary galactose. Although this form of galactosemia is rare, it must be considered in a symptomatic patient with measurable galactose-1-phosphate who has normal transferase activity. Diagnosis is confirmed by the assay of epimerase in erythrocytes.

Patients with the severe form of epimerase deficiency cannot synthesize galactose from glucose and are galactose-dependent. Because galactose is an essential component of many nervous system structural proteins, patients are placed on a galactose-restricted diet rather than a galactose-free diet.

Infants with the mild form of epimerase deficiency have not required treatment. It is advisable to follow urine specimens for reducing substances and exclude aminoaciduria within a few weeks of diagnosis while the infant is still on lactose-containing formula.

The gene for uridine diphosphate galactose-4-epimerase is located on chromosome 1 at 1p36. Carrier detection is possible by measurement of epimerase activity in the erythrocytes. Prenatal diagnosis for the severe form of epimerase deficiency, using an enzyme assay of cultured amniotic fluid cells, is possible.

Bibliography is available at Expert Consult.

87.3 Defects in Fructose Metabolism

Priya S. Kishnani and Yuan-Tsong Chen

Two inborn errors are known in the specialized pathway of fructose metabolism: benign or essential fructosuria and hereditary fructose intolerance (HFI). Fructose-1,6-bisphosphatase deficiency, although strictly speaking not a defect of the specialized fructose pathway, is discussed in Chapter 87.4.

DEFICIENCY OF FRUCTOKINASE (ESSENTIAL OR BENIGN FRUCTOSURIA)

Deficiency of fructokinase is not associated with any clinical manifestations. It is an accidental finding usually made because the asymptomatic patient's urine contains a reducing substance. No treatment is necessary and the prognosis is excellent. Inheritance is autosomal recessive with an incidence of 1 in 120,000 live births. The gene encoding fructokinase is located on chromosome 2p23.3.

Fructokinase catalyzes the first step of metabolism of dietary fructose: conversion of fructose to fructose-1-phosphate (see Fig. 87-1). Without this enzyme, ingested fructose is not metabolized. Its level is increased in the blood, and it is excreted in urine because there is practically no renal threshold for fructose. Clinitest results reveal the urinary-reducing substance, which can be identified as fructose by chromatography.

DEFICIENCY OF FRUCTOSE-1,6-BISPHOSPHATE ALDOLASE (ALDOLASE B, HEREDITARY FRUCTOSE INTOLERANCE)

Deficiency of fructose-1,6-bisphosphate aldolase is a severe condition of infants that appears with the ingestion of fructose-containing food and is caused by a deficiency of fructose aldolase B activity in the liver, kidney, and intestine. The enzyme catalyzes the hydrolysis of fructose-1,6-bisphosphate into triose phosphate and glyceraldehyde phosphate. The same enzyme also hydrolyzes fructose-1-phosphate. Deficiency of this enzyme activity causes a rapid accumulation of fructose-1-phosphate and initiates severe toxic symptoms when exposed to fructose.

Epidemiology and Genetics

The true incidence of HFI is unknown but may be as high as 1 in every 26,000 live births. The gene for aldolase B is on chromosome 9q22.3. At least 40 mutations causing HFI are known. A single missense mutation, a G→C transversion in exon 5 resulting in the normal alanine at position 149 being replaced by a proline, is the most common mutation identified in northern Europeans. This mutation, plus 2 other point mutations (p.A174D and p.N334K), account for 80-85% of HFI in Europe and the United States. Diagnosis of HFI can be made by direct DNA analysis and phosphorus magnetic resonance spectroscopy.

Clinical Manifestations

Patients with HFI are asymptomatic until fructose or sucrose (table sugar) is ingested (usually from fruit, fruit juice, or sweetened cereal). Symptoms may occur early in life, soon after birth if foods or formulas containing these sugars are introduced into the diet. Certain patients are very sensitive to fructose, whereas others can tolerate moderate intakes (up to 250 mg/kg/day). The average intake of fructose in Western societies is 1-2 g/kg/day. Early clinical manifestations resemble galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. There may also be a higher incidence of celiac disease in HFI patients (>10%) than in the general population (1-3%). Laboratory findings include a prolonged clotting time, hypoalbuminemia, elevation of bilirubin and transaminase levels, and proximal tubular dysfunction. Acute fructose ingestion produces symptomatic hypoglycemia; the higher the intake, the more severe is the clinical picture. Chronic ingestion results in failure to thrive and hepatic disease. If the intake of the fructose persists, hypoglycemic episodes recur, and liver and kidney failure progress, eventually leading to death.

Diagnosis

Suspicion of the enzyme deficiency is fostered by the presence of a reducing substance in the urine during an episode. The fructose challenge, although an effective method of diagnosis, causes a rapid fall, first of serum phosphate and then of blood glucose, and a subsequent increase in uric acid and magnesium. Because of high risks to the patient who can become acutely ill after the oral tolerance test, it should not be performed. Definitive diagnosis is made by assay of fructaldolase B activity in the liver. Gene-based diagnosis is available for most patients with this disease; a common mutation (substitution of *Pro* for *Ala* at position 149) accounts for 53% of HFI alleles worldwide.

Treatment

Treatment consists of the complete elimination of all sources of sucrose, fructose, and sorbitol from the diet. It may be difficult because these

sugars are widely used additives, found even in most medicinal preparations. With treatment, liver and kidney dysfunction improves, and catch-up in growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder even after fructose ingestion; the long-term prognosis is good. Because of voluntary dietary avoidance of sucrose, affected patients have few dental caries.

Bibliography is available at Expert Consult.

87.4 Defects in Intermediary Carbohydrate Metabolism Associated with Lactic Acidosis

Priya S. Kishnani and Yuan-Tsong Chen

Lactic acidosis occurs with defects of carbohydrate metabolism that interfere with the conversion of pyruvate to glucose via the pathway of gluconeogenesis or to carbon dioxide and water via the mitochondrial enzymes of the Krebs cycle. Figure 87-4 depicts the relevant metabolic pathways. Type I GSD, fructose-1,6-diphosphatase deficiency, and phosphoenolpyruvate carboxylase deficiency are disorders of gluconeogenesis associated with lactic acidosis. Pyruvate dehydrogenase complex deficiency, respiratory chain defects, and pyruvate carboxylase deficiency are disorders in the pathway of pyruvate metabolism causing lactic acidosis. Lactic acidosis can also occur in defects of fatty acid oxidation, organic acidurias (see Chapters 85.6, 85.10, and 86.1), or biotin utilization diseases. These disorders are easily distinguishable by the presence of abnormal acylcarnitine profiles, amino acids in the blood, and unusual organic acids in the urine. Blood lactate, pyruvate, and acylcarnitine profiles and the presence of these unusual urine organic acids should be determined in infants and children with unexplained acidosis, especially if there is an increase of anion gap.

Lactic acidosis unrelated to an enzymatic defect occurs in hypoxemia. In this case, as well as in defects in the respiratory chain, the serum pyruvate concentration may remain normal (<1.0 mg/dL with an increased lactate: pyruvate ratio), whereas pyruvate is usually increased when lactic acidosis results from an enzymatic defect in gluconeogenesis or pyruvate dehydrogenase complex (both lactate and pyruvate are increased and the ratio is normal). Lactate and pyruvate should be measured in the same blood specimen and on multiple blood specimens obtained when the patient is symptomatic because lactic acidosis can be intermittent. Figure 87-5 is an algorithm for the differential diagnosis of lactic acidosis.

DISORDERS OF GLUCONEOGENESIS

Deficiency of Glucose-6-Phosphatase (Type I Glycogen Storage Disease)

Type I GSD is the only glycogenosis associated with significant lactic acidosis. The chronic metabolic acidosis predisposes these patients to osteopenia; after prolonged fasting, the acidosis associated with hypoglycemia is a life-threatening condition (see Chapter 87.1).

Fructose-1,6-Diphosphatase Deficiency

Fructose-1,6-diphosphatase deficiency impairs the formation of glucose from all gluconeogenic precursors, including dietary fructose. Hypoglycemia occurs when glycogen reserves are limited or exhausted. The clinical manifestations are characterized by life-threatening episodes of acidosis, hypoglycemia, hyperventilation, convulsions, and coma. In about half of the cases, the deficiency presents in the 1st wk of life. In infants and small children, episodes are triggered by febrile infections and gastroenteritis if oral food intake decreases. The frequency of the attacks decreases with age. Laboratory findings include low blood glucose, high lactate and uric acid levels, and metabolic acidosis. In contrast to HFI, there is usually no aversion to sweets; renal tubular and liver functions are normal.

The diagnosis is established by demonstrating an enzyme deficiency in either liver or intestinal biopsy. The enzyme defect can also be demonstrated in leukocytes in some cases. The gene coding for fructose-1,6-diphosphatase is located on chromosome 9q22; mutations are characterized, making carrier detection and prenatal diagnosis possible. Treatment of acute attacks consists of correction of hypoglycemia and acidosis by intravenous glucose infusion; the response is usually rapid. Avoidance of fasting, aggressive management of infections and restriction of fructose and sucrose from the diet can prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Patients who survive childhood develop normally.

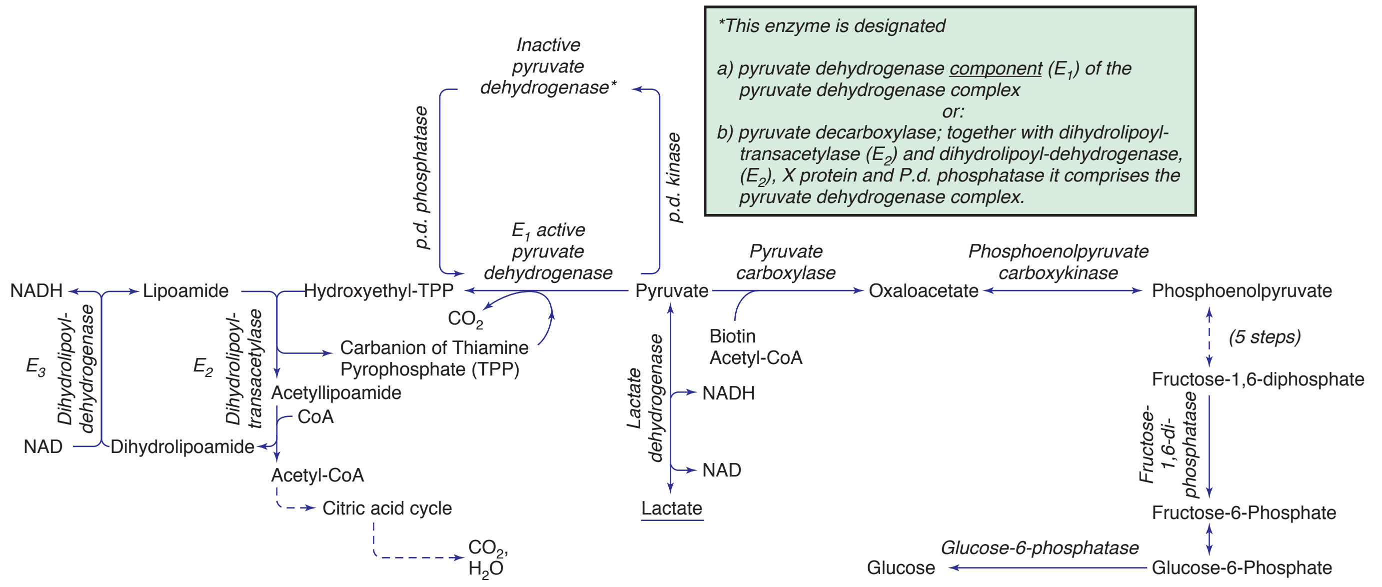

Figure 87-4 Enzymatic reactions of carbohydrate metabolism, deficiencies of which can give rise to lactic acidosis, pyruvate elevations, or hypoglycemia. The pyruvate dehydrogenase complex comprises, in addition to E_1, E_2, and E_3, an extra lipoate-containing protein (not shown), called protein X, and pyruvate dehydrogenase phosphatase.

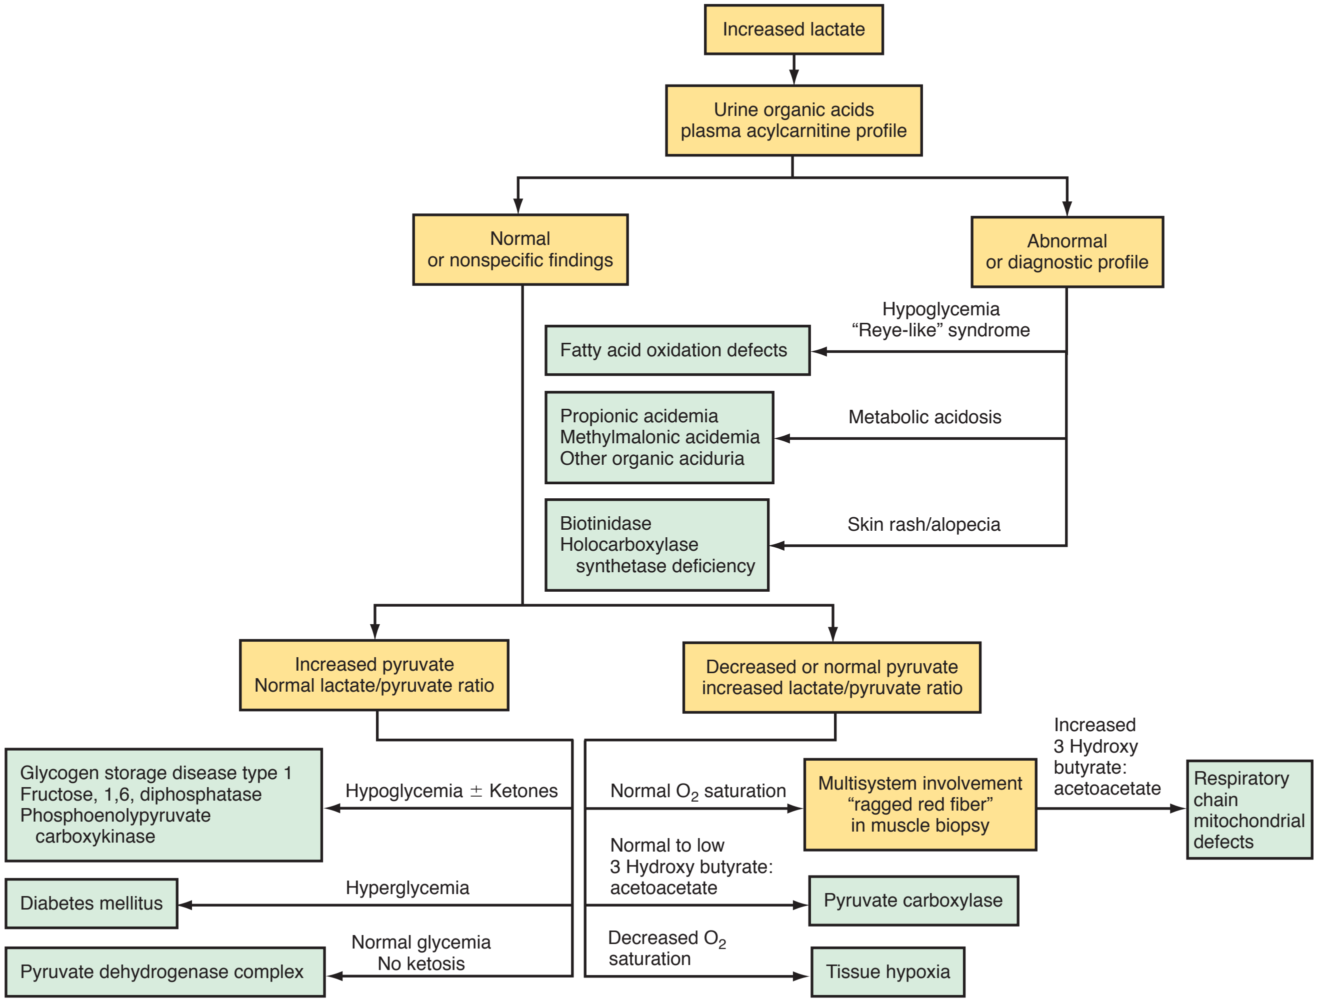

Figure 87-5 Algorithm of the differential diagnosis of lactic acidosis.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) is a key enzyme in gluconeogenesis. It catalyzes the conversion of oxaloacetate to phosphoenolpyruvate (see Fig. 87-4). PEPCK deficiency is both a mitochondrial enzyme deficiency and a cytosolic enzyme deficiency, encoded by 2 distinct genes.

The disease has been reported in only a few cases. The clinical features are heterogeneous, with hypoglycemia, lactic acidemia, hepatomegaly, hypotonia, developmental delay, and failure to thrive as the major manifestations. There may be multisystem involvement, with neuromuscular deficits, hepatocellular damage, renal dysfunction, and cardiomyopathy. The diagnosis is based on the reduced activity of PEPCK in liver, fibroblasts, or lymphocytes. Fibroblasts and lymphocytes are not suitable for diagnosing the cytosolic form of PEPCK deficiency because these tissues possess only mitochondrial PEPCK. To avoid hypoglycemia, patients should be treated with slow-release carbohydrates such as cornstarch, and fasting should be avoided.

DISORDERS OF PYRUVATE METABOLISM

Pyruvate is formed from glucose and other monosaccharides, from lactate, and from alanine. It is metabolized through 4 main enzyme systems: lactate dehydrogenase, alanine aminotransferase, pyruvate carboxylase, and pyruvate dehydrogenase complex. Deficiency of the M subunit of lactate dehydrogenase causes exercise intolerance and myoglobinuria (see Chapter 87.1).

Pyruvate Dehydrogenase Complex Deficiency

After entering the mitochondria, pyruvate is converted into acetyl-CoA by the pyruvate dehydrogenase complex (PDHC), which catalyzes the oxidation of pyruvate to acetyl-CoA, which then enters the tricarboxylic acid cycle for ATP production. The complex comprises 5 components: E_1, an α-ketoacid decarboxylase; E_2, a dihydrolipoyl transacylase; E_3, a dihydrolipoyl dehydrogenase; protein X, an extra lipoate-containing protein; and pyruvate dehydrogenase phosphatase. The most common is a defect in the E_1 (see Fig. 87-4).

Deficiency of the PDHC is the most common of the disorders leading to lactic acidemia and central nervous system dysfunction. The central nervous system dysfunction occurs because the brain obtains its energy primarily from oxidation of glucose. Brain acetyl-CoA is synthesized nearly exclusively from pyruvate.

The E_1 defects are caused by mutations in the gene coding for E_1 α subunit, which is X-linked. Although X-linked, its deficiency is a problem in both males and females even though only 1 E_1 α allele in females carries a mutation.

Clinical Manifestations

The disease has a wide spectrum of presentations from the most severe neonatal presentation to a mild late-onset form. The **neonatal onset** is associated with lethal lactic acidosis, white matter cystic lesions, agenesis of the corpus callosum, and the most severe enzyme deficiency. **Infantile onset** can be lethal or associated with psychomotor delay and chronic lactic acidosis, cystic lesions in the brainstem and basal ganglia, and pathologic features resembling **Leigh disease** (see below).

Neurologic symptoms in PDHC can be categorized into 2 groups: the first, abnormal brain development seen in both males and females, and the second, brain lesions and epilepsy seen in male patients only. Older children, usually boys, may have less acidosis, have greater enzyme activity, and manifest ataxia with high-carbohydrate diets. Intelligence may be normal. Patients of all ages may have facial dysmorphology, features similar to those of fetal alcohol syndrome.

The E_2 and protein X-lipoate defects are rare and result in severe psychomotor retardation. The E_3 lipoamide dehydrogenase defect leads to deficient activity not only in the PDHC, but also in the α-ketoglutarate and branched-chain ketoacid dehydrogenase complexes. This deficiency is more common in the Ashkenazi Jewish population. Recent studies suggest that the reactive oxygen species generated by the mutations responsible for lipoamide dehydrogenase deficiency may in fact explain certain disease characteristics and suggest the utility of antioxidant therapy. Pyruvate dehydrogenase phosphatase deficiency has also been reported. These other PDHC defects have clinical manifestations within the variable spectrum associated with PDHC deficiency due to E_1 deficiency.

Treatment

The general prognosis is poor except in rare cases in which mutation is associated with altered affinity for thiamine pyrophosphate, which may respond to thiamine supplementation. Because carbohydrates can aggravate lactic acidosis, a ketogenic diet is recommended. The diet has been found to lower the blood lactate level; the long-term benefit to patient outcome is unclear. A potential treatment strategy is to maintain any residual PDHC in its active form by **dichloroacetate,** an inhibitor of E_1 kinase. Beneficial effects of controlling postprandial lactic acidosis in some patients have been shown. Young children with congenital acidosis generally tolerate oral dichloroacetate well, but continued exposure is associated with peripheral neuropathy, a condition that could be attributable to the drug or the disease.

Deficiency of Pyruvate Carboxylase

Pyruvate carboxylase is a mitochondrial, biotin-containing enzyme essential in the process of gluconeogenesis; it catalyzes the conversion of pyruvate to oxaloacetate. The enzyme is also essential for Krebs cycle function as a provider of oxaloacetate and is involved in lipogenesis and formation of nonessential amino acids. Clinical manifestations of this deficiency have varied from neonatal severe lactic acidosis accompanied by hyperammonemia, citrullinemia, and hyperlysinemia **(type B)** to late-onset mild to moderate lactic acidosis and developmental delay **(type A).** In both types, patients who survived usually had severe psychomotor retardation with seizures, spasticity, and microcephaly. Some patients have pathologic changes in the brainstem and basal ganglia that resemble **Leigh disease** (see below). The clinical severity appears to correlate with the level of the residual enzyme activity. A "benign" form of pyruvate carboxylase deficiency characterized by recurrent attacks of lactic acidosis and mild neurologic deficits has also been described (type C). Laboratory findings are characterized by elevated levels of blood lactate, pyruvate, alanine, and ketonuria. In the case of type B, blood ammonia, citrulline, and lysine levels are also elevated, which might suggest a primary defect of the urea cycle. The mechanism is likely caused by depletion of oxaloacetate, which leads to reduced levels of aspartate, a substrate for argininosuccinate synthase in the urea cycle (see Chapter 85.12). The gene for pyruvate carboxylase is located on chromosome 11q13.4-q13.5 and approximately 15 mutations have been identified.

Treatment consists of avoidance of fasting, and eating a carbohydrate meal before bedtime. During acute episodes of lactic acidosis, patients should receive continuous intravenous glucose. Aspartate and citrate supplements restore the metabolic abnormalities; whether this treatment can prevent the neurologic deficits is not known. Liver transplantation has been attempted; its benefit remains unknown. Diagnosis of pyruvate carboxylase deficiency is made by the measurement of enzyme activity in liver or cultured skin fibroblasts and must be differentiated from holocarboxylase synthase or biotinidase deficiency.

Deficiency of Pyruvate Carboxylase Secondary to Deficiency of Holocarboxylase Synthase or Biotinidase

Deficiency of either holocarboxylase synthase (HCS) or biotinidase, which are enzymes of biotin metabolism, result in multiple carboxylase deficiency (pyruvate carboxylase and other biotin-requiring carboxylases and metabolic reactions) and in clinical manifestations associated with the respective deficiencies, as well as rash, lactic acidosis, and alopecia (see Chapter 85.6). The course of HCS or biotinidase deficiency can be protracted, with intermittent exacerbation of chronic lactic acidosis, failure to thrive, seizures, and hypotonia leading to spasticity, lethargy, coma, and death. Auditory and optic nerve dysfunction can lead to deafness and blindness, respectively. Late-onset milder forms have also been reported. Laboratory findings include metabolic acidosis and abnormal organic acids in the urine. In HCS deficiency, biotin concentrations in plasma and urine are normal. Diagnosis can be made in skin fibroblasts or lymphocytes by assay for HCS activity, and in the case of biotinidase, in the serum by a screening blood spot.

Treatment consists of biotin supplementation, 5-20 mg/day, and is generally effective if treatment is started before the development of brain damage. Patients identified through newborn screening and treated with biotin have remained asymptomatic.

Both enzyme deficiencies are autosomal recessive traits. The incidence of HCS deficiency is approximately 1 in 87,000 live births. HCS and biotinidase are located on chromosome 21q22 and 3p25, respectively. Ethnic-specific mutations in the HCS gene have been identified. Two common mutations (del7/ins3 and p.R538C) in the biotinidase gene account for 52% of all mutant alleles in symptomatic patients with biotinidase deficiency.

Mitochondrial Respiratory Chain Defects (Oxidative Phosphorylation Disease)

The mitochondrial respiratory chain catalyzes the oxidation of fuel molecules and transfers the electrons to molecular oxygen with concomitant energy transduction into ATP (oxidative phosphorylation). The respiratory chain produces ATP from adenosine diphosphate and inorganic phosphate utilizing the energy from electrons transferred from nicotinamide adenine dinucleotide (NADH) or flavin adenine dinucleotide and includes 5 specific complexes (I: NADH–coenzyme Q reductase; II: succinate–coenzyme Q reductase; III: coenzyme QH_2 cytochrome C reductase; IV: cytochrome C oxidase; V: ATP synthase). Each complex is composed of 4-35 individual proteins and, with the exception of complex II (which is encoded solely by nuclear genes), is encoded by nuclear or mitochondrial DNA (inherited only from the mother by mitochondrial inheritance). Defects in any of these complexes or assembly systems produce chronic lactic acidosis presumably because of a change of the reduction-oxidation state with increased concentrations of NADH. In contrast to PDHC or pyruvate carboxylase deficiency, skeletal muscle and heart are usually involved in the respiratory chain disorders, and in muscle biopsy, "ragged red fibers" (indicating mitochondrial proliferation) are very suggestive when present (see Fig. 87-5). Because of the ubiquitous nature of oxidative phosphorylation, a defect of the mitochondrial respiratory chain accounts for a vast array of clinical manifestations and should be considered in patients in all age groups presenting with multisystem involvement. Some deficiencies resemble **Leigh disease** (see below), whereas others cause infantile myopathies such as **MELAS** (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes), **MERRF** (myoclonic epilepsy and ragged red fibers), and **Kearns-Sayre syndrome** (external ophthalmoplegia, acidosis, retinal degeneration, heart block, myopathy, and high cerebrospinal fluid protein) (Table 87-2; Chapters 598.2 and 611.4). There is a higher incidence of psychiatric disorders in adults with a primary oxidative phosphorylation disease than in the general population. Diagnosis requires demonstration of abnormalities of oxidative phosphorylation enzyme complex activities in tissues or of mitochondrial DNA or a nuclear gene coding for mitochondrial functions, or both (Fig. 87-6). Muscle histology, including

electron microscopy can detect ragged red fibers and other abnormalities typical of mitochondrial myopathies. Analysis of oxidative phosphorylation complexes I-IV from intact mitochondria isolated from fresh skeletal muscle is the most sensitive assay for mitochondrial disorders; however, electron transport chain testing of flash-frozen muscle provides an alternative approach when fresh muscle testing is not available. Next-generation sequencing of mitochondrial DNA and panels of nuclear genes provides a noninvasive alternative to diagnosis, albeit with lower sensitivity. Specific criteria may assist in making a diagnosis (Table 87-3). Table 87-4 lists clues to the diagnosis of mitochondrial diseases.

Treatment remains largely symptomatic and does not significantly alter the outcome of disease. Some patients appear to respond to cofactor supplements, typically coenzyme Q_{10} ± L-carnitine at pharmacologic doses. The addition of creatine monohydrate and α-lipoic acid supplementation may add a significant benefit.

Leigh Disease (Subacute Necrotizing Encephalomyelopathy)

Leigh disease is a heterogenous neurologic disease that remains a neuropathologic description characterized by demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain regions. In decreasing order of severity, the affected areas are the basal ganglia, brainstem cerebellum, and cerebral cortex (see Chapter 598). The classic presentation is of an infant who presents with central hypotonia, developmental regression or arrest, and signs of brainstem or basal ganglia involvement. The clinical presentation is highly variable. Diagnosis is usually confirmed by radiologic or pathologic evidence of symmetric lesions affecting the basal ganglia, brainstem, and subthalamic nuclei. Patients with Leigh disease have defects in several enzyme complexes. Dysfunction in cytochrome C oxidase (complex IV) is the most commonly reported defect, followed by NADH-coenzyme Q reductase (complex I), PDHC, and pyruvate carboxylase. Mutations in the nuclear *SURF1* gene, which encodes a factor involved in the biogenesis of cytochrome C oxidase and mitochondrial DNA mutations in the adenosine triphosphatase 6 coding region, are common molecular findings in patients with Leigh disease. Patients with Leigh disease frequently present with developmental delay, seizures, altered consciousness, failure to thrive, pericardial effusion, and dilated cardiomyopathy. The prognosis for Leigh syndrome is poor. In a study of 14 cases, there were 7 fatalities before the age of 1.5 yr.

Lactic acidosis, hypoglycemia, and encephalopathy have also been reported in patients with thiamine transporter deficiency and with pyridoxine-dependent epilepsy. Both disorders should improve by the provision of thiamine and pyridoxine, respectively.

Bibliography is available at Expert Consult.

Table 87-3 Modified Walker Criteria Applied to Children Referred for Evaluation of Mitochondrial Disease

	MAJOR CRITERIA	MINOR CRITERIA
Clinical	Clinically complete RC encephalomyopathy* or a mitochondrial cytopathy defined as fulfilling 3 criteria†	Symptoms compatible with an RC defect‡
Histology	>2% RRF in skeletal muscle	Smaller numbers of RRF, SSAM, or widespread electron microscopy abnormalities of mitochondria
Enzymology	Cytochrome c oxidase–negative fibers or residual activity of an RC complex <20% in a tissue; <30% in a cell line, or <30% in 2 or more tissues	Antibody-based demonstration of an RC defect or residual activity of an RC complex 20-30% in a tissue, 30-40% in a cell line, or 30-40% in 2 or more tissues
Functional	Fibroblast ATP synthesis rates >3 SD below mean	Fibroblast ATP synthesis rates 2-3 SD below mean, or fibroblasts unable to grow in galactose media
Molecular	Nuclear or mtDNA mutation of undisputed pathogenicity	Nuclear or mtDNA mutation of probable pathogenicity
Metabolic		One or more metabolic indicators of impaired metabolic function

*Leigh disease, Alpers disease, lethal infantile mitochondrial disease, Pearson syndrome, Kearns-Sayre syndrome, MELAS (myopathy, encephalopathy, lactic acidosis, and stroke-like episodes), MERRF (myoclonic epilepsy associated with ragged red fibers), NARP (neuropathy, ataxia and retinitis pigmentosa), MNGIE (mitochondrial neurogastrointestinal encephalomyopathy), and LHON (Leber hereditary optic neuropathy).

†(1) Unexplained combination of multisystemic symptoms that is essentially pathognomonic for an RC disorder, (2) a progressive clinical course with episodes of exacerbation or a family history strongly indicative of an mtDNA mutation, and (3) other possible metabolic or nonmetabolic disorders have been excluded by appropriate testing.

‡Added pediatric features: stillbirth associated with a paucity of intrauterine movement, neonatal death or collapse, movement disorder, severe failure to thrive, neonatal hypotonia, and neonatal hypertonia as minor clinical criteria.

ATP, adenosine triphosphate; mtDNA, mitochondrial DNA; RC, respiratory chain; RRF, ragged red fibers; SSAM, subsarcolemmal accumulation of mitochondria.

Table 87-4 Clues to the Diagnosis of Mitochondrial Disease

NEUROLOGIC
Cerebral stroke-like lesions in a nonvascular pattern
Basal ganglia disease
Encephalopathy: recurrent or with low/moderate dosing of valproate
Neurodegeneration
Epilepsia partialis continua
Myoclonus
Ataxia
MRI findings consistent with Leigh disease
Characteristic MRS peaks
Lactate peak at 1.3 ppm TE (time to echo) at 35 and 135
Succinate peak at 2.4 ppm
CARDIOVASCULAR
Hypertrophic cardiomyopathy with rhythm disturbance
Unexplained heart block in a child
Cardiomyopathy with lactic acidosis (>5 mM)
Dilated cardiomyopathy with muscle weakness
Wolff-Parkinson-White arrhythmia
OPHTHALMOLOGIC
Retinal degeneration with signs of night blindness, color vision deficits, decreased visual acuity, or pigmentary retinopathy
Ophthalmoplegia/paresis
Fluctuating, dysconjugate eye movements
Ptosis
Sudden- or insidious-onset optic neuropathy/atrophy
GASTROENTEROLOGIC
Unexplained or valproate-induced liver failure
Severe dysmotility
Pseudoobstructive episodes
OTHER
A newborn, infant, or young child with unexplained hypotonia, weakness, failure to thrive, and a metabolic acidosis (particularly lactic acidosis)
Exercise intolerance that is not in proportion to weakness
Hypersensitivity to general anesthesia
Episodes of acute rhabdomyolysis

87.5 Defects in Pentose Metabolism

Priya S. Kishnani and Yuan-Tsong Chen

Approximately 90% of glucose metabolism in the body is via the glycolytic pathway, with the remaining 10% via the hexose monophosphate pathway. The hexose monophosphate shunt leads to formation of pentoses, as well as providing NADH. One of the metabolites is ribose-5-phosphate, which is used in the biosynthesis of ribonucleotides and deoxyribonucleotides. Through the transketolase and transaldolase reactions, the pentose phosphates can be converted back to fructose-6-phosphate and glucose-6-phosphate.

ESSENTIAL PENTOSURIA

Essential pentosuria is a benign disorder encountered principally in Ashkenazi Jews and is an autosomal recessive trait. The urine contains L-xylulose, which is excreted in increased amounts because of a block in the conversion of L-xylulose to xylitol as a result of xylitol dehydrogenase deficiency. The condition is usually discovered accidentally in a urine test for reducing substances; no treatment is required.

Transaldolase Deficiency

Few patients have reported symptoms that include liver cirrhosis, hepatosplenomegaly, severe neonatal hepatopathy, and cardiomyopathy. Biochemical abnormalities revealed elevated levels of arabitol, ribitol, and erythritol in the urine. Most recently, erythronic acid has been identified by urine nuclear magnetic resonance spectroscopy as another hallmark metabolite. Enzyme assay in the lymphoblasts and fibroblasts demonstrated low transaldolase activity, which was confirmed by mutations in the transaldolase gene. In addition, measurement of transaldolase activity in fibroblasts, lymphoblasts, or liver tissue, as well as assessing urinary concentrations of polyols also can be used to confirm the diagnosis.

Ribose-5-Phosphate Isomerase Deficiency

Only 1 case of this disorder has been reported. The affected male had psychomotor delay from early in life and developed epilepsy at 4 yr of age. Thereafter, a slow neurologic regression developed, with prominent cerebellar ataxia, some spasticity, optic atrophy, and a mild sensorimotor neuropathy. MRI of the brain at ages 11 yr and 14 yr showed

extensive abnormalities of the cerebral white matter. Proton magnetic resonance spectroscopy (MRS) of the brain revealed elevated levels of ribitol and D-arabitol. These pentitols were also increased in urine and plasma similar to the patient found in transaldolase deficiency. Enzyme assays in cultured fibroblasts showed deficient ribose-5-phosphate isomerase activity, which was confirmed by a molecular study. These results combined with a study of ribose-5-phosphate isomerase–deficient mice converged to demonstrate that the specific genetic pairing of a null allele with an allele coding for a form of the enzyme that is only partly active, allowing for cell-type-dependent expression deficits, is a contributing factor to the rarity of the disease. Ribose-5-phosphate isomerase deficiency may represent an example of a single-gene disease that appears seldom because of its complex molecular etiology.

87.6 Disorders of Glycoprotein Degradation and Structure

Margaret M. McGovern and Robert J. Desnick

The disorders of glycoprotein degradation and structure include several lysosomal storage diseases that result from defects in glycoprotein degradation, and the congenital disorders of glycosylation (CDGs), which are pathophysiologically unrelated. Glycoproteins are macromolecules that are composed of oligosaccharide chains linked to a peptide backbone. They are synthesized by 2 pathways: the glycosyltransferase pathway, which synthesizes oligosaccharides linked *O*-glycosidically to serine or threonine residues; and the dolichol, lipid-linked pathway, which synthesizes oligosaccharides linked *N*-glycosidically to asparagine.

The glycoprotein lysosomal storage diseases result from the deficiency of the enzymes that normally participate in the degradation of oligosaccharides and include sialidosis, galactosialidosis, aspartylglucosaminuria, and α-mannosidosis. In some instances, the underlying abnormality that leads to glycoprotein accumulation also results in abnormal degradation of other classes of macromolecules that contain similar oligosaccharide linkages, such as certain glycolipids and proteoglycans. In these instances, the underlying enzymatic deficiency results in the accumulation of both glycoproteins and glycolipids. The classification of these types of disorders as lipidoses or glycoproteinoses is dependent on the nature of the predominantly stored substance. In general, the glycoprotein disorders are characterized by autosomal recessive inheritance and a progressive disease course with clinical features that resemble those seen in the mucopolysaccharidoses.

SIALIDOSIS AND GALACTOSIALIDOSIS

Sialidosis is an autosomal recessive disorder that results from the primary deficiency of neuraminidase because of mutations in the gene that encodes this protein, which is located on chromosome 10. In contrast, galactosialidosis is caused by the deficiency of 2 lysosomal enzymes—neuraminidase and β-galactosidase. The loss of these enzymatic activities results from mutations in a gene located on chromosome 20 that encodes protective protein/cathepsin A, which functions to stabilize these enzymatic activities. Neuraminidase normally cleaves terminal sialyl linkages of several oligosaccharides and glycoproteins. Its deficiency results in the accumulation of oligosaccharides, and the urinary excretion of sialic acid terminal oligosaccharides and sialylglycopeptides. Examination of tissues from affected individuals reveals pathologic storage of substrate in many tissues including liver, bone marrow, and brain.

The clinical phenotype associated with neuraminidase deficiency is variable and includes type I sialidosis which usually presents in the 2nd decade of life with myoclonus and the presence of a cherry-red spot. These patients typically come to attention secondary to gait disturbances, myoclonus, or visual complaints. In contrast, type II sialidosis occurs as congenital, infantile, and juvenile forms. The congenital and infantile forms result from isolated neuraminidase deficiency, whereas the juvenile form results from both neuraminidase and β-galactosidase deficiency. The congenital type II disease is characterized by hydrops fetalis, neonatal ascites, hepatosplenomegaly, stippling of the epiphyses, periosteal cloaking, and stillbirth or death in infancy. The type II infantile form presents in the 1st yr of life with dysostosis multiplex, moderate intellectual disability, visceromegaly, corneal clouding, cherry red spot, and seizures. The juvenile type II form of sialidosis, which is sometimes designated *galactosialidosis,* has a variable age of onset ranging from infancy to adulthood. In infancy, the phenotype is similar to that of GM_1 gangliosidosis, with edema, ascites, skeletal dysplasia, and cherry-red spot. Patients with later-onset disease have dysostosis multiplex, visceromegaly, mental retardation, dysmorphism, corneal clouding, progressive neurologic deterioration, and bilateral cherry red spots. No specific therapy exists for any form of the disease, although studies in animal models have demonstrated improvement in the phenotype after bone marrow transplantation. The diagnosis of sialidosis and galactosialidosis is achieved by the demonstration of the specific enzymatic deficiency. Prenatal diagnosis using cultured amniotic cells is also possible.

ASPARTYLGLUCOSAMINURIA

This is a rare autosomal recessive lysosomal storage disorder, except in Finland, where the carrier frequency is estimated at 1 in 36 adults. The disorder results from the deficient activity of aspartylglycosaminidase and the subsequent accumulation of aspartylglycosamine, particularly in the liver, spleen, and thyroid. The gene for the enzyme has been localized to the long arm of chromosome 4 and the complementary DNA has been cloned and sequenced. In the Finnish population, a single mutation in the gene *(C163S)* accounts for most mutant alleles, whereas outside of Finland, a large number of private mutations have been described. Affected individuals with aspartylglucosaminuria typically present in the 1st yr of life with recurrent infections, diarrhea, and hernias. Coarsening of the facies and short stature usually develop later. Other features include joint laxity, macroglossia, hoarse voice, crystal-like lens opacities, hypotonia, and spasticity. Psychomotor development is usually near normal until the age of 5 yr when a decline is noted. Behavioral abnormalities are typical and IQ values in affected adults are usually <40. Survival to adulthood is common, with most early deaths attributable to pneumonia or other pulmonary causes. Definitive diagnosis requires measurement of the enzyme in peripheral blood leukocytes. Molecular diagnosis by analysis of DNA for the C163S mutation is possible for Finnish patients. Several patients have undergone allogeneic bone marrow transplants with some reports of stabilization of the neurologic phenotype, but this approach has not been proven effective and no specific treatment is available. Prenatal diagnosis by the determination of the level of aspartylglycosaminidase in cultured amniocytes or chorionic villi has been reported.

α-MANNOSIDOSIS

This autosomal recessive disorder results from the deficient activity of α-mannosidase and the accumulation of mannose-rich compounds. The gene encoding the enzyme has been localized to chromosome 19p13.2-q12, although the complementary DNA has not been cloned. Affected patients with this disorder display clinical heterogeneity. There is a severe infantile form, or type I disease, and a milder juvenile variant, type II disease. All patients have psychomotor retardation, facial coarsening, and dysostosis multiplex. The infantile form of the disorder, however, is characterized by more rapid cognitive deterioration, with death occurring between the ages of 3 and 10 yr. Patients with the infantile form also have more severe skeletal involvement and hepatosplenomegaly. The juvenile disorder is characterized by onset of symptoms in early childhood or adolescence with milder somatic features and survival to adulthood. Hearing loss, destructive synovitis, pancytopenia, and spastic paraplegia have been reported in type II patients. No specific therapy exists for the disorder. The diagnosis is made by the demonstration of the deficiency of α-mannosidase activity in white blood cells or cultured fibroblasts, and prenatal diagnosis has also been achieved.

CONGENITAL DISORDERS OF GLYCOSYLATION

These are a heterogenous group of autosomal recessive disorders that result from defective protein and lipid glycosylation. The protein glycosylation disorders result from defects of *N*-glycosylation, combined *N*- and *O*-glycosylation, the dolichol pathway and the conserved oligomeric Golgi complex. The more recently discovered lipid-glycosylation disorders include defects of ganglioside synthesis (GM_3 synthase deficiency) and the glycophosphatidylinositol anchor system. In addition, there are patients with glycosylation defects for which the molecular and biochemical bases are not yet known.

To date, more than 30 CDG subtypes have been identified (Table 87-5). In general, most CDG disorders are multisystemic and present with variable involvement of the central nervous system (most often hypotonia and ataxia), abnormal fat distribution, ocular movement defects, coagulation abnormalities, gastrointestinal symptoms including protein-losing enteropathy, retinitis pigmentosa, hormonal abnormalities, and, in some cases, dysmorphic features. CDG type Ia, which results from mutations in the gene that encodes phosphomannomutase, is the most common form. The most consistent clinical features of this disorder include variable degrees of psychomotor retardation, subcutaneous fat pads and inverted nipples. Frequent neurologic findings in infancy include cerebellar atrophy (Fig. 87-7), hypotonia, weakness, hyperreflexia, and strokelike episodes (Table 87-6).

In childhood, ataxia, muscle atrophy, decreased deep tendon reflexes, toe walking, and continued stroke-like episodes are observed. The latter events may be related to coagulopathies characterized by reduced antithrombin III and proteins C and S, in conjunction with abnormal levels of factors VIII, IX, XI, and XIII, which together increase risk for bleeding and thrombosis. Growth failure, liver dysfunction, retinal

Table 87-6 Characteristics of Representative Congenital Disorders of Glycosylation

Figure 87-7 Sagittal T2-weighted MR image shows severe spinal cord compression with myelopathy *(white arrow)*, together with cerebellar atrophy *(black arrow)*, and cortical atrophy of the parietal lobe *(red arrow)*. *(From Schade van Westrum SM, Nederkoorn PJ, Schuurman PR, et al: Skeletal dysplasia and myelopathy in congenital disorder of glycosylation type 1A,* J Pediatr *148:115–117, 2006, Fig. 1.)*

degeneration, and skeletal abnormalities have also been described. The skeletal features can include contractures, kyphoscoliosis, and pectus carinatum, all of which may be secondary to the neurologic effects of the disorder. Pericardial effusion in older patients and hypertrophic obstructive cardiomyopathy in the infant also may occur.

Among the other types, few have distinctive phenotypes. These include CDG-Ib, which is characterized by protein-losing enteropathy and normal neurologic function; CDG-If, which includes ichthyosis and growth retardation; and CDG-IIf, in which macrothrombocytopenia is present.

Diagnostic testing for CDG types that result from defects of *N*-glycosylation begins with isoelectric focusing of *N*-glycosylated serum transferring. For some types further confirmation of the diagnosis by enzymatic analysis in fibroblasts or leukocytes and/or mutation analysis of the relevant gene is available. Although prenatal diagnosis by analysis of transferrin has been attempted, it has not proven reliable. Treatment of these disorders is symptomatic, except for CDG-Ib, which responds to oral mannose (100-150 mg/kg/day every 4-6 hr).

Chapter 88

Mucopolysaccharidoses

Jürgen W. Spranger

Mucopolysaccharidoses are hereditary, progressive diseases caused by mutations of genes coding for lysosomal enzymes needed to degrade glycosaminoglycans (acid mucopolysaccharides). Glycosaminoglycans (GAGs) are long-chain complex carbohydrates composed of uronic acids, amino sugars, and neutral sugars. The major GAGs are chondroitin-4-sulfate, chondroitin-6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronan. These substances are synthesized and, with the exception of hyaluronan, linked to proteins to form proteoglycans, major constituents of the ground substance of connective tissue, of nuclear and cell membranes. Degradation of proteoglycans starts with the proteolytic removal of the protein core followed by the stepwise degradation of the glycosaminoglycan moiety. Failure of this degradation because of absent or grossly reduced activity of mutated lysosomal enzymes results in the intralysosomal accumulation of glycosaminoglycan fragments (Fig. 88-1). Distended lysosomes accumulate in the cell, interfere with cell function and lead to characteristic pattern of clinical, radiologic, and biochemical abnormalities (Table 88-1, Fig. 88-2). Within this pattern, specific diseases can be recognized which evolve from the intracellular accumulation of different degradation products (Table 88-2). As a general rule, the impaired degradation of heparan sulfate is more closely associated with intellectual disability, and the impaired degradation of dermatan sulfate, chondroitin sulfates, and keratan sulfate with mesenchymal abnormalities. Variable expression within a given entity results from allelic mutations and varying residual activity of mutated enzymes. For instance, allelic mutations of the gene encoding L-iduronidase may result in severe Hurler disease with early death or in mild Scheie disease manifesting only with limited joint mobility, mild skeletal abnormalities and corneal opacities. Mucopolysaccharidoses are autosomal recessive disorders with the exception of Hunter disease, which is X-linked recessive. Their overall frequency is between 3.5 in 100,000 births and 4.5 in 100,000 births. The most common subtype is MPS-III, followed by MPS-I and MPS-II.

CLINICAL ENTITIES

Mucopolysaccharidosis I

Mucopolysaccharidosis (MPS)-I is caused by mutations of the *IDUA* gene on chromosome 4p16.3 encoding α-L-iduronidase. Mutation analysis has revealed 2 major alleles, W402X and Q70X, account for more than half the MPS-I alleles in the white population. The

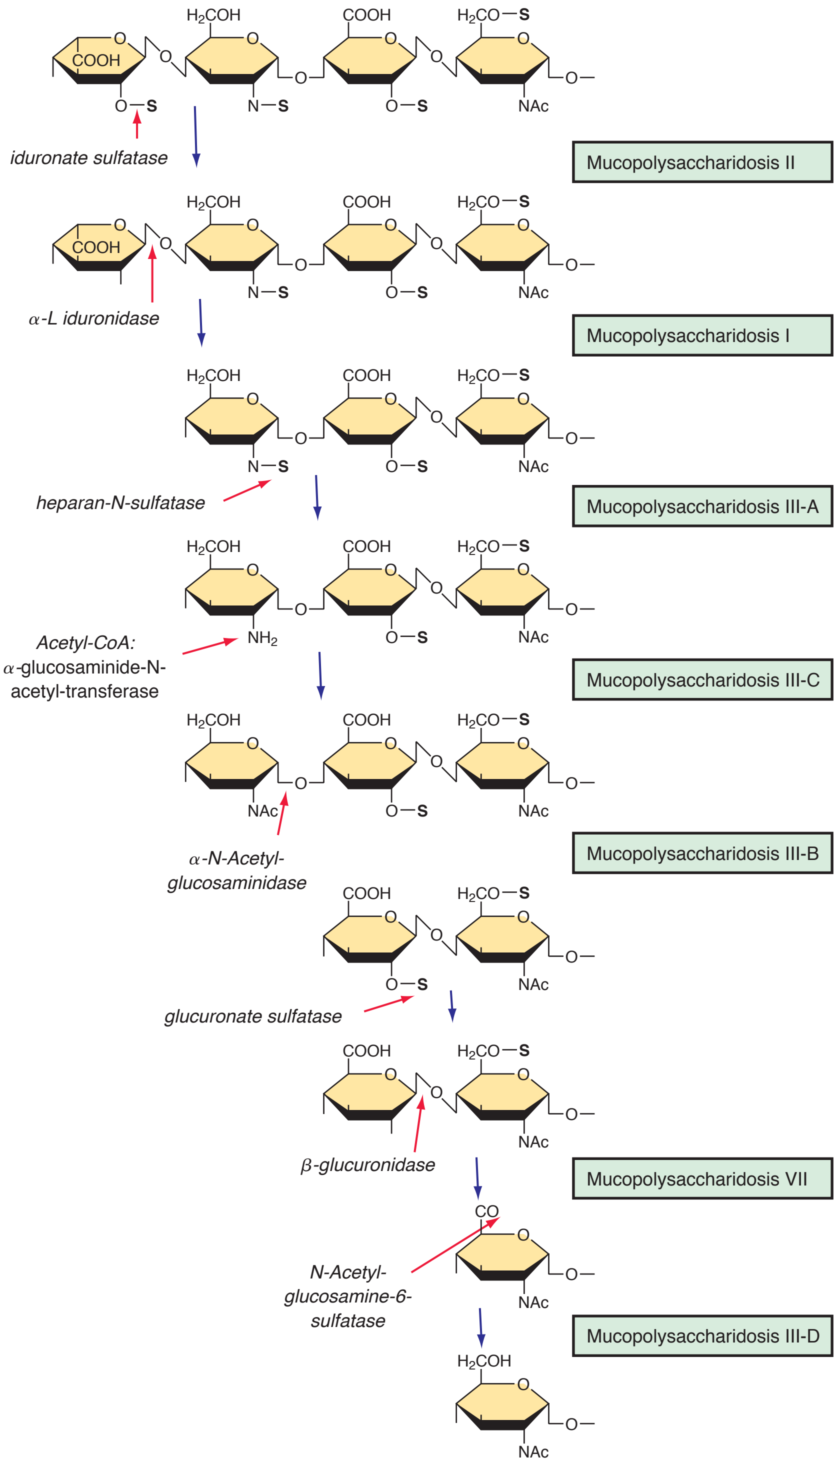

Figure 88-1 Degradation of heparan sulfate and mucopolysaccharidoses resulting from the deficiency of individual enzymes. Some of these enzymes are also involved in the degradation of other glycosaminoglycans (not shown).

mutations introduce stop codons with ensuing absence of functional enzyme (null alleles) and in homozygosity or compound heterozygosity give rise to Hurler disease. Other mutations occur in only 1 or a few individuals.

Deficiency of α-L-iduronidase results in a wide range of clinical involvement from severe Hurler disease to mild Scheie disease, which are ends of a broad clinical spectrum. Homozygous nonsense mutations result in severe forms of MPS-I, whereas missense mutations are more likely to preserve some residual enzyme activity associated with a milder form of the disease.

Hurler Disease

This form of MPS-I (MPS-IH) is a severe, progressive disorder with multiple organ and tissue involvement that results in premature death, usually by 10 yr of age. An infant with Hurler syndrome appears normal at birth, but inguinal herniae are often present. Diagnosis is usually made between 6 and 24 mo with evidence of hepatosplenomegaly, coarse facial features, corneal clouding, large tongue, prominent forehead, joint stiffness, short stature, and skeletal dysplasia. Acute cardiomyopathy has been found in some infants younger than 1 yr of age. Most patients have recurrent upper respiratory tract and

ear infections, noisy breathing, and persistent copious nasal discharge. Valvular heart disease with incompetence notably of the mitral and aortic valves regularly develops and narrowing of the coronary arteries occurs. Obstructive airway disease, notably during sleep, may necessitate tracheotomy. Obstructive airway disease, respiratory infection, and cardiac complications are the common causes of death.

Most children with Hurler syndrome acquire only limited language skills because of developmental delay, combined conductive and neurosensory hearing loss, and an enlarged tongue. Progressive ventricular enlargement with increased intracranial pressure caused by communicating hydrocephalus also occurs. Corneal clouding, glaucoma, and retinal degeneration are common. Radiographs show a characteristic skeletal dysplasia known as dysostosis multiplex (Figs. 88-3 and 88-4). The earliest radiographic signs are thick ribs and ovoid vertebral bodies. Skeletal abnormalities in addition to those shown in the figures include enlarged, coarsely trabeculated diaphyses of the long bones with irregular metaphyses and epiphyses. With progression of the disease macrocephaly develops with thickened calvarium, premature closure of lambdoid and sagittal sutures, shallow orbits, enlarged J-shaped sella, and abnormal spacing of teeth with dentigerous cyst.

I-H, Hurler disease; I-S, Scheie disease; II Hunter disease; III, Sanfilippo disease; IV, Morquio disease; VI, Maroteaux-Lamy disease; VII Sly disease.

Hurler-Scheie Disease

The clinical phenotype of MPS-IH/S is intermediate between Hurler and Scheie diseases and is characterized by progressive somatic involvement, including dysostosis multiplex with little or no intellectual dysfunction. The onset of symptoms is usually observed between 3 and 8 yr of age; survival to adulthood is common. Cardiac involvement and upper airway obstruction contribute to clinical morbidity. Some patients have spondylolisthesis, which may cause cord compression.

Scheie Disease

MPS-IS is a comparatively mild disorder characterized by joint stiffness, aortic valve disease, corneal clouding, and mild dysostosis multiplex. Onset of significant symptoms is usually after the age of 5 yr, with diagnosis made between 10 and 20 yr of age. Patients with Scheie disease have normal intelligence and stature but have significant joint and ocular involvement. A carpal tunnel syndrome often develops. Ophthalmic features include corneal clouding, glaucoma, and retinal degeneration. Obstructive airway disease, causing sleep apnea, develops in some patients, necessitating tracheotomy. Aortic valve disease is common and has required valve replacement in some patients.

Mucopolysaccharidosis II

Hunter disease, (MPS-II) is an X-linked disorder caused by the deficiency of iduronate 2-sulfatase (IDS). The gene encoding IDS is mapped to Xq28. Point mutations of the *IDS* gene have been detected in approximately 80% of patients with MPS-II. Major deletions or rearrangements of the *IDS* gene have been found in the rest, and these are usually associated with a more severe clinical phenotype. As an X-linked recessive disorder, Hunter disease manifests almost exclusively in males. However, it has been observed in females and this is

MPS-I MPS-II MPS-III MPS-IV MPS-VI

explained by skewed inactivation of the X-chromosome carrying the normal gene.

Marked molecular heterogeneity explains the wide clinical spectrum of Hunter disease. Patients with severe MPS-II have features similar to those of Hurler disease except for the lack of corneal clouding and the somewhat slower progression of somatic and central nervous system (CNS) deterioration. Coarse facial features, short stature, dysostosis multiplex, joint stiffness, and intellectual disability manifest between 2 and 4 yr of age. Grouped skin papules are present in some patients. Extensive mongolian spots present at birth have been observed in African and Asian patients and may be an early marker of the disease. Gastrointestinal storage may produce chronic diarrhea. Communicating hydrocephalus and spastic paraplegia may develop due to thickened meninges. In severely affected patients, extensive, slowly progressive neurologic involvement precedes death, which usually occurs between 10 and 15 yr of age.

Patients with the mild form can have a near-normal or normal life span, minimal CNS involvement and slow progression of somatic deterioration with preservation of cognitive function in adult life. Survival to ages 65 and 87 yr has been reported and some patients have had children. Somatic features are Hurler-like but milder with a greatly reduced rate of progression. Adult height may exceed 150 cm. Airway involvement, valvular cardiac disease, hearing impairment, carpal tunnel syndrome, and joint stiffness are common and can result in significant loss of function in both the mild and severe forms.

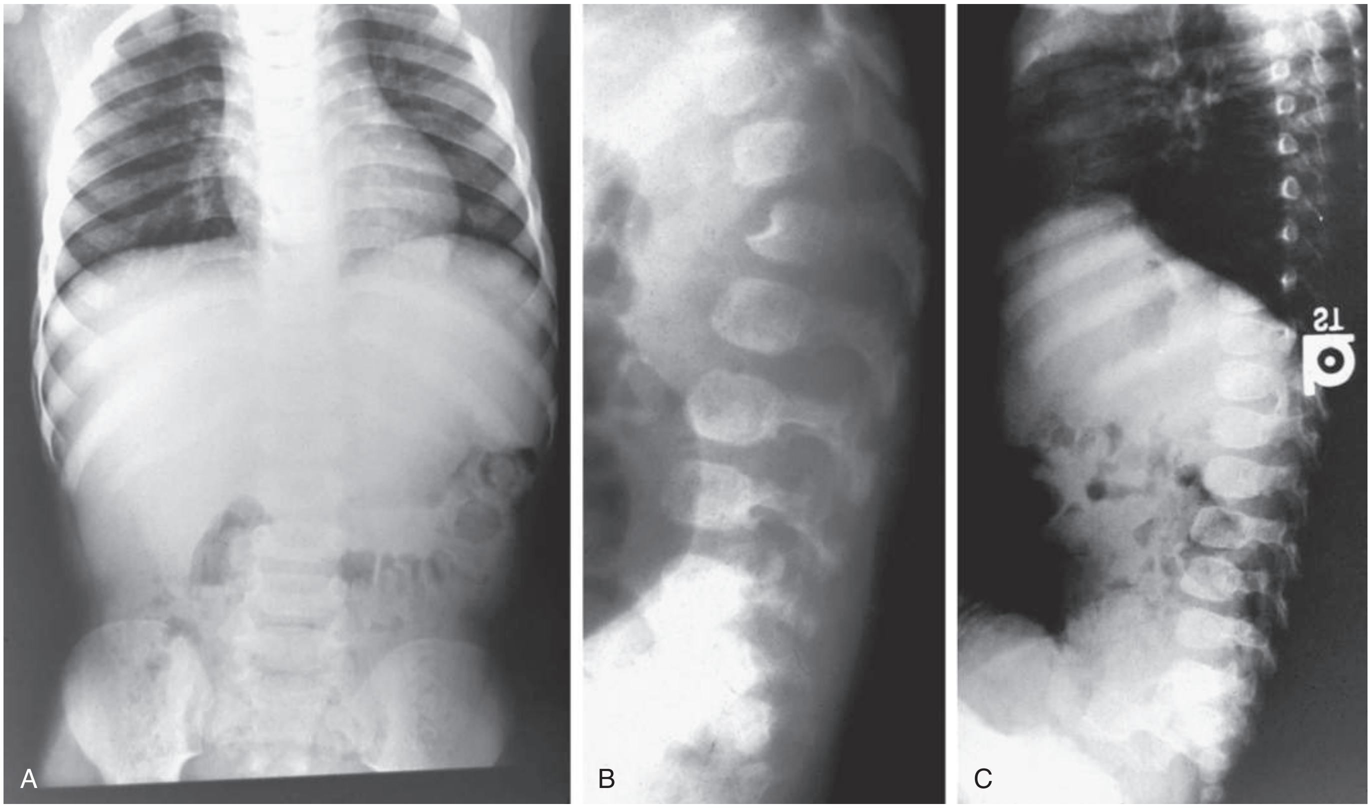

Figure 88-3 Dysostosis multiplex. **A,** Sanfilippo disease, patient age 4 yr: The ribs are wide. **B,** Sanfilippo disease, patient age 4 yr: immature, ovoid configuration of the vertebral bodies. **C,** Hurler disease, patient age 18 mo: anterosuperior hypoplasia of L-1 resulting in hook-shaped appearance.

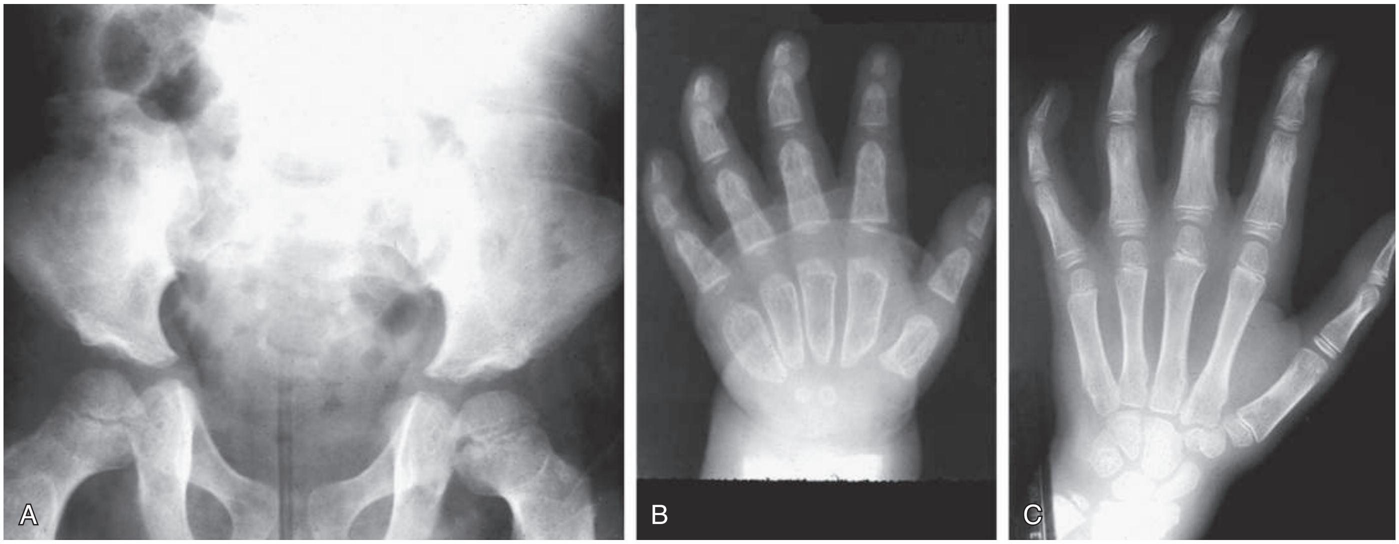

Figure 88-4 Dysostosis multiplex. **A,** MPS-IH, patient age 10 yr. The inferior portions of the ilia are hypoplastic with resulting iliac flare and shallow acetabular fossae. The femoral necks are in valgus position. **B,** MPS-IH, patient age 4 yr. Metacarpals and phalanges are abnormally short, wide and deformed with proximal pointing of the metacarpals and bullet-shaped phalanges. Bone trabeculation is coarse and the cortices are thin. **C,** MPS-IS, patient age 13 yr. The carpal bones are small leading to a V-shaped configuration of the digits. The short tubular bones are well modeled. Flexion of the middle and distal phalanges II-V is caused by joint contractures.

Mucopolysaccharidosis III

Sanfilippo disease makes up a genetically heterogeneous but clinically similar group of 4 recognized types. Each type is caused by a different enzyme deficiency involved in the degradation of heparan sulfate (see Fig. 88-1). Mutations have been found in all the MPS-III disorders for which the genes have been isolated.

Phenotypic variation exists in MPS-III patients, but to a lesser degree than in other MPS disorders. Patients with Sanfilippo disease are characterized by slowly progressive, severe CNS involvement with mild somatic disease. Such disproportionate involvement of the CNS is unique to MPS-III. Onset of clinical features usually occurs between 2 and 6 yr in a child who previously appeared normal. Presenting features include delayed development, hyperactivity with aggressive behavior, coarse hair, hirsutism, sleep disorders, and mild hepatosplenomegaly. Delays in diagnosis of MPS-III are common because of the mild physical features, hyperactivity, and slowly progressive neurologic disease. Severe neurologic deterioration occurs in most patients by 6-10 yr, accompanied by rapid deterioration of social and adaptive

skills. Severe behavior problems such as sleep disturbance, uncontrolled hyperactivity, temper tantrums, destructive behavior, and physical aggression are common. Profound developmental regression and behavior problems often occur in patients with normal physical strength, making management particularly difficult.

Mucopolysaccharidosis IV

Morquio disease (MPS-IV) is caused by a deficiency of *N*-acetylgalactosamine-6-sulfatase (MPS-IVA) or of β-galactosidase (MPS-IVB). Both result in the defective degradation of keratan sulfate. The gene encoding *N*-acetylgalactosamine-6-sulfatase is on chromosome 16q24.3 and the gene encoding β-galactosidase, *GLB1*, on chromosome 3p21.33. β-Galactosidase catalyzes hydrolysis of GM_1 ganglioside in addition to endohydrolysis of keratan sulfate, and most mutations of *GLB1* result in generalized gangliosidosis, a spectrum of neurodegenerative disorders associated with dysostosis multiplex. A W273L mutation of the *GLB1* gene, either in the homozygous state or as part of compound heterozygosity, commonly results in Morquio B disease.

Both types of Morquio disease are characterized by short-trunk dwarfism, fine corneal deposits, a skeletal dysplasia that is distinct from other mucopolysaccharidoses, and preservation of intelligence. MPS-IVA is usually more severe than MPS-IVB with adult heights of less than 125 cm in the former and more than 150 cm in the latter. However, there is considerable variability of expression in both subtypes. The appearance of genua valga, kyphosis, growth retardation with short trunk and neck, and waddling gait with a tendency to fall are early symptoms of MPS-IV. Extraskeletal manifestations include mild corneal clouding, small teeth with abnormally thin enamel, frequent caries formation and occasionally hepatomegaly and cardiac valvular lesions. Instability of the odontoid process and ligamentous laxity is regularly present and can result in life-threatening atlantoaxial instability and dislocation. Surgery to stabilize the upper cervical spine, usually by posterior spinal fusion, before the development of cervical myelopathy can be lifesaving.

Mucopolysaccharidosis VI

Maroteaux-Lamy disease is caused by mutations of the *ARSB* gene on chromosome 5q11-13 encoding *N*-acetylgalactosamine-4-sulfatase (arylsulfatase B). It is characterized by severe to mild somatic involvement, as seen in MPS-I, but with preservation of intelligence. The somatic involvement of the severe form of MPS-IV is characterized by corneal clouding, coarse facial features, joint stiffness, valvular heart disease, communicating hydrocephalus, and dysostosis multiplex. In the severe form, growth can be normal for the first few years of life but seems to virtually stop after age 6-8 yr. The mild to intermediate forms of Maroteaux-Lamy disease can be easily confused with Scheie syndrome. Spinal cord compression from thickening of the dura in the upper cervical canal with resultant myelopathy is a frequent occurrence in patients with MPS-VI.

Mucopolysaccharidosis VII

Sly syndrome (MPS-VII) is caused by mutations of the *GUSB* gene located on chromosome 7q21.11. Mutations result in a deficiency of β-glucuronidase, intracellular storage of glycosaminoglycan fragments and a very wide range of clinical involvement. The most severe form presents as lethal nonimmune fetal hydrops and may be detected in utero by ultrasound. Some severely affected newborns survive for some months and have, or develop, signs of lysosomal storage including thick skin, visceromegaly, and dysostosis multiplex. Less-severe forms of MPS-VII present during the first years of life with features of MPS-I but slower progression. Corneal clouding varies. Patients with manifestation after 4 yr of life have skeletal abnormalities of dysostosis multiplex but normal intelligence and usually clear corneae. They may be found incidentally on the basis of a blood smear that shows coarse granulocytic inclusions.

Mucopolysaccharidosis IX

The disorder is caused by a mutation in the *HYAL1* gene on chromosome 3p21.2-21.2 encoding one of 3 hyaluronidases. Clinical findings in the only known patient, a 14-year old girl, were bilateral nodular soft-tissue periarticular masses, lysosomal storage of GAGs in histiocytes, mildly dysmorphic craniofacial features, short stature, normal joint movement and normal intelligence. Small erosions in both acetabula were the only radiographic findings.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Clinical suspicion of a MPS justifies a skeletal survey. Radiographs of chest, spine, pelvis and hands may show early signs of dysostosis multiplex. The next diagnostic step is to assay the urinary excretion of GAG. Semiquantitative spot tests are quick and inexpensive but subject to both false-positive and false-negative results. Quantitative analysis of single GAG by various methods, or of oligosaccharides by tandem mass spectrometry, is preferable and reveals type-specific profiles. Morquio disease is often missed in urinary assays but can reliably be diagnosed in serum using monoclonal antibodies to keratan sulfate.

Any individual who is suspected of an MPS disorder based on clinical features, radiographic results, or urinary GAG screening tests should have a definitive diagnosis established by enzyme assay. Serum, leukocytes, or cultured fibroblasts are used as the tissue source for measuring lysosomal enzymes (see Table 88-2).

Prenatal diagnosis is available for all MPSs and is carried out on cultured cells from amniotic fluid or chorionic villus biopsy. Measurement of GAGs in amniotic fluid is unreliable. Carrier testing in Hunter syndrome, an X-linked disorder, requires analysis of *IDS* gene once the specific mutation or chromosome arrangement in the family under consideration is known. Prenatal molecular analysis must be offered in a male fetus of a proven female carrier of the *IDS* gene. His risk to be affected is 50%. It is very small, but not zero, in a female fetus as a result of skewed maternal X-chromosome inactivation. Molecular analysis in patients with other enzymatically proven mucopolysaccharidoses or in known carriers is costly and usually not required. MPSs I, II, and VI are candidates for neonatal blood spot screening by tandem mass spectrometry allowing early diagnosis and enzyme replacement therapy.

Mucolipidoses and oligosaccharidoses manifest with the same clinical and radiographic features as mucopolysaccharidoses. In these conditions the urinary excretion of GAGs is not elevated. Hurler-like facial features, joint contractures, dysostosis multiplex and elevated urinary GAG excretion differentiate the mucopolysaccharidoses from congenital disorders of glycosylation and other neurodegenerative and dwarfing conditions.

TREATMENT

Hematopoietic stem cell transplantation and enzyme replacement therapy are performed in specialized institutions (Table 88-3). Experimental forms of therapy include substrate reduction by flavonoids, gene silencing, read-through attempts and transplantation of autologous hematopoietic stem cells that have been genetically modified ex vivo to express the missing protein. Symptomatic measures are listed in Table 88-4.

Bone marrow transplantation from related or unrelated donors and **cord blood transplantation** have resulted in significant clinical improvement of somatic disease in MPSs I, II, and VI. Clinical effects are increased life expectancy, resolution or improvement of growth, hepatosplenomegaly, joint stiffness, facial appearance, pebbly skin changes in MPS-II, obstructive sleep apnea, heart disease, communicating hydrocephalus, and hearing loss. Enzyme activity in serum and urinary GAG excretion normalize. Transplantation does not significantly improve the neuropsychologic outcome of MPS patients with impaired cognition at the time of transplantation. This is true for MPSs IH, II, and III. However, patients with MPS-I who have undergone transplantation before 24 mo of age and with a baseline mental development index greater than 70 have improved long-term outcome. Early transplantation in MPS-II may have the same effect. Transplantation in MPS-VI stabilizes or improves cardiac manifestations, posture and joint mobility. Stem cell transplantation does not correct skeletal and ocular anomalies and they have to be treated with appropriate orthopedic and ophthalmologic procedures. Cord blood

Table 88-3 Therapies Aimed at Proximate Causes of Mucopolysaccharidoses

MPS TYPE	STEM CELL TRANSPLANTATION (SCT)	ENZYME REPLACEMENT	REMARKS
I	Yes	Aldurazyme	Transplantation before age 2 yr. Enzyme replacement before and after transplantation
II	Questionable	Elaprase	Lack of neurologic improvement after stem cell transplantation
III	No	No	Experimental: Substrate reduction by flavanoids
IVA	No	Preclinical	Recombinant GALNS trial in course
VI	Yes	Naglazyme	Sustained improvement
VII	Questionable	?	Single SCT attempt without neurologic improvement

GALNS, galactosamine(*N*-acetyl)-6-sulfate sulfatase.

Table 88-4 Symptomatic Management of Mucopolysaccharidoses

PROBLEM	PREDOMINANTLY IN	MANAGEMENT
NEUROLOGIC		
Hydrocephalus	MPS-I, -II, -VI, -VII	Funduscopy, CT scan
Chronic headaches	All	Ventriculoperitoneal shunting
Behavioral disturbance	MPS-III	Behavioral medication, sometimes CT scan, ventriculoperitoneal shunting
Disturbed sleep/wake circle	MPS-III	Melatonin
Seizures	MPS-I, -II, -III	Electroencephalogram, anticonvulsants
Odontoid hypoplasia	MPS-IV	Cervical MRI, upper cervical fusion
Spinal cord compression	All	Laminectomy, dural excision
OPHTHALMOLOGIC		
Corneal opacity	MPS-I, -VI, -VII	Corneal transplant
Glaucoma	MPS-I, -VI, -VII	Medication, surgery
Retinal degeneration	MPS-I, -II	Night light
EARS, AIRWAYS		
Recurrent otitis media	MPS-I, -II, -VI, -VII	Ventilating tubes
Impaired hearing	All except MPS-IV	Audiometry, hearing aids
Obstruction	All except MPS-III	Adenotomy, tonsillectomy, bronchodilator therapy, continuous positive airway pressure at night, laser excision of tracheal lesions, tracheotomy
CARDIAC		
Cardiac valve disease	MPS-I, -II, -VI, -VII	Endocarditis prevention, valve replacement
Coronary insufficiency	MPS-I, -II, -VI, -VII	Medical therapy
Arrhythmias	MPS-I, -II, -VI, -VII	Antiarrhythmic medication, pacemaker
ORAL, GASTROINTESTINAL		
Hypertrophic gums, poor teeth	MPS-I, -II, -VI, -VII	Dental care
Chronic diarrhea	MPS-II	Diet modification, loperamide
MUSCULOSKELETAL		
Joint stiffness	All except MPS-IV	Physical therapy
Weakness	All	Physical therapy, wheelchair
Gross long bone malalignment	All	Corrective osteotomies
Carpal tunnel syndrome	MPS-I, -II, -VI, -VII	Electromyography, surgical decompression
ANESTHESIA	All except MPS-III	Avoid atlantoaxial dislocation, use angulated video intubation laryngoscope and small endotracheal tubes

transplantation is the therapy of choice in children with MPS-IH, and possibly MPS-II, before the age of 2 yr, but transplantation-related death or primary graft failure, which occur in approximately one-third of the patients, must be weighed against other therapeutic options.

Enzyme replacement using recombinant α-L-iduronidase has been approved for patients with MPS-I. It reduces organomegaly and ameliorates rate of growth, joint mobility, reduces the number of episodes of sleep apnea and urinary GAG excretion. The enzyme does not cross the blood–brain barrier and does not prevent deterioration of cognition and other neurologic functions. Consequently, this therapy is reserved for patients with mild CNS involvement. To stabilize extraneural manifestations, it is also recommended in young patients before stem cell transplantation. Recombinant iduronate-2-sulfatase ameliorates the nonneurologic manifestations of Hunter disease, and recombinant *N*-acetylgalactosamine-4-sulfatase has been successfully tested in patients with MPS-VI.

Primary prevention through genetic counseling and tertiary prevention to avoid or arrest complications remain the mainstay of pediatric care. Multidisciplinary attention to respiratory and cardiovascular complications, hearing loss, carpal tunnel syndrome, spinal cord compression, hydrocephalus and other problems can greatly improve the quality of life for patients and their families (see Table 88-4). The progressive nature of clinical involvement in MPS patients dictates the need for specialized and coordinated evaluation.

Chapter 89

Disorders of Purine and Pyrimidine Metabolism

James C. Harris

The inherited disorders of purine and pyrimidine metabolism cover a broad spectrum of illnesses with various presentations. These include hyperuricemia, acute renal failure, renal stones, gout, unexplained neurologic deficits (seizures, muscle weakness, choreoathetoid and dystonic movements), developmental disability, intellectual disability, compulsive self-injury and aggression, autistic-like behavior, unexplained anemia, failure to thrive, susceptibility to recurrent infection (immune deficiency), and deafness. When identified, all family members should be screened.

Purines and pyrimidines form the basis of nucleotides and nucleic acids (DNA and RNA) and so are involved in all biologic processes. Metabolically active nucleotides are formed from heterocyclic nitrogen-containing purine bases (guanine and adenine) and pyrimidine bases (cytosine, uridine, and thymine): all cells require a balanced supply of nucleotides for growth and survival. Purines provide the primary source of cellular energy through adenosine triphosphate (ATP) and the basic coenzymes (nicotinamide adenine dinucleotide and its reduced form) for metabolic regulation and play a major role in signal transduction (guanosine triphosphate [GTP], cyclic adenosine monophosphate, cyclic guanosine monophosphate). Figure 89-1 shows the early steps in the biosynthesis of the purine ring. Purines are primarily produced from endogenous sources, and in the usual circumstances dietary purines have a small role. The end product of purine metabolism in humans is uric acid (2,6,8-trioxypurine).

Uric acid is not a specific disease marker so the cause of its elevation must be determined. The serum level of uric acid present at any time depends on the size of the purine nucleotide pool which is derived from de novo purine synthesis, catabolism of tissue nucleic acids, and increased turnover of preformed purines. Uric acid is poorly soluble and must be excreted continuously to avoid toxic accumulation in the body. Its renal excretion involves the following components: (1) glomerular filtration, (2) reabsorption in the proximal convoluted tubule, (3) secretion near the terminus of the proximal tubule, and (4) limited reabsorption near these secretory sites. Thus, renal loss of uric acid is a result of renal tube excretion and is a function of serum uric acid concentration and non-specific transporters that remove uric acid. Because renal tubule excretion is greater in children than in adults, serum uric acid levels are a less reliable indicator of uric acid production in children than in adults, and, consequently, measurement of the level in urine may be required to determine excessive production. Clearance of a smaller portion of uric acid is via the gastrointestinal tract (biliary and intestinal secretion). Owing to poor solubility of uric acid under normal circumstances, uric acid is near the maximal tolerable limits, and small alterations in production or solubility or changes in secretion may lead to hyperuricemia and can result in precipitation in extremities such as fingers or toes, which defines clinical gout. In renal insufficiency, urate excretion is increased by residual nephrons and by the gastrointestinal tract. Increased production of uric acid is found in malignancy, Reye syndrome, Down syndrome, psoriasis, sickle cell anemia, cyanotic congenital heart disease, pancreatic enzyme replacement, glycogen storage disease types I, III, IV, and V, hereditary fructose intolerance, and acyl-coenzyme A dehydrogenase deficiency.

The metabolism of both purines and pyrimidines can be divided into biosynthetic, salvage and catabolic pathways. The first, the de novo pathway, involves a multistep biosynthesis of phosphorylated ring structures from precursors such as CO_2, glycine, and glutamine. Purine and pyrimidine nucleotides are produced from ribose-5-phosphate or carbamyl phosphate, respectively. The second, a single-step salvage pathway, recovers purine bases and pyrimidine nucleosides derived from either dietary intake or the catabolic pathway (Figs. 89-2 and 89-3). In the de novo pathway, the nucleosides guanosine, adenosine, cytidine, uridine, and thymidine are formed by the addition of ribose-1-phosphate to the purine bases guanine or adenine, and to the pyrimidine bases cytosine, uracil, and thymine respectively. The phosphorylation of these nucleosides produces monophosphate, diphosphate, and triphosphate nucleotides, as well as the deoxy-nucleotides that are utilized for DNA formation. Under usual circumstances, the salvage pathway predominates over the biosynthetic pathway, as nucleotide salvage saves energy for cells. Only a small fraction of the nucleotides turned over by the body each day are degraded and excreted. Synthesis of nucleotides is most active in tissues with high rates of cellular turnover, such as gut epithelium, skin, and bone marrow. The third pathway is catabolism. The end product of the catabolic pathway of the purines in humans is uric acid, whereas catabolism of pyrimidines produces citric acid cycle intermediates.

Inborn errors in the **synthesis** of **purine nucleotides** comprise the phosphoribosylpyrophosphate synthetase spectrum of disorders, including deficiency and superactivity, adenylosuccinate lyase deficiency, and 5-amino-4-imizolecarboxamide (AICA) riboside deficiency (AICA-ribosiduria). Disorders resulting from abnormalities in purine **catabolism** comprise muscle adenosine monophosphate (AMP) deaminase deficiency, adenosine deaminase deficiency, purine nucleoside phosphorylase deficiency, and xanthine oxidoreductase deficiency. Disorders resulting from the purine **salvage** pathway comprise hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency, and adenine phosphoribosyltransferase (APRT) deficiency.

The sole inborn error of **pyrimidine synthesis** is hereditary orotic aciduria (uridine monophosphate synthase deficiency). Disorders resulting from abnormalities in pyrimidine catabolism comprise dihydropyrimidine dehydrogenase (DPD) deficiency, dihydropyrimidinase (DPH) deficiency, and β-ureidopropionase deficiency, pyrimidine 5′-nucleotidase deficiency, and mitochondrial thymidine phosphorylase deficiency. A disorder resulting from the **pyrimidine salvage** is thymidine kinase 2 deficiency.

GOUT

Gout presents with hyperuricemia, uric acid nephrolithiasis, and acute inflammatory arthritis. Gouty arthritis is caused by monosodium urate crystal deposits that result in inflammation in joints and surrounding tissues. The presentation is most commonly monoarticular, typically in the metatarsophalangeal joint of the big toe. Tophi, deposits of monosodium urate crystals, may occur over points of insertion of tendons at the elbows, knees, and feet or over the helix of the ears. Primary gout ordinarily occurs in middle-aged men, results mainly from decreased renal excretion of uric acid, or purine overconsumption, or high intake of alcohol or fructose, or a combination of these factors. Gout occurs in any condition that leads to reduced clearance of uric acid: during therapy for malignancy or with dehydration, lactic acidosis, ketoacidosis, starvation, diuretic therapy, and renal failure. Excessive purine, alcohol, or fructose ingestion may increase uric acid levels. The biochemical etiology of gout is unknown for most of those affected, and it is considered to be a polygenic trait. Purine overproduction is a rare cause of primary gout, and is associated with several genetic disorders discussed below. Secondary gout is either the result of another disorder in which there is rapid tissue breakdown or cellular turnover leading to increased production or decreased excretion of uric acid, or the result of some types of drug treatment, for example diuretics cause plasma volume reduction and can precipitate a gouty attack.

Gout resulting from endogenous purine overproduction is associated with hereditary disorders of 3 different enzymes that result in

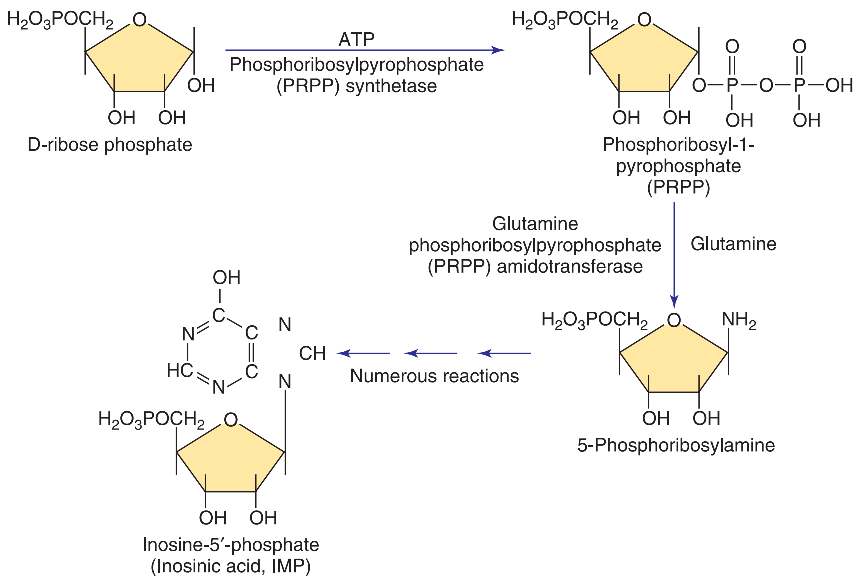

Figure 89-1 Early steps in the biosynthesis of the purine ring.

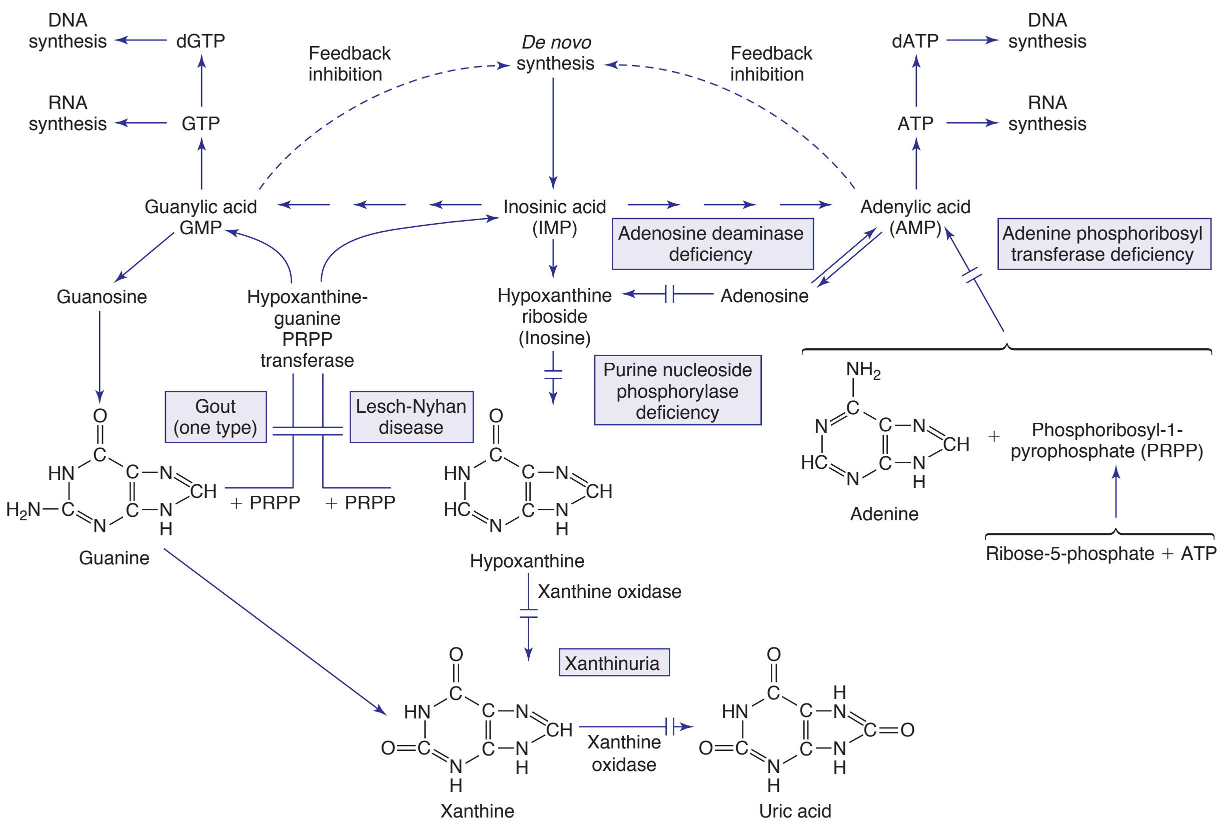

Figure 89-2 Pathways in purine metabolism and salvage.

hyperuricemia. These comprise the HPRT deficiency spectrum (ranging from severe deficiency or Lesch-Nyhan syndrome to partial HPRT deficiency), 2 forms of superactivity of PP-ribose-P synthetase, and glycogen storage disease type I (glucose-6-phosphatase deficiency; see Chapter 87.1). In the first two, the basis of hyperuricemia is purine nucleotide and uric acid overproduction, whereas in the third it is both excessive uric acid production and diminished renal excretion of urate. Glycogen storage disease types III, V, and VII are associated with exercise-induced hyperuricemia, the consequence of rapid ATP utilization and failure to regenerate it effectively during exercise (see Chapter 87.1).

Juvenile gout resulting from purine underexcretion is polygenic, consisting of the familial juvenile hyperuricemic nephropathy group of disorders. This includes medullary cystic kidney disease type 2, mapped to chromosome 16p11.2, which has been shown to result from uromodulin mutations; the term *uromodulin-associated kidney disease* has been proposed for them. Other genes classified as forms of familial juvenile hyperuricemic nephropathy include those for renin and hepatic nuclear factor-1β. Unlike the 3 inherited purine disorders that are X-linked and the recessively inherited glycogen storage disease, these are autosomal dominant conditions. Familial juvenile hyperuricemic nephropathy is associated with severe renal hypoexcretion of

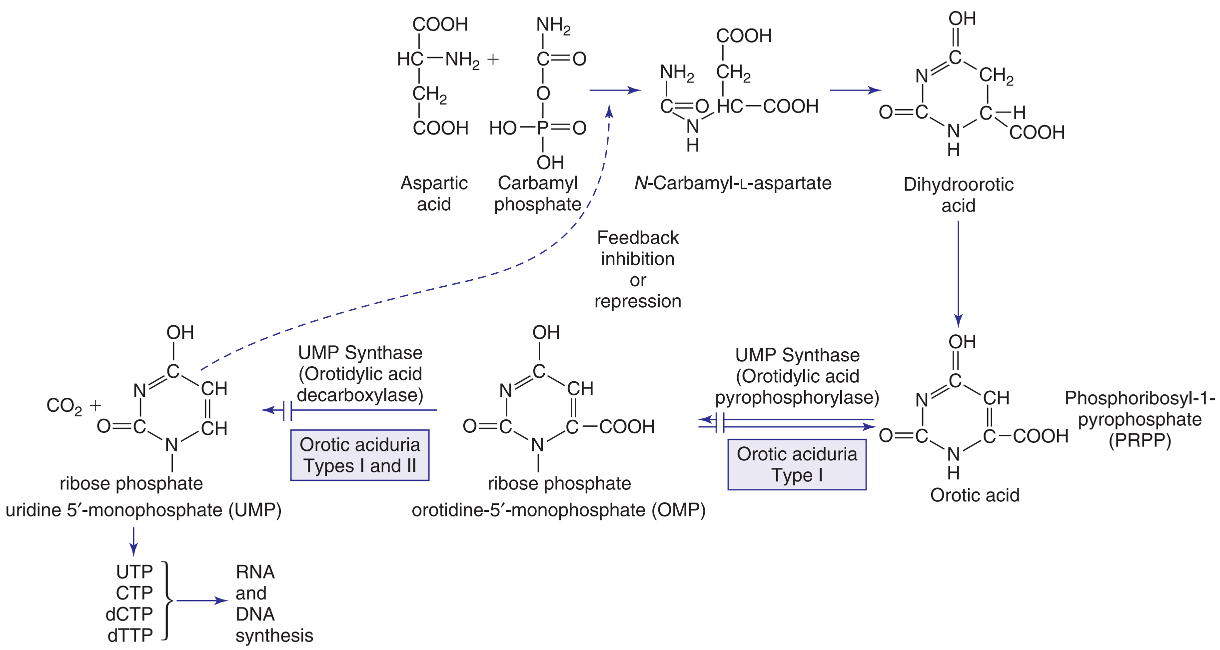

Figure 89-3 Pathways in pyrimidine biosynthesis.

uric acid. Although it most commonly presents from puberty up to the 3rd decade, it has been reported in infancy. It is characterized by early onset, hyperuricemia, gout, familial renal disease, and low urate clearance relative to glomerular filtration rate. It occurs in both males and females and is frequently associated with a rapid decline in renal function that may lead to death unless diagnosed and treated early. Once familial juvenile hyperuricemic nephropathy is recognized, presymptomatic detection is of critical importance to identify asymptomatic family members with hyperuricemia and to begin treatment, when indicated, to prevent nephropathy.

Genetics

Familial juvenile hyperuricemic nephropathy-2 (HNFJ2; 613092) is caused by mutation in the renin gene (*REN*; 179820) on chromosome 1q32. HNFJ3 (614227) has been mapped to chromosome 2p22.1-p21.

Treatment

Treatment of hyperuricemia involves the combination of allopurinol or febuxostat (xanthine oxidase inhibitors) to decrease uric acid production, probenecid to increase uric acid clearance in those with normal renal function, and increased fluid intake to reduce the concentration of uric acid. A low purine diet, weight reduction, and reduced alcohol and reduced fructose intake (as fructose both reduces urate clearance and accelerates ATP breakdown to uric acid) are recommended.

ABNORMALITIES IN PURINE SALVAGE

HPRT Deficiency

Lesch-Nyhan disease (LND) is a rare X-linked disorder of purine metabolism that results from HPRT deficiency. This enzyme is normally present in each cell in the body, but its highest concentration is in the brain, especially in the basal ganglia. Clinical manifestations include hyperuricemia, intellectual disability, dystonic movement disorder that may be accompanied by choreoathetosis and spasticity, dysarthric speech, and compulsive self-biting, usually beginning with the eruption of teeth.

There is a severity spectrum for the clinical presentations of HPRT deficiency. HPRT levels are related to the extent of motor symptoms, to the presence or absence of self-injury, and possibly to the level of cognitive function. Purine overproduction is present. The majority of individuals with classic LND have low or undetectable levels of the HPRT enzyme. Partial deficiency in HPRT **(Kelley-Seegmiller syndrome)** with more than 1.5-2.0% enzyme is associated with purine overproduction and variable neurologic dysfunction (neurologic HPRT deficiency). HPRT deficiency with activity levels >8% of normal still exhibit purine (and uric acid) overproduction but apparently normal cerebral functioning (HPRT-related hyperuricemia) although cognitive deficits may occur. Qualitatively similar cognitive deficit profiles have been reported in both LND and variant cases. Variants produced scores that are intermediate between those of patients with LND and normal controls on nearly every neuropsychological measure tested.

Genetics

The HPRT gene has been localized to the long arm of the X chromosome (q26-q27). The complete amino acid sequence for HPRT is known (approximately 44 kb; 9 exons). The disorder appears in males; occurrence in females is extremely rare and ascribed to nonrandom inactivation of the normal X chromosome. Absence of HPRT activity prevents the normal metabolism of hypoxanthine resulting in excessive uric acid production and manifestations of gout, necessitating specific drug treatment (allopurinol). Because of the enzyme deficiency, hypoxanthine accumulates in the cerebrospinal fluid, but uric acid does not; uric acid is not produced in the brain and does not cross the blood–brain barrier. The behavior disorder is not caused by hyperuricemia or excess hypoxanthine because patients with partial HPRT deficiency, the variants with hyperuricemia, do not self-injure and infants having isolated hyperuricemia from birth do not develop self-injurious behavior.

The prevalence of the classic LND has been estimated at 1 in 100,000 to 1 in 380,000 persons based on the number of known cases in the United States. The incidence of partial variants is not known. Those with the classic syndrome rarely survive the 3rd decade because of renal or respiratory compromise. The life span may be normal for patients with partial HPRT deficiency without severe renal involvement.

Pathology

No specific brain abnormality is documented after detailed histopathology and electron microscopy of affected brain regions. Magnetic resonance imaging has documented reductions in the volume of basal ganglia nuclei. Abnormalities in neurotransmitter metabolism have been identified in 3 autopsied cases. All 3 patients had very low HPRT levels (less than 1% in striatal tissue and 1-2% of control in thalamus cortex). There was a functional loss of 65-90% of the nigrostriatal and

mesolimbic dopamine terminals, although the cells of origin in the substantia nigra did not show dopamine reduction. The brain regions primarily involved were the caudate nucleus, putamen, and nucleus accumbens. It is proposed that the neurochemical changes may be linked to functional abnormalities, possibly resulting from a diminution of arborization or branching of dendrites rather than cell loss. A neurotransmitter abnormality is demonstrated by changes in cerebrospinal fluid neurotransmitters and their metabolites, and confirmed by positron emission tomography scans of dopamine function. Reductions in vivo in the presynaptic dopamine transporter have been documented in the caudate and putamen of 6 individuals.

The mechanism whereby HPRT leads to the neurologic and behavioral symptoms is unknown. However, both hypoxanthine and guanine metabolism are affected and GTP and adenosine have substantial effects on neural tissues. The functional link between purine nucleotides and the dopamine system is through salvage of guanine by HPRT to form GTP: this is essential for GTP cyclohydrolase activity, the first step in the synthesis of pterins and dopamine. Patients with inherited GTP cyclohydrolase deficiency show clinical features in common with LND. Dopamine reduction in brain is documented in HPRT-deficient strains of mutant mice. Dopamine binding to its receptor results in either an activation (D1 receptor) or an inhibition (D2 receptor) of adenylcyclase. Both receptor effects are mediated by G proteins (GTP-binding proteins) dependent on guanine diphosphate in the guanine diphosphate/GTP exchange for cellular activation. Dopamine and adenosine systems are also linked through the role of adenosine as a neuroprotective agent in preventing neurotoxicity. Adenosine derives from AMP which depends on hypoxanthine salvage in the brain by HPRT. Adenosine agonists mimic the biochemical and behavioral actions of dopamine antagonists, whereas adenosine receptor antagonists act as functional dopamine agonists. LND can thus be seen as arising ultimately from nucleotide depletion specifically in the brain, which relies upon the HPRT salvage pathway, leading to dopamine and adenosine depletions.

Clinical Manifestations

At birth, infants with LND have no apparent neurologic dysfunction. After several months, developmental delay, intellectual disability and neurologic signs become apparent. Before the age of 4 mo, hypotonia, recurrent vomiting, and difficulty with secretions may be noted. By approximately 8-12 mo, extrapyramidal signs appear, primarily dystonic movements. In some cases, spasticity may become apparent at this time; in some instances, it becomes apparent later in life.

Cognitive function is usually reported to be in the mild-to-moderate range of intellectual disability, although some individuals test in the low normal range. Because test scores may be influenced by difficulty in testing the subjects owing to their movement disorder and dysarthric speech, overall intelligence may be underestimated.

The age of onset of self-injury may be as early as 1 yr and occasionally as late as the teens. Self-injury occurs, although all sensory modalities, including pain, are intact. The self-injurious behavior usually begins with self-biting, although other patterns of self-injurious behavior emerge with time. Most characteristically, the fingers, mouth, and buccal mucosa are mutilated. Self-biting is intense and causes tissue damage and may result in the amputation of fingers and substantial loss of tissue around the lips. Extraction of primary teeth may be required. The biting pattern can be asymmetric, with preferential mutilation of the left or right side of the body. The type of behavior is different from that seen in other intellectual disability syndromes involving self-injury. Self-hitting and head-banging are the most common initial presentations in other syndromes. The intensity of the self-injurious behavior generally requires that the patient be restrained. When restraints are removed, the patient with LND may appear terrified, and stereotypically place a finger in the mouth. The patient may ask for restraints to prevent elbow movement; when the restraints are placed or replaced, he may appear relaxed and more good humored. Dysarthric speech may cause interpersonal communication problems; however, the higher-functioning children can express themselves fully and participate in verbal therapy.

The self-mutilation presents as a compulsive behavior that the child tries to control but frequently is unable to resist. Older individuals may enlist the help of others and notify them when they are comfortable enough to have restraints removed. In some instances, the behavior may lead to deliberate self-harm. The LND individual may also show compulsive aggression and inflict injury to others through pinching, grabbing, or hitting or by using verbal forms of aggression. Afterward he may apologize, stating that this behavior was out of his control. Other maladaptive behaviors include head- or limb-banging, eye-poking, and psychogenic vomiting.

Diagnosis

The presence of dystonia along with self-mutilation of the mouth and fingers suggests LND. With partial HPRT deficiency, recognition is linked to either hyperuricemia alone or hyperuricemia and a dystonic movement disorder. Serum levels of uric acid that exceed 4-5 mg uric acid/dL and a urine uric acid : creatinine ratio of ≥3-4 : 1 are highly suggestive of HPRT deficiency, particularly when associated with neurologic symptoms. The definitive diagnosis requires an analysis of the HPRT enzyme. This is assayed in an erythrocyte lysate. Individuals with classic LND have near 0% enzyme activity and those with partial variants show values between 1.5% and 60%. The intact cell HPRT assay in skin fibroblasts offers a good correlation between enzyme activity and the severity of the disease. Molecular techniques are used for gene sequencing and the identification of carriers.

Differential diagnosis includes other causes of infantile hypotonia and dystonia. Children with LND are often initially incorrectly diagnosed as having athetoid cerebral palsy. When a diagnosis of cerebral palsy is suspected in an infant with a normal prenatal, perinatal, and postnatal course, then LND should be considered. Partial HPRT deficiency may be associated with acute renal failure in infancy; therefore, clinical awareness of partial HPRT deficiency is of particular importance. The simplest test to exclude LND or partial deficiency is the urinary uric acid : creatinine ratio.

An understanding of the molecular disorder has led to effective drug treatment for uric acid accumulation and arthritic tophi, renal stones, and neuropathy. However, reduction in uric acid alone does not influence the neurologic and behavioral aspects of LND. Despite treatment from birth for uric acid elevation, behavioral and neurologic symptoms are unaffected. The most significant complications of LND are renal failure and self-mutilation.

Treatment

Medical management of this disorder focuses on the prevention of renal failure by pharmacologic treatment of hyperuricemia with high fluid intake along with alkalinization and allopurinol (or more febuxostat). A low purine diet and reduced fructose intake are desirable.

Allopurinol treatment must be monitored because urinary oxypurine excretion with all overproduction disorders is sensitive to allopurinol, resulting in an increased urine concentration of xanthine, which is extremely insoluble. Self-mutilation is reduced through behavior management, and the use of restraints or removal of teeth or both. Pharmacologic approaches to decrease anxiety and spasticity with medication have mixed results. Drug therapy focuses on symptomatic management of anticipatory anxiety, mood stabilization and reduction of self-injurious behavior. Although there is no standard drug treatment, diazepam may be helpful for anxiety symptoms, Risperdal for aggressive behavior and carbamazepine or gabapentin for mood stabilization. Each of these medications may reduce self-injurious behavior by helping to reduce anxiety and stabilize mood. *S*-adenosylmethionine (SAMe), which is thought to act by countering nucleotide depletion in the brain, has been reported to specifically reduce the rate of self-injury in some cases.

Bone marrow transplantation, based on the hypothesis that the central nervous system damage is produced by a circulating toxin, has been carried out in several patients. Several infant patients have died of complications of bone marrow transplantation. To date, there is no evidence that bone marrow transplantation is a beneficial treatment

approach; it remains an experimental and potentially dangerous therapy. Two patients received partial exchange transfusions every 2 mo for 3-4 yr. Erythrocyte HPRT activity was 10-70% of normal during this period, but no reduction of neurologic or behavioral symptoms was apparent. Successful preimplantation genetic diagnosis and in vitro fertilization for LND has been reported with the birth of an unaffected male infant.

Both the motivation for self-injury and its biologic basis must be addressed in treatment programs. Yet behavioral techniques alone, using operant conditioning approaches, have not proved to be an adequate general treatment. Although behavioral procedures have had some selective success in reducing self-injury, generalization outside the experimental setting limits this approach and patients under stress may revert to their previous self-injurious behavior. Behavioral approaches may also focus on reducing the self-injurious behavior through the treatment of phobic anxiety associated with being unrestrained. The most common techniques are systematic desensitization, extinction, and differential reinforcement of other (competing) behavior. Stress management has been recommended to assist patients to develop more effective coping mechanisms. Individuals with LND do not respond to contingent electric shock or similar aversive behavioral measures. An increase in self-injury may be observed when aversive methods are utilized.

Restraint (day and night) and dental procedures are common means to prevent self-injury. The time in restraints is linked to the age of onset of self-injury. Children with LND can participate in making decisions regarding restraints and the type of restraints. The time in restraints may potentially be reduced with systematic behavior treatment programs. Many patients have teeth extracted to prevent self-injury. Others use a protective mouth guard designed by a dentist. Most parents suggest that stress reduction and awareness of the patient's needs are the most effective in reducing self-injury. Positive behavioral techniques of reinforcing appropriate behavior are rated effective by almost half of the families.

Deep brain stimulation to the anteroventral internal globus pallidus is a procedure that has successfully treated self-injury and lessened dystonia in several case reports.

Adenine Phosphoribosyltransferase Deficiency (Dihydroxyadeninuria)

Adenine phosphoribosyltransferase (APRT), a purine salvage enzyme, catalyzes the synthesis of AMP from adenine and 5-phosphoribosyl-1-pyrophosphate (PP-ribose-P). The absence of this enzyme results in the cellular accumulation of adenine and its being oxidized as an alternative substrate by xanthine dehydrogenase to form 2,8-dihydroxyadenine, which is extremely insoluble. APRT deficiency is present from birth, becoming apparent as early as 5 mo and as late as the 7th decade.

Genetics

The disorder is an autosomal recessive trait with considerable clinical heterogeneity. The APRT gene is located on chromosome 16q (16q24.3) and encompasses 2.8 kb of genomic DNA.

Clinical Manifestations

Clinical manifestations include urinary calculus formation with crystalluria, urinary tract infections, hematuria, renal colic, dysuria and acute renal failure. The presence of brownish spots on the infant's diaper or of yellow-brown crystals in the urine is suggestive of the diagnosis. The 2,8-dihydroxyadenine is cleared efficiently by the kidneys and so does not accumulate in plasma, but precipitates readily in the renal lumen.

Laboratory

Urinary levels of adenine, 8-hydroxyadenine, and 2,8-dihydroxyadenine are elevated while plasma uric acid is normal. The deficiency may be complete (type I) or partial (type II); the partial deficiency is reported in Japan. The diagnosis is made based on the level of residual enzyme in erythrocyte lysates. The renal calculi, composed of 2,8-dihydroxyadenine, are radiolucent, soft, and easily crushed. These stones are not distinguishable from uric acid stones by routine tests but require high-performance liquid chromatography, UV, infrared, mass spectrometry, x-ray crystallography, or capillary electrophoresis for diagnosis, particularly to distinguish from stones in HPRT deficiency.

Treatment

Treatment includes high fluid intake, dietary purine restriction, and allopurinol, which inhibits the conversion of adenine to its metabolites, further 2,8-dihydroxyadenine excretion, and further stone formation. Alkalinization of the urine is to be avoided, because, unlike that of uric acid, the solubility of 2,8-dihydroxyadenine does not increase up to pH 9. Shockwave lithotripsy has been reported to be successful. The prognosis depends on renal function at the time of diagnosis. Early treatment is critical in the prevention of stones because severe renal insufficiency may accompany late recognition.

DISORDERS LINKED TO PURINE NUCLEOTIDE SYNTHESIS

Phosphoribosylpyrophosphate Synthetase Superactivity and Deficiency

Phosphoribosylpyrophosphate (PRPP) is a substrate involved in the synthesis of essentially all nucleotides and important in the regulation of the de novo pathways of purine and pyrimidine nucleotide synthesis. The synthetase enzyme (PRPS) produces PRPP from ribose-5-phosphate and ATP, as shown in Figures 89-1 and 89-2. PRPP is the first intermediary compound in the de novo synthesis of purine nucleotides that lead to the formation of inosine monophosphate, then to ATP and GTP.

Genetic disorders of this enzyme affect only the PRPS-1 isoform; PRPS-2 mutations have not been described. PRPS-1 disorders are all X-linked and are divided into "superactivity," which occurs as 2 phenotypes (infantile or early-childhood onset, and a milder form with late-juvenile or early-adult onset), and "deficiency," which is a spectrum disorder that is distinguished clinically according to severity as 3 disorders: Arts syndrome, Charcot-Marie-Tooth disease X-linked-5, and X-linked deafness-2 (DFN2).

Superactivity of the enzyme results in an increased generation of PRPP in dividing cells. Because PRPP aminotransferase, the first enzyme of the purine de novo pathway, is not physiologically saturated by PRPP, the synthesis of purine nucleotides increases, and, consequently, the production of uric acid is increased. PRPP synthetase superactivity is one of the few hereditary disorders in which there is enhancement of the activity of an enzyme. The infantile or early-childhood form of PRPS-1 superactivity has severe neurologic attributes accompanied by uric acid overproduction, whereas individuals with the late-juvenile or early-adult presentation are neurologically normal but still have uric acid overproduction.

Deficiency of PRPS-1 produces depleted purine nucleotide synthesis in tissues dependent upon PRPS-1, which includes brain as well as other neural tissues and lung.

Genetics

Three distinct complementary DNAs for PRPS have been cloned and sequenced. Two forms, PRPS-1 and PRPS-2, are X-linked to Xq22-q24 and Xp22.2-p.22.3 (escapes X inactivation), respectively, and are widely expressed; the third locus maps to human chromosome 7 and appears to be transcribed only in the testes. PRPS-1 defects are thus inherited as X-linked traits and present with varying degrees of severity. The late-onset form of superactivity arises from increased transcription of normal messenger RNA; the cause of this has not been discovered. The early-onset form of superactivity arises from mutations affecting allosteric regulation of the protein that controls feedback inhibition by inorganic phosphate and dinucleotides. At the same time, these mutations destabilize the protein, so that in slow or nonreplicating cells, such as neurons and red blood cells, the enzyme becomes inactive. In contrast, the deficiency phenotypes of PRPS-1 are produced by mutations directly affecting enzyme function, usually in the substrate

binding site. Even though the defect is X-linked it should be considered in a child or young adult of either sex with hyperuricemia and/or hyperuricosuria and normal HPRT activity in lysed red cells.

Clinical Manifestations

Clinical manifestations in affected hemizygous males with the early-onset form of superactivity include signs of uric acid overproduction that are apparent in infancy or early childhood and neurodevelopmental retardation and sensorineural deafness. Hypotonia, delays in motor milestones, ataxia, and autistic-like behavior have been described. Heterozygous female carriers may also develop gout and hearing impairment. The late-onset type is found in males who show only hyperuricemia and hyperuricosuria, but no neurologic signs. The mildest form of PRPS-1 deficiency manifests as progressive post-lingual hearing loss in X-linked deafness-2. More severe mutations constitute the Charcot-Marie-Tooth disease X-linked-5 phenotype, which includes peripheral neuronopathy, hearing impairment, and optic atrophy. The most severe PRPS-1 mutations occur in patients with Arts syndrome who also have central neuropathy and an impaired immune system. Females appear to be unaffected, but hemizygous males have usually not survived beyond the 1st decade, typically succumbing to lung disease. Therapy with *S*-adenosylmethionine has prolonged survival, although the neurologic deficits, including the deafness, do not appear to be responsive.

A mechanism for the neurologic symptoms is unknown but it can be hypothesized that nucleotide depletion is present in neural tissues including the brain. Abnormalities of hearing and vision are typical of PRPS-1 deficiency, where the absence of this enzyme presumably compromises these highly energy-dependent neural functions. The high transcript level of PRPS-1 in lung and bone marrow also suggests that its absence may be causal for the recurrent lung infections that characterize Arts syndrome.

Laboratory

For PRPS-1 "superactivity" (both juvenile and adult presentations), serum uric acid may be grossly raised and the urinary excretion of uric acid increased. For PRPS "deficiency," uric acid is normal, not low, probably because PRPS-2 provides the major uric acid forming activity in liver and other major organs. Diagnosis requires that PRPS-1 activity be measured in erythrocytes and cultured fibroblasts. The adult superactivity disorder must be differentiated from partial HPRT deficiency involving the salvage pathway, which also presents with mild or absent neurologic traits accompanied by hyperuricemia.

Treatment

Treatment of PRPS deficiency, specifically Arts syndrome, has involved mainly experimental therapy with *S*-adenosylmethionine, as a dietary supplement to correct the depletion of purines. Dietary purines are usually not absorbed into the body but are degraded to uric acid by the gut. *S*-adenosylmethionine supplementation (beginning at 20 mg/kg/day orally) has been effective in greatly reducing the acute hospitalization episodes of 2 brothers with Arts syndrome, over a period of 10 yr. Treatment of PRPS superactivity is aimed at controlling the hyperuricemia with allopurinol, which inhibits xanthine oxidase, the last enzyme of the purine catabolic pathway. Uric acid production is reduced and is replaced by hypoxanthine, which is more soluble, and xanthine. The initial dose of allopurinol is 10-20 mg/kg/24 hr in children and is adjusted to maintain normal uric acid levels in plasma. The risk of xanthine stone formation is similar to that described for LND. A low purine diet (one free of organ meats, dried beans, and sardines), high fluid intake, and alkalinization of the urine to establish a urinary pH of 6.0-6.5 is necessary. These measures control the hyperuricemia and urate nephropathy but do not affect the neurologic symptoms. There is no known treatment for the neurologic complications.

Adenylosuccinate Lyase Deficiency (Succinylpurinuria)

Adenylosuccinase lyase deficiency is an inherited deficiency of de novo purine synthesis in humans. adenylosuccinase lyase is an enzyme that catalyzes 2 pathways in de novo synthesis and purine nucleotide recycling. These are the conversion of succinylaminoimidazole carboxamide ribotide into aminoimidazole carboxamide ribotide (AICAR) in the de novo synthesis of purine nucleotides and the conversion of adenylosuccinate (S-AMP) into AMP, the second step in the conversion of inosine monophosphate (IMP) into AMP, in the purine nucleotide cycle. Adenylosuccinase lyase deficiency results in the accumulation in urine, cerebrospinal fluid, and to a smaller extent, in plasma, of succinylaminoimidazole carboxamide riboside and succinyladenosine (S-Ado), the dephosphorylated derivatives of succinylaminoimidazole carboxamide ribotide and S-AMP, respectively.

Genetics

This is an autosomal recessive disorder; the gene has been mapped to chromosome 22q13.1-q13.2 and approximately 20 gene mutations have been identified. Laboratory investigations show grossly raised succinylpurines in urine and cerebrospinal fluid, which are normally undetectable.

Clinical Manifestations

Clinical manifestations include varying degrees of psychomotor retardation, generally accompanied by a seizure disorder and/or autistic-like behaviors (poor eye contact and repetitive behaviors). Neonatal seizures and a severe infantile epileptic encephalopathy are often the first manifestations of this disorder. Others demonstrate moderate to severe intellectual disability sometimes associated with growth retardation and muscle hypotonia. One reported case, a girl, tested in the mild range of intellectual disability. The form with profound intellectual disability has been designated type I; the variant case with mild intellectual disability as type II. Other patients have an intermediate clinical symptom pattern with moderately delayed psychomotor development, seizures, stereotypies, and agitation.

Pathology

CT and MRI of the brain may show hypotrophy or hypoplasia of the cerebellum, particularly the vermis. It is proposed that rather than being caused by purine nucleotide depletion, the symptoms are from the neurotoxic effects of accumulating succinylpurines. The ratio of S-Ado : succinylaminoimidazole carboxamide riboside has been linked to phenotype severity, suggesting that succinylaminoimidazole carboxamide riboside is the more toxic compound and that S-Ado might be neuroprotective.

The laboratory diagnosis is based on the presence in urine and cerebrospinal fluid of succinylaminoimidazole carboxamide riboside and S-Ado, both normally undetectable.

Treatment

No successful treatment has been demonstrated for this disorder. *S*-adenosylmethionine supplementation therapy was tested for 6 mo for a baby diagnosed in the early postnatal period, but no amelioration of symptoms were noted, providing further evidence that the disorder arises from nucleotide toxicity rather than depletion. Prenatal diagnosis has been reported. Systematic screening is suggested in infants and children with unexplained psychomotor retardation, and/or seizures disorder.

Aminoimidazole Carboxamide Ribotide Transformylase/Inosine Monophosphate Cyclohydrolase Deficiency

AICA riboside is the dephosphorylated product of AICAR, also termed ZMP. Along with its di- and triphosphates, ZMP accumulates in red blood cells and fibrocytes in inherited deficiency of the bifunctional enzyme AICAR transformylase/IMP cyclohydrolase (ATIC), which catalyzes the conversion of AICAR to formyl-AICAR.

Genetics

This is an inborn error of purine biosynthesis caused by a mutation of the *ATIC* gene effecting AICAR transformylase activity. In a single

reported case AICAR transformylase was profoundly deficient, whereas the IMP cyclohydrolase level was 40% of normal.

Clinical Features

The disorder is described in a female infant with profound intellectual disability, epilepsy, dysmorphic features (prominent forehead and metopic suture, brachycephaly, wide mouth with thin upper lip, low-set ears, and prominent clitoris because of fused labia minora), and congenital blindness.

Laboratory

Urinary screening with the Bratton-Marshall test to detect AICA resulted in the identification of this disorder. The transformylase was found to be deficient in fibroblasts in this disorder, confirming diagnosis.

Treatment

No successful treatment is described.

DISORDERS RESULTING FROM ABNORMALITIES IN PURINE CATABOLISM

Myoadenylate Deaminase Deficiency (Muscle Adenosine Monophosphate Deaminase Deficiency)

Myoadenylate deaminase is a muscle-specific isoenzyme of AMP deaminase that is active in skeletal muscle. During exercise, the deamination of AMP leads to increased levels of IMP and ammonia in proportion to the work performed by the muscle. Two forms of myoadenylate deaminase deficiency are known: an inherited (primary) form that may be asymptomatic or associated with cramps or myalgia with exercise, and a secondary form that may be associated with other neuromuscular or rheumatologic disorders.

Clinical Manifestations

Clinical manifestations are most commonly isolated muscle weakness, fatigue, myalgias following moderate-to-vigorous exercise, or cramps. Myalgia may be associated with an increased serum creatine kinase level and detectable electromyelographic abnormalities. Muscle wasting or histologic changes on biopsy are absent. The age of onset may be as early 8 mo of life with approximately 25% of cases recognized between 2 and 12 yr of age. The enzyme defect has been identified in asymptomatic family members. Secondary forms of muscle AMP deaminase deficiency have been identified in Werdnig-Hoffmann disease, Kugelberg-Welander syndrome, polyneuropathies, and amyotrophic lateral sclerosis (see Chapter 612.2). The metabolic disorder involves the purine nucleotide cycle. As shown in Figure 89-2, the enzymes involved in this cycle are AMP deaminase, S-AMP synthetase, and S-AMP lyase. It is proposed that muscle dysfunction in AMP deaminase deficiency results from impaired energy production during muscle contraction. It is unclear how individuals may carry the deficit and be asymptomatic. In addition to muscle dysfunction, a mutation of liver AMP deaminase has been proposed as a cause of primary gout, leading to overproduction of uric acid.

Genetics

The inherited form of the disorder is an autosomal recessive trait. *AMP-D1,* the gene responsible for encoding muscle AMP deaminase, is located on the short arm of chromosome 1 (1p13-21). Population studies reveal that a mutant allele is found at high frequency in white populations, but alternative splicing of the gene can result in removal of the mutation and normal enzyme function. As a result, the disorder is usually screened by performing the forearm ischemic exercise test. The elevation of venous plasma ammonia following exercise that is seen in normal subjects is absent in AMP deaminase deficiency.

Laboratory

The final diagnosis is made by histochemical or biochemical assays of a muscle biopsy. The primary form is distinguished by the finding of enzyme levels below 2% with little or no immunoprecipitable enzyme. Affected individuals are advised to exercise with caution to prevent rhabdomyolysis and myoglobinuria.

Treatment

Although there are no documented fully effective treatments, it has been proposed that enhancing the rate of replenishment of the ATP pool might be beneficial. Using this rationale treatment with ribose (2-60 g/24 hr orally, in divided doses) or xylitol, that is converted to ribose, has been reported to improve endurance and muscle strength in some cases but is ineffective in others. Genetic approaches may be feasible in the future for inherited cases while treatment of the underlying condition is essential in secondary cases.

Adenosine Deaminase Deficiency

See Chapter 126.1.

Purine Nucleoside Phosphorylase Deficiency

See Chapter 126.2.

Xanthine Oxidoreductase Deficiency (Hereditary Xanthinuria/Molybdenum Cofactor Deficiency)

Xanthine oxidoreductase (XOR) is the catalytic enzyme in the final step of the purine catabolic pathway and oxidizes hypoxanthine to xanthine and xanthine to uric acid. Because XOR exists in 2 forms, xanthine dehydrogenase and xanthine oxidase, the deficiency is also referred to as xanthine dehydrogenase/xanthine oxidase deficiency. Xanthine, the immediate precursor of uric acid, is less soluble than uric acid in urine and deficiency of the enzyme results in xanthinuria. XOR deficiency may occur in isolated form (xanthinuria type 1), in a combined form involving XOR and aldehyde oxidase deficiencies (xanthinuria type II), or multiple deficiencies of XOR, aldehyde oxidase, and sulfite oxidase (molybdenum cofactor deficiency). All 3 forms result in an almost total replacement of uric acid by hypoxanthine and xanthine in urine, while plasma uric acid is very low or undetectable.

Patients with the isolated form can be asymptomatic or have mild symptoms; renal stones, often not visible on radiography, are a risk for renal damage and may appear at any age, when patients may present with loin pain or renal insufficiency. For type II xanthinuria the clinical presentation is similar to type I, but patients also have aldehyde oxidase deficiency, which has no known clinical attributes. Molybdenum cofactor deficiency arises from inherited deficiency of molybdenum cofactor synthase, which affects all 3 molybdoenzymes, and like isolated sulfite oxidase deficiency, it usually presents with neonatal feeding problems, neonatal seizures, increased or decreased muscle tone, ocular lens dislocation, severe intellectual disability, and death in early childhood. Milder cases have presented with lens dislocation only.

Genetics

The inheritance of all 3 types of xanthinuria is complex and autosomal recessive. Type I results from mutations in the human *XDH* gene located on chromosome 2p22. Type II xanthinuria arises from mutations in the molybdenum cofactor synthase gene located on chromosome 18q12.2; this encodes molybdenum cofactor sulfurase, which is essential for the activity of both XOR and aldehyde oxidase. Type III xanthinuria (XOR, aldehyde oxidase and sulfite oxidase deficiencies) can arise from functional mutations in any of 3 genes: *MOCS1* (encoding 2 enzymes for synthesis of the precursor via a bicistronic transcript), *MOCS2* (encoding molybdopterin synthase), or *GPHN* (encoding gephyrin), located at 6p21.2, 5q11.2, and 14q23.3, respectively.

Laboratory

Diagnosis is made initially by measuring plasma and/or urinary concentrations of uric acid. Plasma uric acid is very low or absent (<1 mg/dL). Urinary uric acid is reduced, being replaced by xanthine and hypoxanthine. Type II patients can be distinguished by the absence in urine of methyl-2-pyridone-carboxamide, the product of nicotinamide (niacin) breakdown by aldehyde oxidase. Alternately, type II patients

can be distinguished from type I by their inability to oxidize a test dose of allopurinol to oxypurinol, via aldehyde oxidase. Molybdenum cofactor deficiency is distinguished by an additional excessive urinary excretion of sulfite and other sulfur-containing metabolites such as sulfocysteine.

Enzyme assay of XOR is not usually offered because it requires jejunal or liver biopsy, as these are the only human tissues that contain appreciable amounts of the enzyme. Sulfite oxidase and the molybdenum cofactor synthase can be measured in liver and fibroblasts. Molecular genetic analysis can be used to confirm diagnosis by searching for functional mutations among the three groups of genes.

Treatment

Although isolated deficiency is generally benign, treatment with a diet of low purines and low fructose (which reduces ATP breakdown to xanthine) with increased fluid intake is recommended. Allopurinol is not recommended. The prognosis for molybdenum cofactor deficiency has previously been very poor, but trials of cyclic pyranopterin monophosphate are promising.

DISORDERS OF PYRIMIDINE METABOLISM

The pyrimidines are the building blocks of DNA and RNA and involved in the formation of active intermediates in carbohydrate and phospholipid metabolism (e.g., uridine diphosphate glucose, cytidine diphosphate choline), glucuronidation in detoxification processes (uridine diphosphate), and glycosylation of proteins and lipids.

The essential precursor for pyrimidine biosynthesis is carbamylphosphate, which is shared with the urea cycle. Consequently, proximal blockages of the urea cycle results in carbamyl-phosphate overflowing into the pyrimidine pathway. Pyrimidine synthesis differs from that of purines in that the single pyrimidine ring is first assembled to form orotic acid and then linked to ribose phosphate to form the central pyrimidine nucleotide uridine monophosphate (UMP). The pyrimidine bases, uracil and thymine, are catabolized in 4 steps, as shown in Figure 89-3. Eight disorders of pyrimidine metabolism are reviewed. Purine catabolism has an easily measurable end point in uric acid; however, there is no equivalent compound in pyrimidine catabolism. The first defect (hereditary orotic aciduria) is in the de novo synthetic pathway, 1 defect (thymidine kinase) is part of pyrimidine salvage, and the other disorders involve overactivity (in 1 syndrome) or defects in the pyrimidine degradation pathway. Pyrimidine disorders may present as anemia, neuropathologies, or multisystem mitochondrial disorders. The first 3 steps of the degradation pathways for thymine and uracil, respectively, make use of the same enzymes (DPD, DPH, and UP). These 3 steps result in the conversion of uracil into β-alanine. There is increasing evidence that pyrimidines play an important role in the regulation of the nervous system. Reduced production of the neurotransmitter function of β-alanine is hypothesized to produce clinical symptoms. Clinically, pyrimidine disorders may be overlooked because they are rare and their symptoms are not highly specific; however, they should be considered as possible causes of anemia and neurologic disease and are a contraindication for treatment of cancer patients with certain pyrimidine analogs.

Uridine Monophosphate Synthase Type 1 Deficiency (Hereditary Orotic Aciduria)

Hereditary orotic aciduria is a disorder of pyrimidine synthesis associated with deficient activity of the last 2 steps of the de novo pyrimidine synthetic pathway, orotate phosphoribosyltransferase, orotidine-5′-monophosphate decarboxylase (ODC). The activities of these 2 steps reside in separate domains of a bifunctional protein, UMP synthase. This catalyzes the 2-step conversion of orotic acid to UMP, via orotidine monophosphate. Hereditary orotic aciduria (UMP synthase deficiency) results in the excessive accumulation of orotic acid.

Genetics

UMP synthase deficiency is inherited as an autosomal recessive disorder, with both functional domains encoded on a single gene, UMPS, which is located on the long arm of chromosome 3 (3q13). Theoretically, random mutations in the gene should have equal chances of producing either orotate phosphoribosyltransferase or ODC deficiency, but there has been only a single case of ODC deficiency reported. Genetic metabolic defects that involve 4 of the 6 enzymes associated with the urea cycle may also result in orotic aciduria, secondary to PPRP depletion resulting from a substantial increased flux through the pyrimidine synthesis pathway.

Clinical

Clinically patients with hereditary orotic aciduria (UMPS type 1 deficiency) have a macrocytic hypochromic megaloblastic anemia that is unresponsive to the usual forms of therapy (iron, folic acid, and vitamin B_{12}), and may develop leukopenia. Onset is usually in first months of life. Untreated, this disorder can lead to developmental disability, intellectual disability, failure to thrive, cardiac disease, strabismus, crystalluria, and occasional ureteric obstruction. Renal function is generally normal. Heterozygotes may have mild orotic aciduria but are not otherwise affected. The clinical features are thought to be related to pyrimidine nucleotide depletion. Metabolites derived from several pharmacologic agents (5-azauridine, allopurinol) can produce secondary orotic aciduria and orotidinuria by specifically inhibiting the ODC step of UMP synthase. Orotic aciduria may also occur in association with parenteral nutrition, essential amino acid deficiency, and Reye syndrome.

Laboratory

The enzymatic defect may be demonstrated in liver, lymphoblasts, erythrocytes, leukocytes, and cultured skin fibroblasts. A carrier detection test is available, as is prenatal diagnosis, although the condition is treatable.

Treatment

The administration of uridine in doses of 50-300 mg/kg/day has been used in treatment leading to clinical improvement and reduction in orotic acid excretion. Lifelong treatment is required. Uracil is ineffective because, unlike purines, pyrimidine salvage occurs at the nucleoside (uridine) level. The long-term prognosis in uncomplicated cases is good; however, congenital malformations and other associated features may adversely affect outcome.

Dihydropyrimidine Dehydrogenase Deficiency (Thymine-Uraciluria, Pyrimidinuria)

DPD catalyzes the initial and rate-limiting step in the degradation of the pyrimidine bases uracil and thymine. DPD has been identified in most tissues, with the highest activity being in lymphocytes.

Genetics

DPD deficiency is an autosomal recessive disorder, with the *DPYD* gene mapping to chromosome 1p22, with at least 32 polymorphisms detected. It is estimated that the frequency of heterozygosity may be as high as 3%.

The clinical manifestations in children may include seizure disorder, intellectual disability and motor delay. Less frequent are growth retardation, microcephaly, autistic-like behavior, and ocular anomalies. Others do not show developmental abnormalities but may have milder neurological symptoms and language disorder. Unaffected cases have been reported, raising discussion about possible secondary gene effects. In most cases, there is an initial period of normal psychomotor development, followed by subsequent developmental delays. Symptoms may be linked to altered uracil, thymine, or β-alanine homeostasis. Because β-alanine is a structural analog of γ-aminobutyric acid and glycine, it has been proposed that it may affect inhibitory neurotransmission. DPD is the initial and rate-limiting enzyme in the inactivation of the neoplastic drug 5-fluorouracil, being responsible for 80% of its catabolism. Patients with partial DPD deficiency are at risk for developing a severe 5-fluorouracil-associated toxicity. In adult patients, neurotoxicity (headache, somnolence, visual illusions and memory impairment) linked to pyrimidinemia following 5-fluorouracil treatment for cancer is reported in previously healthy individuals.

Laboratory
DPD deficiency is characterized by a variable phenotype and diagnosed by the gross accumulation of thymine and uracil in urine (thymine-uraciluria), plasma and cerebrospinal fluid. Uric acid levels have been reported to be normal. Prenatal diagnosis has been reported.

Treatment
There is no established treatment for this disorder, however, patients with seizures do respond to anticonvulsant medications. DPYD*5 (rs1801159) and 1896 T > C (rs17376848) are potentially useful predictive markers of patients' responses to 5-FU chemotherapy.

Dihydropyrimidinase Deficiency (Dihydropyrimidinuria)
DPH is the second enzyme in the 3-step degradation pathway of uracil and thymine. DPH deficiency is characterized by increased urinary excretion of dihydrouracil and dihydrothymine (dihydropyrimidinuria), as well as uracil and thymine. Similar to DPD deficiency, there is a variable clinical phenotype.

Genetics
This is an autosomal recessive disorder, with the *DPYS* gene mapped to chromosome 8q22. In 1 study there was no significant difference in residual activity between mutations observed in symptomatic and asymptomatic individuals, again similar to DPD deficiency. Population prevalence in a Japanese sample was 0.1%.

Clinical
Clinical manifestations are similar to DPD deficiency, which is evidence that defects in these sequential steps produce a common disorder. Symptoms in 3 unrelated affected cases include seizures with dysmorphic features and developmental delay in 2 of these cases. However, 3 unrelated infant and 2 adult asymptomatic cases were identified in a screening program for pyrimidine degradation disorders in Japan and were asymptomatic despite the accumulation of pyrimidine degradation products in body fluids.

Laboratory
Organic acid screening may identify increased amounts of uracil and thymine in urine. Oral loading tests with uracil, dihydrouracil, thymine, and dihydrothymine have been used to detect carriers of the deficiency. In symptomatic cases, treatment with β-alanine has been attempted with equivocal results. A single case of increased sensitivity to 5-fluorouracil has been reported.

Deficiency of β-Ureidopropionase (*N*-Carbamyl-β-Amino Aciduria)
The pyrimidine bases uracil and thymine are degraded via the consecutive action of 3 enzymes to β-alanine and β-aminoisobutyric acid, respectively. The third enzyme in the pathway is ureidopropionase, and its deficiency leads to *N*-carbamyl-β-amino aciduria. 3-ureidopropionic acid (3-UPA) acts as endogenous neurotoxin via inhibition of mitochondrial energy metabolism resulting in the initiation of secondary, energy-dependent excitotoxic mechanisms.

Genetics
Fluorescence in situ hybridization localized the human β-ureidopropionase gene, *UPB1,* to 22q11.2.

Clinical
Clinical manifestations in a reported case include muscular hypotonia, dystonic movements, and severe developmental delay.

Laboratory
Neuropathology involves both gray and white matter. Ureidopropionase deficiency leads to pathologic accumulation of 3-UPA in body fluids. Urinary analysis in a reported case showed elevated levels of *N*-carbamyl-β-alanine and *N*-carbamyl-β-aminoisobutyric acid (ureidoisobutyric acid). The enzyme is expressed only in the liver and no activity of β-ureidopropionase is detected in a liver biopsy.

Treatment
There is no known treatment for ureidopropionase deficiency.

Pyrimidine 5′-Nucleotidase Deficiency
Erythrocyte maturation is accompanied by RNA degradation and the release of mononucleotides. Pyrimidine 5′-nucleotidase is the first degradative enzyme of the pyrimidine salvage cycle and catalyzes the hydrolysis of pyrimidine 5′-nucleotides to the corresponding nucleosides. Enzyme deficiency results in the accumulation of high levels of cytidine and uridine nucleotides in the erythrocytes that, in turn, results in hemolysis. Deficiency of pyrimidine 5′-nucleotidase may be at least in part compensated in vivo by other nucleotidases or perhaps other nucleotide metabolic pathways.

Genetics
This is an autosomal recessive disorder involving the gene *pyrimidine 5′-nucleotidase deficiency* on chromosome 7 (7p15). Affected pyrimidine 5′-nucleotidase deficiency patients clinically present with a defect restricted to erythrocytes that is characterized by nonspherocytic hemolytic anemia with basophilic stippling. Other characteristic features include splenomegaly, increased indirect bilirubin, and hemoglobinuria. Lead is a powerful inhibitor of pyrimidine 5′-nucleotidase and assessment of lead levels should be included whenever hemolytic anemia, pyrimidine 5′-nucleotidase deficiency, and basophilic stippling are found together.

Laboratory
Diagnosis requires assay of erythrocyte UMP hydrolysis to form uridine and inorganic phosphate. The enzyme defect should be suspected in patients with nonspherocytic hemolytic anemia with basophilic stippling. The anemia is usually moderate, and transfusions are rarely necessary.

Treatment
There is no specific treatment. Splenectomy has not proved to be an effective treatment. Lead-induced acquired pyrimidine 5′ nucleotidase deficiency is treatable, unlike the congenital deficiency.

OVERACTIVE CYTOSOLIC 5′-NUCLEOTIDASE (PYRIMIDINE NUCLEOTIDE DEPLETION)
Pyrimidine nucleotide depletion and overactive cytosolic 5′-nucleotidase, may lead to a neurodevelopmental disorder. Four unrelated patients showed 6-10–fold elevation in the activity of pyrimidine 5′-nucleotidase in fibroblasts with both purine and pyrimidine substrates. Investigation in cultured fibroblasts derived from these patients showed normal incorporation of purine bases into nucleotides but decreased incorporation of uridine and orotic acid.

Clinical
Clinical manifestations include developmental delay, seizures, ataxia, recurrent infections, severe language deficit, hyperactivity, short attention span, and aggressive behavior appearing within the first few years of life. Affected patients show electroencephalogram abnormalities. Metabolic testing is normal except for persistent hypouricosuria. It is proposed that increased catabolic activity and decreased pyrimidine salvage cause a deficiency of pyrimidine nucleotides.

Treatment
Treatment is with oral uridine based on compensating for the increased nucleotide catabolism. All reported patients treated with uridine showed improved speech and behavior, decreased seizure activity with discontinuation of seizure medications, and decreased frequency of infections.

Thymidine Phosphorylase Deficiency (Mitochondrial Neurogastrointestinal Encephalomyopathy)
Thymidine phosphorylase catalyzes the catabolism in mitochondria of thymidine to thymine. This enzyme is also known as "platelet-derived

endothelial cell growth factor" because of its angiogenic properties, or "gliostatin" indicating its inhibitory effects on glial cell proliferation. It has been implicated in mitochondrial nucleoside metabolism. Plasma thymidine level is increased more than 20-fold in patients compared to controls. Loss of function of thymidine phosphorylase causes mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), which is inherited as a single autosomal recessive disorder, causing mitochondrial DNA depletion and instability. In MNGIE, loss of thymidine phosphorylase activity causes toxic accumulations of the nucleosides thymidine and deoxyuridine that are incorporated by the mitochondrial pyrimidine salvage pathway and cause deoxynucleoside triphosphate pool imbalances.

Genetics

The *TYMP* gene encoding thymidine phosphorylase has been identified as the MNGIE gene and is mapped to chromosome 22q13.32-qter, but the protein is imported into mitochondria.

Clinical Manifestations

Clinical manifestations of MNGIE include ptosis, progressive external ophthalmoparesis, gastrointestinal dysmotility and malabsorption, cachexia, peripheral neuropathy, skeletal muscle myopathy and leukoencephalopathy.

Laboratory

Muscle biopsies typically reveal mitochondrial abnormalities. Screening is performed by detection of grossly raised thymidine and deoxyuridine in urine, which are normally absent. Confirmation of the diagnosis can made by assay of thymidine phosphorylase activity in peripheral leukocytes. Molecular genetic analysis will show functional mutations in the *TYMP* gene. Increased thymidine and/or deoxyuridine nucleotides may cause mitochondrial nucleotide pool imbalance resulting in mitochondrial DNA alterations, in particular DNA depletion.

Treatment

Supportive treatment is indicated. There is no established therapy for MNGIE; bone marrow transplantation has been performed on several patients but no improvement in symptoms or progression of the disease has been reported. Allogeneic hematopoietic stem cell transplantation to restore thymidine phosphorylase activity and eliminate toxic metabolites is a potential therapy for MNGIE.

THYMIDINE KINASE 2 DEFICIENCY

Thymidine kinase 2 (TK2) is a key enzyme for the pyrimidine salvage pathway to provide precursor nucleotide for mitochondrial DNA. TK2 deficiency causes tissue-specific depletion of mitochondrial DNA. TK2 normally phosphorylates thymidine and deoxycytidine.

Genetics

The TK2 gene is located on chromosome 16q 22; the deficiency is inherited in an autosomal recessive manner.

Clinical

Clinically, affected individuals with TK2 deficiency have severe myopathy and depletion of muscular mitochondrial DNA in infancy.

Treatment

No specific treatment is available. Supportive treatment is indicated.

Chapter 90

Hutchinson-Gilford Progeria Syndrome

Leslie B. Gordon

Hutchinson-Gilford progeria syndrome (progeria) is a rare, fatal, autosomal dominant segmental premature aging disease. With an estimated incidence of 1 in 4,000,000 live births and prevalence of 1 in 18 million, there were a total of 350 children living with progeria in 2013 worldwide. There is no gender, ethnic, or regional bias. Progeria is caused by a single base mutation in *LMNA*, which results in the production of a mutant lamin A protein called progerin. Progerin is found in increased concentration in skin and the vascular wall of normal older compared to younger individuals, suggesting a role in normal aging. Children develop progressive atherosclerosis and die of heart attacks or strokes at a median age of 14.5 yr, most often between ages 5 and 20 yr.

CLINICAL MANIFESTATIONS

Children develop the appearance of accelerated aging. Physical appearance changes dramatically each year that the children age (Fig. 90-1).

Dermatologic Changes

Skin findings are often apparent as initial signs of progeria. These are variable in severity and include areas of discoloration, stippled pigmentation, tightened areas that can restrict movement, and areas of the trunk or legs where small (1-2 cm) soft, bulging skin is present. Although usually born with normal hair present, patients lose cranial hair within the first few years, and are left with soft, downy, sparse immature hair on the scalp, no eyebrows, and scant eye lashes.

Failure to Thrive

Children with progeria experience apparently normal fetal and early postnatal development. Within the first year of life, abnormalities in growth and body composition are readily apparent; severe failure to thrive ensues, heralding generalized lipoatrophy, with apparent wasting of limbs, circumoral cyanosis, and prominent veins around the scalp, neck, and trunk. The mean weight, which is normal at birth, decreases to below the third percentile for normal children despite adequate caloric intake for normal growth and normal resting energy expenditure. A retrospective data set of 35 children showed an average weight gain of only 0.44 kg/year, beginning at 24 mo of age and persisting throughout life. There is interpatient variation in weight gain, but the projected weight gain over time in an individual patient is constant, linear, and very predictable. Children with progeria reach a final height of approximately 1 m and weight of approximately 14 kg. Head circumference is normal. Weight deficit is more pronounced than height deficit and this, associated with the loss of subcutaneous fat, results in the emaciated appearance characteristic of children with progeria. Clinical problems caused by the lack of subcutaneous fat include insulin resistance, sensitivity to cold temperatures, and foot discomfort because of a lack of fat cushioning. Although overt diabetes is very unusual in progeria, approximately 30-40% of children suffer from insulin resistance.

Ocular Abnormalities

Tightened skin and a paucity of subcutaneous fat around the eyes causes most patients to sleep with eyelids partially open, resulting in corneal dryness and eye tearing. Patients can develop exposure keratopathy and/or corneal ulcers, which can disrupt sight. Artificial tears

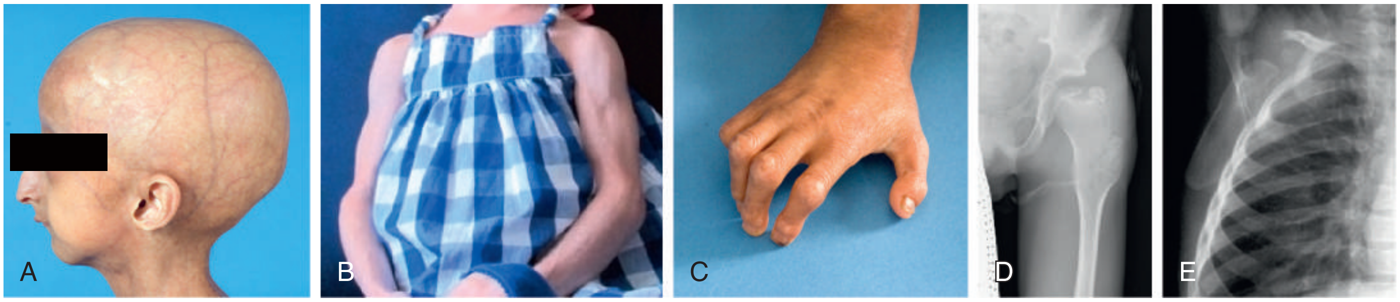

Figure 90-1 **A,** Profile of head and face of a child with progeria. Note the alopecia, beaked nose, and retrognathia. **B,** The arms of this child demonstrate absence of subcutaneous fat. **C,** Contractures in multiple joints including fingers, elbows, hips, knees, and ankles may be present at birth and/or in later years. **D,** Hip dysplasia is often progressive and may result in avascular necrosis, hip dislocation, and inability to bear weight. **E,** A pyriform chest structure and a small clavicle can lead to reducible shoulder dislocations. *(Photos courtesy of The Progeria Research Foundation and Boston Children's Hospital.)*

during the day and taping or covering the eyes at night are recommended. Some degree of photophobia is common.

Dental Abnormalities

Dentition is severely delayed in development and crowded due to micrognathia. Eruption may be delayed for many months, and primary teeth may persist for the duration of life. Secondary teeth are present, but may or may not erupt. They sometimes erupt on the lingual and palatal surfaces of the mandibular and maxillary alveolar ridges, rather than in place of the primary incisors. In some but not all cases, extracting primary teeth promotes movement of secondary teeth into place.

Bone and Cartilaginous Abnormalities

Aberrant development of bone structure and bone density represents a unique skeletal dysplasia which is not based in malnutrition. Acroosteolysis of the distal phalanges, distal clavicular resorption and thin, tapered ribs are early signs of progeria that appear as early as 3 mo of age. Facial disproportion, a narrowed nasal bridge and retrognathia make intubation extremely difficult, and fiberoptic intubation is recommended. A pyriform chest structure and a small clavicle can lead to reducible shoulder dislocations (Fig. 90-1*E*). Long bone remodeling of the femoral head–neck axis following knee and ankle contractures results in coxa valga, straightening of the femoral head-neck axis to >125 degrees. The bony pelvis is normal and these changes give rise to a "horse riding" stance. Hip dysplasia is often progressive and may result in avascular necrosis, hip dislocation, and inability to bear weight (Fig. 90-1*D*). Other long bone changes include flaring of the humeral and femoral metaphyses and constriction of the radial neck. Bone age is generally normal, with variable readings within a single radiograph. Growth plates are normal. Bone structure assessed by peripheral quantitative computed tomography of the radius demonstrates distinct and severe abnormalities in bone structural geometry and skeletal strength. Areal bone density Z scores by dual-energy X-ray absorptiometry are abnormally low, but improve after adjustment for height and age. Fracture rates in progeria are normal.

Joint contractures, a result of ligamentous and skin changes, limit range of motion. Contractures in multiple joints including fingers, elbows, hips, knees and ankles may be present at birth and/or in later years (Fig. 90-1*C*). Physical therapy is recommended routinely and throughout life to maximize joint function.

Hearing

Low tone conductive hearing loss is pervasive in progeria, and is indicative of a stiff tympanic membrane, and/or deficits in the middle ear bony and ligamentous structures. Overall, this does not affect ability to hear the usual spoken tones but preferential classroom seating is recommended.

Cardiovascular Disease

Death occurs primarily from myocardial infarction, and less often from strokes. Progeria is a primary vasculopathy, characterized by pervasive accelerated vascular stiffening, followed by large and small vessel occlusive disease as a result of atherosclerotic plaque formation, with valvular and cardiac insufficiency in later years. Hypertension, angina, cardiomegaly, metabolic syndrome, and heart failure are common end-stage events. Routine carotid ultrasound for plaque monitoring, carotid-femoral pulse wave velocity measures for vascular stiffening, and echocardiography are recommended.

Cerebrovascular Arteriopathy and Stroke

Cerebral infarction may occur while the child exhibits a normal electrocardiogram. The earliest incidence of stroke occurred at the age of 0.4 yr. More often they occur in the later yr. Radiographic evidence on MRI of infarction can be found in 60% of the patients, in whom half are clinically silent. Both large- and small-vessel disease is found; collateral vessel formation is extensive. Carotid artery occlusions are well documented, but infarction can occur in their absence. Propensity toward strokes and an underlying stiff vasculature make maintaining adequate blood pressure through hydration (i.e., habitually drinking well) a priority in progeria; special care should be taken when considering maintenance of consistent blood pressure during general anesthesia, airplane trips, and hot weather.

Normally Functioning Systems

Liver, kidney, thyroid, immune, gastrointestinal, and neurologic systems (other than stroke-related) remain intact. Intellect is normal for age.

Laboratory Findings

The most consistent laboratory findings are low serum leptin and insulin resistance. Platelet count is often moderately high. Lipid panels, blood chemistries, endocrine and coagulation and other tests are generally normal.

MOLECULAR PATHOGENESIS

Mutations in the *LMNA* gene cause progeria. The normal *LMNA/C* gene encodes the proteins lamins A and C, of which only lamin A is associated with human diseases. The lamin proteins are the principal proteins of the nuclear lamina, a complex molecular interface located between the inner membrane of the nuclear envelope and chromatin. The integrity of the lamina is central to many cellular functions, creating and maintaining structural integrity of the nuclear scaffold, DNA replication, RNA transcription, organization of the nucleus, nuclear pore assembly, chromatin function, cell cycling, and apoptosis.

Progeria is almost always a sporadic autosomal dominant disease. There is 1 proven case of mosaicism. Progeria is caused by the accelerated use of an alternative, internal splice site that results in the deletion of 150 base pairs in the 3' portion of exon 11 of the *LMNA* gene. In approximately 90% of cases, this results from a single C to T transition at nucleotide 1824 that is silent (Gly608Gly), but optimizes an internal splice site within exon 11. The remaining 10% of cases possess 1 of several single base mutations within the intron 11 splice donor site,

thus reducing specificity for this site and altering the splicing balance in favor of the internal splice. Subsequent to all of these mutations, translation followed by posttranslational processing of the altered messenger RNA produces progerin, a shortened abnormal lamin A protein with a 50-amino-acid deletion near its C-terminal end. An understanding of the posttranslational processing pathway and how it is altered to create progerin has led to a number of treatment prospects for the disease.

Both lamin A and progerin possess a farnesyl side group attached during posttranslational processing. This is a lipophilic moiety which facilitates intercalation of proteins into the inner nuclear membrane where most of the lamin and progerin functions are performed. For normal lamin A, loss of the farnesyl anchor releases prelamin from the nuclear membrane, rendering it soluble for autophagic degradation. However, progerin retains its farnesyl moiety. It remains anchored to the membrane, binding other proteins, causing blebbing of the nucleus, disrupting mitosis, and altering gene expression.

Disease in progeria is produced by a ***dominant negative*** mechanism; it is the action of progerin, not the diminution of lamin A that causes the disease phenotype. The severity of disease is determined in part by progerin levels, which are regulated by the particular mutation, tissue type, or other factors influencing use of the internal splice site.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Overall, the constellation of small body habitus, bone, hair, subcutaneous fat, and skin changes results in the marked physical resemblance among patients with progeria (Fig. 90-2). For this reason, clinical diagnosis can be achieved or excluded with relative confidence even at young ages, though there have been a few cases of low progerin-expressing patients with extremely mild signs. Clinical suspicion should be followed by *LMNA* genetic sequence testing. The disorders that resemble progeria are those grouped as the senile-like syndromes and include Wiedemann-Rautenstrauch syndrome, Werner syndrome, Cockayne syndrome, Rothmund-Thomson syndrome, restrictive dermopathy, and Nestor-Guillermo progeria syndrome (Table 90-1). Patients often fall under none of these diagnoses and represent ultrarare, unnamed progeroid laminopathies that carry either non–progerin-producing mutations in lamin or the lamin-associated enzyme Zmpste24, or progeroid syndromes without lamin mutations.

PROGNOSIS, TREATMENT, AND PATIENT RESOURCES

Children with progeria develop a severe premature form of atherosclerosis. Prior to death, cardiac decline with left-sided hypertrophy, valvular insufficiency, and pulmonary edema develop; neurovascular decline with transient ischemic attack, strokes, and occasionally seizures can result in significant morbidity. Death occurs as a result of heart attack (~80%) and stroke (~20%), generally between age 5 and 20 yr, with a median life span of 14.5 yr.

No specific FDA-approved treatment for this condition exists. Growth hormone has resulted in increased rate of weight gain and overall size when administered at 0.05 mg/kg/day SC, but weight still remained well below that seen in normal children. Low-dose aspirin therapy is recommended at 2 mg/kg body weight per day, as an extension of what is known about decreasing cardiovascular risk in the general at-risk adult population. It is not known whether growth hormone or low-dose aspirin has any effect on morbidity or mortality.

The first potentially beneficial treatment prospect for progeria was published in 2011. Inhibiting posttranslational progerin farnesylation with a drug named lonafarnib was aimed at preventing this disease-causing protein from anchoring to the nuclear membrane where it carries out much of its damage. A prospective single-arm clinical trial was initiated with a cohort of 25 progeria patients between 3 and 16 yr of age, treated for a minimum of 2 yr (NCT00425607). Lonafarnib was well tolerated; the most common side effects were diarrhea, nausea, and loss of appetite, which generally improved with time. Subgroups of patients experienced increased rate of weight gain, decreased vascular stiffness measured via improved carotid-femoral wave velocity, and carotid artery echodensity, increased radial bone structural rigidity, improved sensorineural hearing, and early evidence of decreased headache, transient ischemic attack and stroke rates. Dermatologic, dental, joint contracture, insulin resistance, lipodystrophy, bone mineral density, and joint contractures were unaffected by drug treatment. The evidence for improved cardiovascular status in children with progeria is most encouraging. A study published in 2014 demonstrated increased estimated lifespan for children with progeria taking farnesylation inhibitors such as lonafarnib.

An ongoing clinical trial which adds pravastatin and zoledronate, 2 FDA-approved drugs, to the lonafarnib regimen is similarly aimed at inhibiting progerin farnesylation (NCT00916747).

The Progeria Foundation (www.progeriaresearch.org) maintains an international registry, diagnostics program, and complete patient care manual and coordinates clinical treatment trials.

Chapter 91

The Porphyrias

Manisha Balwani, Robert J. Desnick, and Karl E. Anderson

Porphyrias are metabolic diseases resulting from altered activities of specific enzymes of the heme biosynthetic pathway. These enzymes are most active in bone marrow and liver. Erythropoietic porphyrias, in which overproduction of heme pathway intermediates occurs primarily in bone marrow erythroid cells, usually present at birth or in early childhood with cutaneous photosensitivity, or in the case of congenital erythropoietic porphyria (CEP), even in utero as nonimmune hydrops. Erythropoietic protoporphyria (EPP) is the most common porphyria in children and of most interest to pediatricians. Most porphyrias are hepatic, with overproduction and initial accumulation of porphyrin precursors or porphyrins in the liver. Activation of hepatic porphyrias is very rare during childhood, reflecting the distinct hepatic regulatory mechanisms for heme biosynthesis that are influenced by pubertal development. Homozygous forms of the hepatic porphyrias may manifest clinically prior to puberty. Children who are heterozygous for inherited hepatic porphyrias may present with nonspecific and unrelated symptoms, and parents often request advice about long-term prognosis and express concerns about drugs that may exacerbate these conditions.

The DNA sequences and chromosomal locations are established for the human genes of the enzymes in this pathway, and multiple disease-related mutations have been found for each porphyria. The inherited porphyrias display autosomal dominant, recessive or X-linked inheritance. Although initial diagnosis of porphyria by biochemical methods remains essential, it is especially important to confirm the diagnosis by demonstrating a specific gene mutation(s).

THE HEME BIOSYNTHETIC PATHWAY

Heme is required for a variety of hemoproteins such as hemoglobin, myoglobin, respiratory cytochromes, and cytochrome P450 enzymes (CYPs). It is believed that the 8 enzymes in the pathway for heme biosynthesis are active in all tissues. Hemoglobin synthesis in erythroid precursor cells accounts for approximately 85% of daily heme synthesis in humans. Hepatocytes account for most of the rest, primarily for synthesis of CYPs, which are especially abundant in the liver endoplasmic reticulum, and turn over more rapidly than many other hemoproteins, such as the mitochondrial respiratory cytochromes. Pathway intermediates are the porphyrin precursors δ-aminolevulinic acid (ALA, also known as 5-aminolevulinic acid) and porphobilinogen (PBG), and porphyrins (mostly in their reduced forms, known as porphyrinogens) (Fig. 91-1). At least in humans, these intermediates do not accumulate in significant amounts under normal conditions or have important physiologic functions.

A deficiency of each enzyme in the pathway is associated with a specific porphyria (Table 91-1). The first enzyme, ALA synthase (ALAS), occurs in 2 forms. An erythroid specific form, termed ALAS2, is deficient in X-linked sideroblastic anemia, as a result of mutations of the *ALAS2* gene on chromosome Xp11.2. Gain of function mutations of *ALAS2* because of deletions in the last exon cause X-linked protoporphyria (XLP), a cutaneous porphyria which is phenotypically identical to EPP.

Regulation of heme synthesis differs in the 2 major heme-forming tissues. Liver heme biosynthesis is primary controlled by ALAS1. Synthesis of ALAS1 in liver is regulated by a "free" heme pool (see Fig. 91-1), which can be augmented by newly synthesized heme or by existing heme released from hemoproteins and destined for breakdown to biliverdin by heme oxygenase.

In the erythron, novel regulatory mechanisms allow for the production of the very large amounts of heme needed for hemoglobin synthesis. The response to stimuli for hemoglobin synthesis occurs during cell differentiation, leading to an increase in cell number. Also, unlike the liver, heme has a stimulatory role in hemoglobin formation, and the stimulation of heme synthesis in erythroid cells is accompanied by increases not only in ALAS2, but also by sequential induction of other heme biosynthetic enzymes. Separate erythroid-specific and nonerythroid or "housekeeping" transcripts are known for the first 4 enzymes in the pathway. The separate forms of ALAS are encoded by genes on different chromosomes, but for each of the other 3, erythroid and nonerythroid transcripts are transcribed by alternative promoters in the same gene. Heme also regulates the rate of its synthesis in erythroid cells by controlling the transport of iron into reticulocytes.

Intermediates of the heme biosynthetic pathway are efficiently converted to heme and, normally, only small amounts of the intermediates are excreted. Some may undergo chemical modifications before excretion. Whereas the porphyrin precursors ALA and PBG are colorless, nonfluorescent, and largely excreted unchanged in urine, PBG may degrade to colored products such as the brownish pigment called *porphobilin* or spontaneously polymerize to uroporphyrins. Porphyrins are red in color and display bright red fluorescence when exposed to long wavelength UV light. Porphyrinogens, which are colorless and nonfluorescent, are the reduced form of porphyrins, and when they

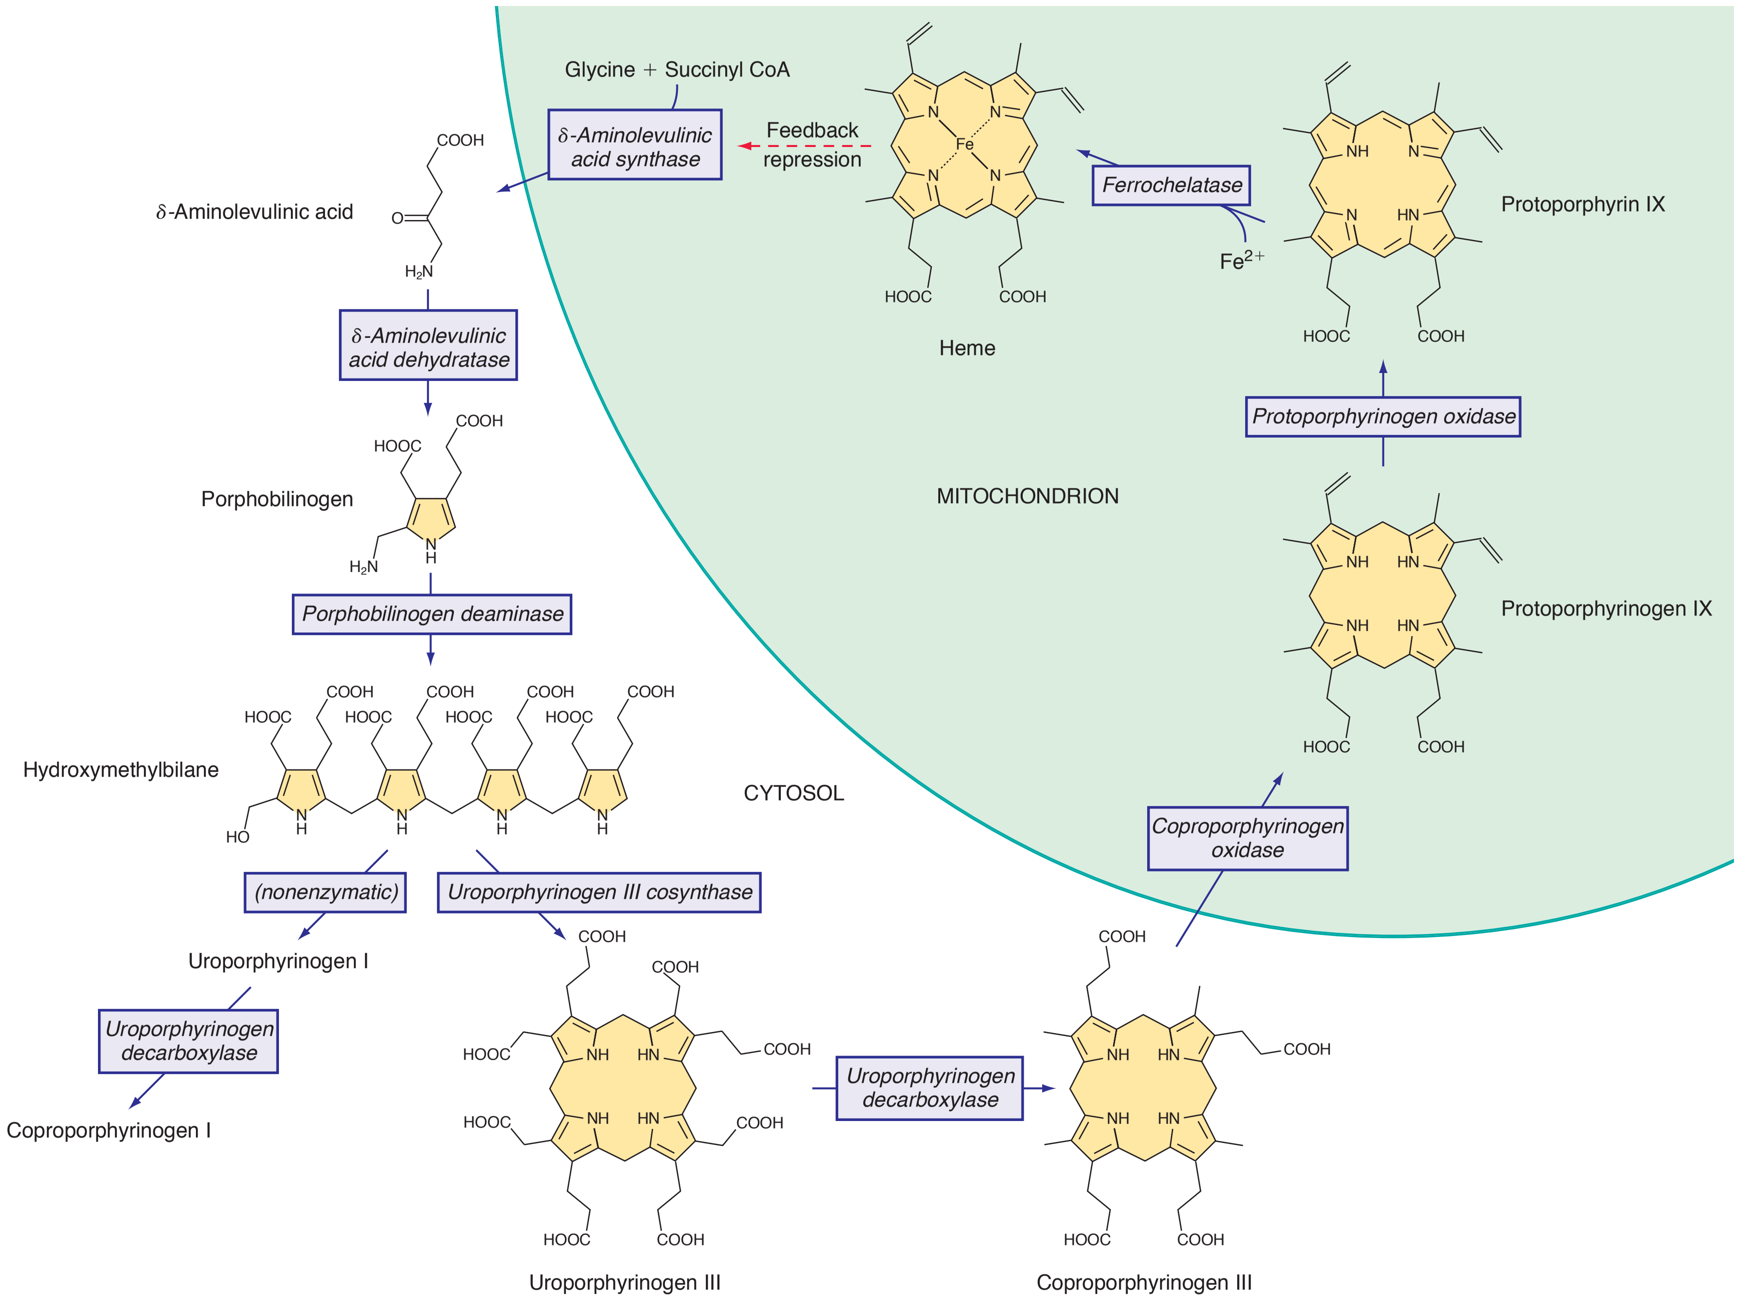

Figure 91-1 **Enzymes and intermediates of the heme biosynthetic pathway.** The pathway is regulated in the liver by the end product, heme, mainly by feedback repression *(dashed arrow).*

Table 91-1 The Human Porphyrias: Mutations, Time of Presentation, and Tissue- and Symptom-Based Classifications

				Classifications			
DISEASE (ABBREVIATION)	ENZYME (ABBREVIATION)	INHERITANCE	PRESENTATION	HEPATIC	ERYTHROPOIETIC	ACUTE/ NEUROLOGIC	CUTANEOUS
X-Linked protoporphyria (XLP)	*δ-Aminolevulinate synthase 2 (ALAS2)*	X-linked	Childhood		X		X
δ-Aminolevulinic acid dehydratase porphyria (ADP)	*δ-Aminolevulinic acid dehydratase (ALAD)*	Autosomal recessive	Mostly post puberty	X	X*	X	
Acute intermittent porphyria (AIP)	*Porphobilinogen deaminase (PBGD)*	Autosomal dominant	Post puberty	X		X	
Homozygous AIP		Homozygous dominant	Childhood	X	X	X	
Congenital erythropoietic porphyria (CEP)	*Uroporphyrinogen III synthase (UROS)*	Autosomal recessive	In utero or infancy		X		X
Porphyria cutanea tarda (PCT) type 1	*Uroporphyrinogen decarboxylase (UROD)*	Sporadic	Adults	X			X
PCT type 2†		Autosomal dominant	Adults	X			X
PCT type 3		Unknown	Adults	X			X
Hepatoerythropoietic porphyria (HEP)		Homozygous dominant	Childhood	X	X*		X
Hereditary coproporphyria (HCP)	*Coproporphyrinogen oxidase (CPOX)*	Autosomal dominant	Post puberty	X		X	X
Homozygous HCP		Homozygous dominant	Childhood	X	X	X	X
Variegate porphyria (VP)	*Protoporphyrinogen oxidase (PPOX)*	Autosomal dominant	Post puberty	X		X	X
Homozygous VP		Homozygous dominant	Childhood	X	X	X	X
Erythropoietic protoporphyria (EPP)	*Ferrochelatase (FECH)*	Autosomal recessive(most commonly heteroallelic with hypomorphic allele)	Childhood		X		X

*ADP and HEP are considered primarily hepatic porphyrias, but substantial increases in erythrocyte zinc protoporphyrin suggest an erythropoietic component.
†PCT is a result of inhibition of hepatic UROD. Autosomal dominant inheritance of a partial deficiency of UROD is a predisposing factor in cases defined as familial (type 2) PCT.

Table 91-2 The 3 Most Common Human Porphyrias and Their Major Features

	PRESENTING SYMPTOMS	EXACERBATING FACTORS	MOST IMPORTANT SCREENING TESTS	TREATMENT
Acute intermittent porphyria	Neurologic, adult onset	Drugs (mostly P450-inducers), progesterone, dietary restriction	Urinary porphobilinogen	Hemin, glucose
Porphyria cutanea tarda	Skin blistering and fragility (chronic), adult onset	Iron, alcohol, smoking, estrogens, hepatitis C, HIV, halogenated hydrocarbons	Plasma (or urine) porphyrins	Phlebotomy, low-dose hydroxychloroquine
Erythropoietic protoporphyria	Skin pain and swelling (mostly acute), childhood onset		Erythrocyte (or plasma) porphyrins	Beta-carotene

accumulate are readily autoxidized to the corresponding porphyrins when outside the cell. Only the type III isomers of uroporphyrinogen and coproporphyrinogen are converted to heme (see Fig. 91-1).

ALA and PBG are excreted in urine. Excretion of porphyrins and porphyrinogens in urine or bile is determined by the number of carboxyl groups. Those with many carboxyl groups, such as uroporphyrin (octacarboxyl porphyrin) and heptacarboxyl porphyrin, are water soluble and readily excreted in urine. Those with fewer carboxyl groups, such as protoporphyrin (dicarboxyl porphyrin), are not water soluble and are excreted in bile and feces. Coproporphyrin (tetracarboxyl porphyrin) is excreted partly in urine and partly in bile. Because coproporphyrin I is more readily excreted in bile than is coproporphyrin III, impaired hepatobiliary function may increase total urinary coproporphyrin excretion and the ratio of these isomers.

CLASSIFICATION AND DIAGNOSIS OF PORPHYRIAS

Two classification schemes reflect either the underlying pathophysiology or clinical features, and both are useful for diagnosis and treatment (see Table 91-1). In **hepatic** and **erythropoietic** porphyrias, the source of excess production of porphyrin precursors and porphyrins is the liver and bone marrow, respectively. **Acute porphyrias** cause neurologic symptoms that are associated with increases of 1 or both of the porphyrin precursors, ALA and PBG. In the **cutaneous porphyrias,** photosensitivity results from transport of porphyrins in blood from the liver or bone marrow to the skin. **Dual porphyria** refers to the very rare cases of porphyria with deficiencies of 2 different heme pathway enzymes.

It is notable that, porphyria cutanea tarda (PCT), acute intermittent porphyria (AIP) and EPP in that order the 3 most common porphyrias considering all age groups are very different in clinical presentation, precipitating factors, methods of diagnosis, and effective therapy (Table 91-2). Two of the 4 acute porphyrias, hereditary coproporphyria (HCP) and variegate porphyria (VP), can also cause lesions indistinguishable from PCT (see Table 91-1). CEP causes more severe blistering lesions, often with secondary infection and mutilation. EPP and XLP have the same phenotype and are distinct from the other cutaneous porphyrias in causing nonblistering photosensitivity that occurs acutely after sun exposure. EPP is also the most common porphyria to become manifest before puberty.

First-Line Laboratory Diagnostic Testing

A few sensitive and specific first-line laboratory tests should be obtained whenever symptoms or signs suggest the diagnosis of porphyria. If a first-line or screening test is significantly abnormal, more comprehensive testing should follow to establish the type of porphyria. Overuse of laboratory tests for screening can lead to unnecessary expense and even delay in diagnosis. In patients who present with a past diagnosis of porphyria, laboratory reports that were the basis for the original diagnosis must be reviewed, and if these were inadequate, further testing considered.

Acute porphyria should be suspected in patients with neurovisceral symptoms such as abdominal pain after puberty, when initial clinical evaluation does not suggest another cause, and *urinary porphyrin precursors (ALA and PBG)* and *total porphyrins* should be measured. Urinary PBG is virtually always increased during acute attacks of acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), and variegate porphyria (VP), and is not substantially increased in any other medical conditions. Therefore, this measurement is both sensitive and specific. A method for rapid, in-house testing for urinary PBG, such as the Trace PBG kit (Thermo Scientific, 1-800-640-0640), should be available in-house at all major medical facilities. Results from **spot** (**single void**) urine specimens are highly informative because very substantial increases are expected during acute attacks of porphyria. A 24 hr collection can unnecessarily delay diagnosis. The same spot urine specimen should be saved for quantitative determination of ALA and PBG to confirm the qualitative PBG result and total porphyrins. This will detect patients with ALA dehydratase porphyria (ADP) and some cases of HCP and VP, as urinary porphyrins may remain increased longer than porphyrin precursors in the latter disorders. Measurement of urinary porphyrins alone should be avoided for screening, because these are often increased in many disorders other than porphyrias, such as chronic liver disease, and misdiagnoses of porphyria can result from minimal increases in urinary porphyrins that have no diagnostic significance.

PBG is a colorless pyrrole that forms a violet pigment with Ehrlich reagent (*p*-dimethylaminobenzaldehyde). Other substances, principally urobilinogen, also react with Ehrlich aldehyde. A reliable quantitative method for both ALA and PBG, which uses small anion and cation exchange columns to separate interfering substances before adding Ehrlich reagent, has been available for many years. ALA is reacted to form a pyrrole, which is then also measured using Ehrlich reagent. The Trace PBG kit to detect increased PBG is based on this method.

Blistering Cutaneous Porphyrias

Blistering skin lesions caused by porphyria are virtually always accompanied by increases in *total plasma porphyrins.* A fluorometric method is preferred, because the porphyrins in plasma in VP are mostly covalently linked to plasma proteins and may be less readily detected by high-pressure liquid chromatography. The normal range for plasma porphyrins is somewhat increased in patients with end-stage renal disease. Urinary porphyrins are also increased in these porphyrias, but also in many other medical conditions.

Nonblistering Cutaneous Porphyria

Although a total plasma porphyrin determination will usually detect EPP and XLP, an erythrocyte protoporphyrin determination is more sensitive. Increases in erythrocyte protoporphyrin occur in many other conditions. Therefore, the diagnosis of EPP must be confirmed by showing a predominant increase in metal-free protoporphyrin rather than zinc protoporphyrin. In XLP, both free and zinc protoporphyrin can be elevated. Interpretation of laboratory reports can be misleading, because the term *free erythrocyte protoporphyrin* often refers to iron-free protoporphyrin (including zinc protoporphyrin) rather than metal-free protoporphyrin.

Second-Line Testing

More extensive testing is well justified when a first-line test is positive. A substantial increase in PBG may be caused by AIP, HCP, or VP. These acute porphyrias can be distinguished by measuring erythrocyte porphobilinogen deaminase (PBGD), urinary porphyrins (using the same spot urine sample), fecal porphyrins, and plasma porphyrins. The various porphyrias that cause blistering skin lesions are differentiated by measuring porphyrins in urine, feces, and plasma. Confirmation at the DNA level is important once the diagnosis is established by biochemical testing.

Testing for Subclinical Porphyria

It is often difficult to diagnose or “rule out” porphyria in patients who had suggestive symptoms months or years in the past, and in relatives of patients with acute porphyrias, because porphyrin precursors and porphyrins may be normal. More extensive testing and consultation with a specialist laboratory and physician may be needed. Before evaluating relatives, the diagnosis of porphyria should be firmly established in an index case, and the laboratory results reviewed to guide the choice of tests for the family members. The index case or another family member with confirmed porphyria should be retested if necessary. Identification of a disease-causing mutation in an index case greatly facilitates detection of additional gene carriers as biochemical tests in latent carriers may be normal.

δ-AMINOLEVULINIC ACID DEHYDRATASE PORPHYRIA

This porphyria is sometimes termed *Doss porphyria* after the investigator who described the first cases. The term *plumboporphyria* emphasizes the similarity of this condition to lead poisoning, but incorrectly implies that it is due to lead exposure.

Etiology

This porphyria results from a deficiency of δ-aminolevulinic acid dehydratase (ALAD), which is inherited as an autosomal recessive trait. Only 6 cases have been confirmed by mutation analysis. The prevalence of heterozygous ALAD deficiency was estimated to be <1% in Germany and approximately 2% in Sweden.

Pathology and Pathogenesis

ALAD catalyzes the condensation of 2 molecules of ALA to form the pyrrole PBG (see Fig. 91-1). The enzyme is subject to inhibition by a number of exogenous and endogenous chemicals. ALAD is the principal lead-binding protein in erythrocytes, and lead can displace the zinc atoms of the enzyme. Inhibition of erythrocyte ALAD activity is a sensitive index of lead exposure.

Eleven abnormal ALAD alleles, most with point mutations, have been identified, some expressing partial activity, such that heme synthesis is partially preserved. The amount of residual enzyme activity may predict the phenotypic severity of this disease. Immunochemical studies in 3 cases demonstrated nonfunctional enzyme protein that cross-reacted with anti-ALAD antibodies. Five of the 6 reported ADP cases inherited a different ALAD mutation from each parent. One reported patient with late-onset disease who was heterozygous for a mutant allele developed ADP associated with a myeloproliferative disorder and expansion of an affected clone of erythroid cells.

ADP is often classified as a hepatic porphyria, although the site of overproduction of ALA is not established. A patient with severe, early-onset disease underwent liver transplantation, without significant clinical or biochemical improvement, which might suggest that the excess intermediates did not originate in the liver. Excess urinary coproporphyrin III in ADP might originate from metabolism of ALA to porphyrinogens in a tissue other than the site of ALA overproduction. Administration of large doses of ALA to normal subjects also leads to substantial coproporphyrinuria. Increased erythrocyte protoporphyrin may, as in all other homozygous porphyrias, be explained by accumulation of earlier pathway intermediates in bone marrow erythroid cells during hemoglobin synthesis, followed by their transformation to protoporphyrin after hemoglobin synthesis is complete. Neurologic symptoms are attributed to neurotoxic effects of ALA, but this is unproven.

Clinical Manifestations

In most cases, symptoms resemble other acute porphyrias, including acute attacks of abdominal pain and neuropathy. Precipitating factors, such as exposure to harmful drugs, have not been evident in most cases. Four of the reported cases were adolescent males. A Swedish infant had more severe disease, with neurologic impairment and failure to thrive. A 63 yr old man in Belgium developed an acute motor polyneuropathy concurrently with a myeloproliferative disorder.

Laboratory Findings

Urinary ALA, coproporphyrin III, and erythrocyte zinc protoporphyrin are substantially increased. Urinary PBG is normal or slightly increased. Erythrocyte ALAD activity is markedly reduced and both parents should have approximately half-normal activity of this enzyme and normal urinary ALA.

Diagnosis and Differential Diagnosis

The 3 other acute porphyrias are characterized by substantial increases in both ALA and PBG. In contrast, ALA but not PBG is substantially increased in ADP. A marked deficiency of erythrocyte ALAD and half-normal activity in the parents support the diagnosis. Other causes of ALAD deficiency, such as **lead poisoning,** must be excluded. Succinylacetone accumulates in hereditary tyrosinemia type 1 and is structurally similar to ALA, inhibits ALAD, and can cause increased urinary excretion of ALA and clinical manifestations that resemble acute porphyria. Idiopathic acquired ALAD deficiency has been reported. Unlike lead poisoning, the deficient ALAD activity in ADP is not restored by the in vitro addition of sulfhydryl reagents such as dithiothreitol. Even if no other cause of ALAD deficiency is found, it is essential to confirm the diagnosis of ADP by molecular studies.

Treatment

Treatment experience is limited but is similar to other acute porphyrias. Glucose seems not very effective but may be tried for mild symptoms. Hemin therapy was apparently effective for acute attacks in adolescent male cases, and weekly infusions prevented attacks in 2 of these cases. Hemin was not effective either biochemically or clinically in the Swedish child with severe disease, and produced a biochemical response but no clinical improvement in the Belgian man with a late-onset form, who had a peripheral neuropathy but no acute attacks. Hemin is also effective in treating porphyria-like symptoms associated with hereditary tyrosinemia, and can significantly reduce urinary ALA and coproporphyrin in lead poisoning. Avoidance of drugs that are harmful in other acute porphyrias is advisable. Liver transplantation was not effective in the child with severe disease.

Prognosis

The outlook is generally good in typical cases, although recurrent attacks may occur. The course was unfavorable in the Swedish child with more severe disease, and is uncertain in adults with late-onset disease associated with myeloproliferative disorders.

Prevention and Genetic Counseling

Heterozygous parents should be aware that subsequent children are at risk for the disease, as in any autosomal recessive disorder. Prenatal diagnosis is possible, but has not been reported.

ACUTE INTERMITTENT PORPHYRIA

This disorder is also termed *pyrroloporphyria, Swedish porphyria,* and *intermittent acute porphyria* and is the most common type of acute porphyria in most countries.

Etiology

AIP results from the deficient activity of the housekeeping form of PBGD. This enzyme is also known as hydroxymethylbilane (HMB)

synthase; the prior term, uroporphyrinogen I synthase, is obsolete. PBGD catalyzes the deamination and head-to-tail condensation of 4 PBG molecules to form the linear tetrapyrrole, HMB (also known as preuroporphyrinogen; see Fig. 91-1). A unique dipyrromethane cofactor binds the pyrrole intermediates at the catalytic site until 6 pyrroles (including the dipyrrole cofactor) are assembled in a linear fashion, after which the tetrapyrrole HMB is released. The apo-deaminase generates the dipyrrole cofactor to form the holodeaminase, and this occurs more readily from HMB than from PBG. Indeed, high concentrations of PBG may inhibit formation of the holodeaminase. The product HMB can cyclize nonenzymatically to form nonphysiologic uroporphyrinogen I, but in the presence of the next enzyme in the pathway is more rapidly cyclized to form uroporphyrinogen III.

Erythroid and housekeeping forms of the enzyme are encoded by a single gene on human chromosome 11 (11q24.1→q24.2), which contains 15 exons. The 2 isoenzymes are both monomeric proteins and differ only slightly in molecular weight (approximately 40 and 42 kDa, respectively), and result from alternative splicing of 2 distinct messenger RNA (mRNA) transcripts arising from 2 promoters. The housekeeping promoter functions in all cell types, including erythroid cells.

The pattern of inheritance of AIP is autosomal dominant, with very rare homozygous cases that present in childhood. More than 380 *PBGD* mutations, including missense, nonsense, and splicing mutations, and insertions and deletions have been identified in AIP, and in many population groups, including blacks. Most mutations are found in only 1 or a few families. But because of founder effects, some are more common in certain geographic areas such as northern Sweden (W198X), Holland (R116W), Argentina (G116R), Nova Scotia (R173W), and Switzerland (W283X). De novo mutations may be found in approximately 3% of cases. *Chester porphyria* was initially described as a variant form of acute porphyria in a large English family but was found to be caused by a *PBGD* mutation. The nature of the *PBGD* mutation does not account for the severity of the clinical presentation, which varies markedly within families.

Most mutations lead to approximately half-normal activity of the housekeeping and erythroid isozymes and half-normal amounts of their respective enzyme proteins in all tissues of heterozygotes. In approximately 5% of unrelated AIP patients, the housekeeping isozyme is deficient, but the erythroid-specific isozyme is normal. Mutations causing this variant are usually found within exon 1 or its 5′ splice donor site or initiation of translation codon. Immunochemical methods can distinguish mutations that are cross-reactive immunologic material (CRIM)–positive (i.e., having excess CRIM relative to the mutant enzyme activity), whereas CRIM-negative mutations either do not synthesize a mutant enzyme protein, or the protein is not stable and not immunologically detectable using anti-PBGD antibodies. A child with homozygous AIP was found to have inherited a different CRIM-positive mutation from each parent.

Pathology and Pathogenesis

Induction of the rate-limiting hepatic enzyme ALAS1 is thought to underlie acute exacerbations of this and the other acute porphyrias. AIP remains latent (or asymptomatic) in the great majority of those who are heterozygous carriers of *PBGD* mutations, and this is almost always the case before puberty. In those with no history of acute symptoms, porphyrin precursor excretion is usually normal, suggesting that half-normal hepatic PBGD activity is sufficient and hepatic ALAS1 activity is not increased. Many nongenetic factors that lead to clinical expression of AIP, including certain drugs and steroid hormones, have the capacity to induce hepatic ALAS1 and CYPs. Under conditions in which heme synthesis is increased in the liver, half-normal PBGD activity may become limiting and ALA, PBG, and other heme pathway intermediates may accumulate. In addition, heme synthesis becomes impaired and heme-mediated repression of hepatic ALAS1 is less effective.

It is not proven, however, that hepatic PBGD remains constant at approximately 50% of normal activity during exacerbations and remission of AIP, as in erythrocytes. An early report suggested that the enzyme activity is considerably less than half-normal in the liver during an acute attack. Hepatic PBGD activity might be reduced further once AIP becomes activated if, as suggested, excess PBG interferes with assembly of the dipyrromethane cofactor for this enzyme. It also seems likely that currently unknown genetic factors play a contributing role in, for example, patients who continue to have attacks even when known precipitants are avoided.

The fact that AIP is almost always latent before puberty suggests that **endocrine factors,** and especially adult levels of steroid hormones, are important for clinical expression. Symptoms are more common in women suggesting a role for female hormones. Premenstrual attacks are probably the result of endogenous progesterone. Acute porphyrias are sometimes exacerbated by exogenous steroids, including oral contraceptive preparations containing progestins. Surprisingly, pregnancy is usually well tolerated, suggesting that beneficial metabolic changes may ameliorate the effects of high levels of progesterone.

Drugs that are unsafe in acute porphyrias (Table 91-3) include those having the capacity to induce hepatic ALAS1, which is closely associated with induction of CYPs. Some chemicals (e.g., griseofulvin) can increase heme turnover by promoting the destruction of specific CYPs to form an inhibitor (e.g., *N*-methyl protoporphyrin) of ferrochelatase (FECH, the final enzyme in the pathway). Sulfonamide antibiotics are harmful but apparently not inducers of hepatic heme synthesis. Ethanol and other alcohols are inducers of ALAS1 and some CYPs.

Nutritional factors, principally reduced intake of calories and carbohydrates, as may occur with illness or attempts to lose weight, can increase porphyrin precursor excretion and induce attacks of porphyria. Increased carbohydrate intake may ameliorate attacks. Hepatic ALAS1 is modulated by the peroxisome proliferator-activated receptor γ coactivator-1α, which is an important link between nutritional status and exacerbations of acute porphyria.

Other factors have been implicated. Chemicals in cigarette smoke, such as polycyclic aromatic hydrocarbons, can induce hepatic CYPs and heme synthesis. A survey of AIP patients found an association between smoking and repeated porphyric attacks. Attacks may result from metabolic stress and impaired nutrition associated with major illness, infection, or surgery.

The additive effect of multiple predisposing factors, including drugs, endogenous hormones, nutritional factors, and smoking, is suggested by clinical observations. Exposure to drugs and other precipitating factors is less likely to cause an attack in patients who have had no recent symptoms than in those with recent and frequent porphyric symptoms.

Neurologic Mechanisms

The mechanism of neural damage in acute porphyrias is poorly understood. The most favored hypothesis at present is that 1 or more heme precursors, or perhaps a derivative, are neurotoxic. Increased ALA in AIP, HCP, VP, ADP, plumbism, and hereditary tyrosinemia type 1, which have similar neurologic manifestations, suggests that this substance or a derivative may be neuropathic. Porphyrins derived from ALA after its uptake into cells may have toxic potential. ALA can also interact with γ-aminobutyric acid receptors. Severe AIP improves markedly after allogeneic liver transplantation, which supports the hypothesis that heme precursors from the liver cause the neurologic manifestations.

Epidemiology

AIP occurs in all races and is the most common acute porphyria, with a roughly estimated prevalence in most countries of approximately 5 in 100,000. In Sweden, prevalence was estimated to be 7.7 in 100,000, including latent cases with normal porphyrin precursors. A much higher prevalence of 60-100 in 100,000 in northern Sweden is the result of a founder effect. The combined prevalence of AIP and VP in Finland is approximately 3.4 in 100,000. A survey of chronic psychiatric patients in the United States using an erythrocyte PBGD determination found a high prevalence (210 in 100,000) of PBGD deficiency, but a study in Mexico found a similar prevalence in psychiatric patients and controls. Population screening by erythrocyte PBGD activity or DNA analysis revealed a prevalence of 200 heterozygotes per 100,000

Table 91-3 Drugs Regarded as Unsafe and Safe in Acute Porphyrias

UNSAFE	SAFE
Barbiturates	Narcotic analgesics
Sulfonamide antibiotics*	Aspirin
Meprobamate* (also mebutamate,* tybutamate*)	Acetaminophen
Carisoprodol*	Phenothiazines
Glutethimide*	Penicillin and derivatives
Methyprylon	Streptomycin
Ethchlorvynol*	Glucocorticoids
Mephenytoin	Bromides
Phenytoin*	Insulin
Succinimides	Atropine
Carbamazepine*	Cimetidine
Clonazepam‡	Ranitidine†
Primidone*	Acetaminophen (paracetamol)
Valproic acid*	Acetazolamide
Pyrazolones (aminopyrine, antipyrine)	Allopurinol
Griseofulvin*	Amiloride
Ergots	Bethanidine
Metoclopramide*‡	Bumetanide
Rifampin*	Cimetidine
Pyrazinamide*‡	Coumarins
Diclofenac*‡	Fluoxetine
Progesterone and synthetic progestins*	Gabapentin
Danazol*	Gentamicin
Alcohol	Guanethidine
Angiotensin-converting enzyme inhibitors (especially enalapril)‡	Ofloxacin
Calcium channel blockers (especially nifedipine)‡	Propranolol
Ketoconazole	Succinylcholine Tetracycline

This partial listing does not include all available information about drug safety in acute porphyrias. Other sources should be consulted for drugs not listed here.

*Porphyria has been listed as a contraindication, warning, precaution, or adverse effect in U.S. labeling for these drugs. Estrogens are also listed as harmful in porphyria, but have been implicated as harmful in acute porphyrias mostly based only on experience with estrogen-progestin combinations. Although estrogens can exacerbate PCT, there is little evidence they are harmful in the acute porphyrias.

†Porphyria has been listed as a precaution in U.S. labeling for this drug. However, this drug is regarded as safe by other sources.

‡These drugs have been classified as probably safe by some sources, but this is controversial and they should be avoided.

people in Finland, and 1 in approximately 1,675 (60 in 100,000 people) in France. Therefore, carriers of *PBGD* mutations that can cause AIP may be common.

Clinical Manifestations

Neurovisceral manifestations of acute porphyrias may appear any time after puberty, but rarely before. Very rare cases of homozygous AIP develop severe neurologic manifestations early in childhood.

In affected heterozygotes, acute attacks are characterized by a constellation of nonspecific symptoms, which may become severe and life-threatening. **Abdominal pain** occurs in 85-95% of cases, is usually severe, steady, and poorly localized, but sometimes cramping, and accompanied by signs of ileus, including abdominal distention and decreased bowel sounds. Nausea, vomiting, and constipation are common, but increased bowel sounds and diarrhea may occur. Bladder dysfunction may cause hesitancy and dysuria. **Tachycardia,** the most common physical sign, occurs in up to 80% of attacks. This is often accompanied by hypertension, restlessness, coarse or fine tremors, and excess sweating, which are attributed to sympathetic overactivity and increased catecholamines. Other common manifestations include mental symptoms; pain in the extremities, head, neck, or chest; muscle weakness; and sensory loss. Because all these manifestations are neurologic rather than inflammatory, there is little or no abdominal tenderness, fever, or leukocytosis.

Porphyric neuropathy is primarily motor and appears to result from axonal degeneration rather than demyelinization. Sensory involvement is indicated by pain in the extremities, which may be described as muscle or bone pain, and by numbness, paresthesias, and dysesthesias. Paresis may occur early in an attack, but is more often a late manifestation in an attack that is not recognized and adequately treated. Rarely, severe neuropathy develops when there is little or no abdominal pain. Motor weakness most commonly begins in the proximal muscles of the upper extremities and then progresses to the lower extremities and the periphery. It is usually symmetric, but occasionally asymmetric or focal. Initially, tendon reflexes may be little affected or hyperactive and become decreased or absent. Cranial nerves, most commonly X and VII, may be affected, and blindness from involvement of the optic nerves or occipital lobes has been reported. More common central nervous system manifestations include seizures, anxiety, insomnia, depression, disorientation, hallucinations, and paranoia. Seizures may result from hyponatremia, porphyria itself, or an unrelated cause. Chronic depression and other mental symptoms occur in some patients, but attribution to porphyria is often difficult.

Hyponatremia is common during acute attacks. Inappropriate antidiuretic hormone secretion is often the most likely mechanism, but salt depletion from excess renal sodium loss, gastrointestinal loss, and poor intake have been suggested as causes of hyponatremia in some patients. Unexplained reductions in total blood and red blood cell volumes are sometimes found, and increased antidiuretic hormone secretion might then be an appropriate physiologic response. Other electrolyte abnormalities may include hypomagnesemia and hypercalcemia.

The attack usually resolves within several days, unless treatment is delayed. Abdominal pain may resolve within a few hours and paresis within a few days. Even severe motor neuropathy can improve over months or several years, but may leave some residual weakness. Progression of neuropathy to respiratory and bulbar paralysis and death is uncommon with appropriate treatment and removal of harmful drugs. Sudden death may result from cardiac arrhythmia.

Laboratory Findings

Levels of ALA and PBG are substantially increased during acute attacks and these may decrease after an attack but usually remain increased unless the disease becomes asymptomatic for a prolonged period. A population-based study in Sweden indicated that symptoms suggestive of porphyria may occur in heterozygotes during childhood, in contrast to adults, even when urinary porphyria precursors are not elevated. This study lacked a comparison with the frequency of such nonspecific symptoms in a control group of children.

Porphyrins are also markedly increased, which accounts for reddish urine in AIP. These are predominantly uroporphyrins, which can form nonenzymatically from PBG. But because the increased urinary porphyrins in AIP are predominantly isomer III, their formation is likely to be largely enzymatic, which might occur if excess ALA produced in the liver enters cells in other tissues and is then converted to porphyrins via the heme biosynthetic pathway. Porphobilin, a degradation product of PBG, and dipyrrylmethenes appear to account for brownish

urinary discoloration. Total fecal porphyrins and plasma porphyrins are normal or slightly increased in AIP. Erythrocyte protoporphyrin may be somewhat increased in patients with manifest AIP.

Erythrocyte PBGD activity is approximately half-normal in most patients (70-80%) with AIP. The normal range is wide and overlaps with the range for AIP heterozygotes. As noted, some PBGD gene mutations cause the enzyme to be deficient only in nonerythroid tissues. PBGD activity is also highly dependent on erythrocyte age, and an increase in erythropoiesis from concurrent illness in an AIP patient may raise the activity into the normal range.

Diagnosis and Differential Diagnosis

An increased urinary PBG establishes that a patient has 1 of the 3 most common acute porphyrias (see Table 91-2). Measuring PBG in serum is preferred when there is coexistent severe renal disease, but is less sensitive when renal function is normal. Measurement of urinary ALA is less sensitive than PBG and also less specific, but will detect ADP, the fourth type of acute porphyria. Erythrocyte PBGD activity is decreased in most AIP patients and helps confirm the diagnosis in a patient with high PBG. A normal enzyme activity in erythrocytes does not exclude AIP.

Knowledge of the *PBGD* mutation in a family enables reliable identification of other gene carriers. PBGD deficiency can be documented in a fetus by finding a *PBGD* mutation in these cells.

Complications

AIP and other acute porphyrias are commonly associated with mild abnormalities in liver function tests. The risk of more advanced liver disease and hepatocellular carcinoma is also increased during adult life, perhaps 60-70–fold, even in asymptomatic individuals who have increased porphyrins or porphyrin precursors. Few patients who developed this neoplasm had increases in serum α-fetoprotein. Patients with acute porphyrias, especially older than age 50 yr must be screened at least yearly by ultrasound or an alternative imaging method.

The risk of chronic hypertension and impaired renal function, most often with evidence of interstitial nephritis, is increased in AIP. A nephrotoxic effect of ALA may contribute. This may progress to severe renal failure and require renal transplantation.

Increased serum thyroxin levels because of increased thyroxin-binding globulin occur in some AIP patients. Hypercholesterolemia and elevated low-density lipoprotein cholesterol appear to be less common in this disorder than previously thought.

Treatment

Hemin

Intravenous hemin, combined with symptomatic and supportive measures, is the treatment of choice for most acute attacks of porphyria. There is a favorable biochemical and clinical response to early treatment with hemin, but less rapid clinical improvement if treatment is delayed. It is no longer recommended that therapy with hemin for a severe attack be started only after an unsuccessful trial of intravenous glucose for several days. Mild attacks, without severe manifestations such as paresis and hyponatremia, may be treated initially with intravenous glucose. After intravenous administration, hemin binds to hemopexin and albumin in plasma and is taken up primarily in hepatocytes. Hemin then enters and augments the regulatory heme pool in hepatocytes, represses the synthesis of hepatic ALAS1, and dramatically reduces porphyrin precursor overproduction.

Hemin* is available for IV administration in the United States as a lyophilized hematin preparation (Panhematin, Recordati). Degradation products begin to form as soon as the lyophilized product is reconstituted with sterile water, and these are responsible for phlebitis at the site of infusion and a transient anticoagulant effect. Loss of venous access due to phlebitis is common after repeated administration. Stabilization of lyophilized hematin by reconstitution with 30% human albumin can prevent these adverse effects, and is recommended, especially if a peripheral vein is used for the infusion. Uncommon side effects of hemin include fever, aching, malaise, hemolysis, anaphylaxis, and circulatory collapse. Heme arginate, a more stable hemin preparation, is available in Europe and South Africa.

Hemin treatment should be instituted only after a diagnosis of acute porphyria has been initially confirmed by a marked increase in urinary PBG (determined most rapidly using a kit). When prior documentation of the diagnosis is available for review, it is not essential to confirm an increase in PBG with every recurrent attack, if other causes of the symptoms are excluded clinically. The standard regimen of hemin for treatment of acute porphyric attacks is 3-4 mg/kg daily for 4 days. Lower doses have less effect on porphyrin precursor excretion and probably less clinical benefit.

*Hemin is the generic name for all heme preparations used for intravenous administration. Hemin is also a chemical term that refers to the oxidized (ferric) form of heme (iron protoporphyrin IX), and is usually isolated as hemin chloride. In alkaline solution, the chloride is replaced by the hydroxyl ion, forming hydroxyheme, or hematin.

General and Supportive Measures

Drugs that may exacerbate porphyrias (see Table 91-3) should be discontinued whenever possible, and other precipitating factors identified. Hospitalization is warranted, except for mild attacks, for treatment of severe pain, nausea, and vomiting; for administration of hemin and fluids; and for monitoring vital capacity, nutritional status, neurologic function, and electrolytes. Pain usually requires a narcotic analgesic; there is low risk for addiction after recovery from the acute attack. Ondansetron or a phenothiazine such as chlorpromazine is needed for nausea, vomiting, anxiety, and restlessness. Chloral hydrate or low doses of short-acting benzodiazepines can be given for restlessness or insomnia. β-Adrenergic blocking agents may be useful during acute attacks to control tachycardia and hypertension, but may be hazardous in patients with hypovolemia and incipient cardiac failure.

Carbohydrate Loading

The effects of carbohydrates on repressing hepatic ALAS1 and reducing porphyrin precursor excretion are weak compared to those of hemin. Therefore, only mild attacks (mild pain, no paresis or hyponatremia) are treated with carbohydrate loading. Glucose polymer solutions by mouth are sometimes tolerated. At least 300 g of intravenous glucose, usually given as a 10% solution, has been recommended for adults hospitalized with attacks of porphyria. Amounts up to 500 g daily may be more effective, but large volumes may favor development of hyponatremia.

Other Therapies

Liver transplantation was effective in several patients with severe AIP. A group from the United Kingdom reported their experience with liver transplantation in 10 AIP patients with significantly impaired quality of life and recurrent attacks which were refractory to medical management. Patients had a complete biochemical and symptomatic resolution posttransplantation; 2 patients in this series, however, succumbed to multiorgan failure posttransplantation. Liver transplantation is a high-risk procedure and should be considered as a last resort in patients with severe recurrent attacks that are refractory to other treatment. Cimetidine, a well-known inhibitor of hepatic CYPs, can prevent experimental forms of porphyria induced by chemical agents that undergo activation by these enzymes, but these models are not highly relevant to human AIP. The drug's use is based on uncontrolled observations.

Seizures and Other Complications

Seizures caused by hyponatremia or other electrolyte imbalances may not require prolonged treatment with anticonvulsant drugs, most of which have at least some potential for exacerbating acute porphyrias. Bromides, gabapentin, and probably vigabatrin are safe. Clonazepam may be less harmful than phenytoin or barbiturates. Control of hypertension may help prevent chronic renal impairment, which can progress and require renal transplantation.

Safe and Unsafe Drugs

Patients often do well with avoidance of harmful drugs. Table 91-3 lists some drugs known or strongly suspected to be harmful or safe in the

acute porphyrias. More extensive listings are available on websites of the European Porphyria Network (www.porphyria-europe.com) and the American Porphyria Foundation (www.porphyriafoundation.com), but some listings are controversial. Information regarding safety is lacking for many drugs, especially for those recently introduced.

Exogenous progestins, usually in combination with estrogens, can induce attacks of porphyria. Estrogens are seldom reported to be harmful when given alone or in animal and hepatocyte culture systems. Synthetic steroids with an ethynyl substituent can cause a mechanism-based destruction of hepatic CYPs and should probably be avoided in patients with acute porphyria. Danazol is especially contraindicated.

Other Situations

Major surgery can be carried out safely in patients with acute porphyria, especially if barbiturates are avoided. Halothane has been recommended as an inhalation agent and propofol and midazolam as intravenous induction agents.

Pregnancy is usually well tolerated, which is surprising, because levels of progesterone, a potent inducer of hepatic ALAS1, are considerably increased during pregnancy. Some women do experience continuing attacks during pregnancy. This has sometimes been attributed to reduced caloric intake or metoclopramide, a drug sometimes used to treat hyperemesis gravidarum and considered harmful in acute porphyrias.

Diabetes mellitus and other endocrine conditions are not known to precipitate attacks of porphyria. In fact, the onset of diabetes mellitus and resulting high circulating glucose levels may decrease the frequency of attacks and lower porphyrin precursor levels in AIP.

Prognosis

The outlook for patients with acute porphyrias has improved markedly in the past several decades. In Finland, for example, 74% of patients with AIP or VP reported that they led normal lives, and <30% had recurrent attacks during several years of follow-up. In those presenting with acute symptoms, recurrent attacks were most likely within the next 1-3 yr. Moreover, only 6% of gene carriers who had never had attacks developed symptoms. The improved outlook may result from earlier detection, better treatment of acute attacks, and replacement of harmful drugs such as barbiturates and sulfonamides with safer drugs. Some patients continue to have recurrent attacks, chronic pain, and other symptoms even after avoiding known exacerbating factors.

Prevention

For prevention of attacks, it is important to identify multiple inciting factors and remove as many as possible. Drugs for concurrent medical conditions should be reviewed. Because dietary factors are often inapparent, consultation with a dietitian may be useful. A well-balanced diet that is somewhat high in carbohydrate (60-70% of total calories) and sufficient to maintain weight is recommended. There is little evidence that additional dietary carbohydrate helps further in preventing attacks, and it may lead to weight gain. Patients who wish to lose excess weight should do so gradually and when they are clinically stable. Rapid weight loss after bariatric surgery may exacerbate acute porphyrias. Iron deficiency, which can be detected by a low serum ferritin, should be corrected.

Gonadotropin-releasing hormone analogs, which reversibly suppress ovulation, can be dramatically effective for preventing frequently recurring luteal phase attacks, but baseline and continuing gynecologic evaluation and bone density measurements are important, and transdermal estrogen or a bisphosphonate may be added to prevent bone loss. Hemin administered once or twice weekly can prevent frequent, noncyclic attacks of porphyria in some patients.

Genetic Counseling

Children with a family history of porphyria are often seen by pediatricians for evaluation and counseling. Information and laboratory results from a relative with proven porphyria must be reviewed in order to guide testing of the child, which is different depending on the type of acute porphyria. A mutation identified in the index case can be sought in the child. If the child is found to have inherited the mutation, counseling to avoid potentially harmful drugs is appropriate. Counseling should also emphasize that the great majority of those who inherit a *PBGD* mutation never develop symptoms, and the prognosis of those who do is favorable. Therefore, a normal, healthy life is expected, especially with avoidance of harmful drugs and other factors and prompt recognition and treatment of symptoms should they occur. Given the favorable outlook for most mutation carriers, even during pregnancy, having children is not precluded, and prenatal diagnosis of acute porphyrias is less important than it is for many other inherited diseases.

CONGENITAL ERYTHROPOIETIC PORPHYRIA

Also termed *Günther disease,* this rare disease usually presents with photosensitivity shortly after birth or in utero as nonimmune hydrops.

Etiology

CEP is an autosomal recessive disease caused by a marked deficiency of uroporphyrinogen III synthase (UROS). Many *UROS* mutations have been identified among CEP families. Later-onset disease in adults is likely to be associated with myeloproliferative disorders and expansion of a clone of erythroblasts that carry a *UROS* mutation.

Pathology and Pathogenesis

UROS, which is markedly deficient in CEP, catalyzes inversion of pyrrole ring D of HMB (the pyrrole ring shown on the right end of the molecule in Fig. 91-1) and rapid cyclization of the linear tetrapyrrole to form uroporphyrinogen III. This enzyme is also termed *uroporphyrinogen III cosynthase.* The human enzyme is a monomer. The gene for the enzyme is found on chromosome 10q25.3→q26.3, and contains 10 exons. Erythroid and housekeeping transcripts are generated by alternative promoters but encode the same enzyme.

In CEP, HMB accumulates in erythroid cells during hemoglobin synthesis and cyclizes nonenzymatically to form uroporphyrinogen I, which is auto-oxidized to uroporphyrin I. Some of the uroporphyrinogen I that accumulates is metabolized to coproporphyrinogen I, which accumulates because it is not a substrate for coproporphyrinogen oxidase. Thus, both uroporphyrin I and coproporphyrin I accumulate in the bone marrow and are then found in circulating erythrocytes, plasma, urine, and feces.

A variety of *UROS* mutations have been identified in CEP, including missense and nonsense mutations, large and small deletions and insertions, splicing defects, and intronic branch point mutations. At least 4 mutations have been identified in the erythroid-specific promoter. Many patients inherited a different mutation from each parent, and most mutations have been detected in only 1 or a few families. An exception is a common mutation, C73R, which is at a mutational hotspot and was found in ≈33% of alleles. One child with CEP had a *GATA1* mutation, with no *UROS* mutation. The CEP phenotype may be modulated by gain of function *ALAS2* mutations, which were first identified as causing XLP.

Genotype–phenotype correlations have been based on the in vitro expression of various CEP mutations and the severity of associated phenotypic manifestations. The C73R allele, which is associated with a severe phenotype in homozygotes or in patients heteroallelic for C73R and another mutation expressing little residual activity, resulted in <1% of normal enzyme activity. Patients with the C73R allele and heteroallelic for other mutations expressing more residual activity have milder disease.

Hemolysis is a common feature of CEP. Excess porphyrins in circulating erythrocytes cause cell damage, perhaps by a phototoxic mechanism, leading to both intravascular hemolysis and increased splenic clearance of erythrocytes. Also important is ineffective erythropoiesis, with intramedullary destruction of porphyrin-laden erythroid cells and breakdown of heme. Expansion of the bone marrow as a result of erythroid hyperplasia may contribute to **bone loss.** Nutrient deficiencies sometimes cause erythroid hypoplasia. Despite the marked deficiency of UROS, heme production in the bone marrow is increased because of hemolysis and a compensatory increase in hemoglobin

Figure 91-2 Congenital erythropoietic porphyria. The diaper of an affected baby demonstrates the red color of urine. *(From Paller AS, Macini AJ:* Hurwitz clinical pediatric dermatology, *ed 3, Philadelphia, 2006, Elsevier Saunders, p. 517.)*

Figure 91-3 Congenital erythropoietic porphyria. Vesicles, bullae, and crusts on sun-exposed areas. *(From Paller AS, Macini AJ:* Hurwitz clinical pediatric dermatology, *ed 3, Philadelphia, 2006, Elsevier Saunders, p. 517.)*

Figure 91-4 Congenital erythropoietic porphyria. Brownish teeth that fluoresce under Wood lamp examination. *(From Paller AS, Macini AJ:* Hurwitz clinical pediatric dermatology, *ed 3, Philadelphia, 2006, Elsevier Saunders, p. 517.)*

production. This occurs, however, at the expense of marked accumulation of HMB, which is converted to porphyrinogens and porphyrins.

Clinical Manifestations

In severe cases, CEP can cause fetal loss, or be recognized in utero as intrauterine hemolytic anemia and **nonimmune hydrops fetalis.** CEP may be associated with neonatal hyperbilirubinemia, and **phototherapy may unintentionally induce severe photosensitivity and scarring.**

The most characteristic presentation is reddish urine or pink staining of diapers by urine or meconium shortly after birth (Fig. 91-2). With sun exposure, severe blistering lesions appear on exposed areas of skin on the face and hands, and have been termed *hydroa aestivale* because they are more severe with greater sunlight exposure during summer (Fig. 91-3). Vesicles and bullae, as well as friability, hypertrichosis, scarring, thickening, and areas of hypopigmentation and hyperpigmentation are very similar to those seen in PCT but usually much more severe. Infection and scarring sometimes cause loss of facial features and fingers and damage to the cornea, ears, and nails. Porphyrins are deposited in dentine and bone in utero. Reddish-brown teeth in normal light, an appearance termed **erythrodontia,** display reddish fluorescence under long-wave UV light (Fig. 91-4). Unaffected children born to a mother with CEP may have erythrodontia. Hemolysis and splenomegaly are common in CEP. Bone marrow compensation may be adequate, especially in milder cases. Patients with severe phenotypes, however, are often transfusion-dependent. Splenomegaly may contribute to the anemia and cause leukopenia and thrombocytopenia, which may be complicated by significant bleeding. Neuropathic symptoms are absent, and there is no sensitivity to drugs, hormones, and carbohydrate restriction. The liver may be damaged by iron overload or viral hepatitis acquired from blood transfusions.

Milder cases of CEP with onset of symptoms in adult life and without erythrodontia may mimic PCT. These late-onset cases are likely to be associated with myeloproliferative disorders, and expansion of a clone of cells carrying a *UROS* mutation.

Laboratory Findings

Urinary porphyrin excretion and circulating porphyrin levels in CEP are much higher than in almost all other porphyrias. Urinary porphyrin excretion can be as high as 50-100 mg daily, and consists mostly of uroporphyrin I and coproporphyrin I. ALA and PBG are normal. Fecal porphyrins are markedly increased, with a predominance of coproporphyrin I.

Marked increases in erythrocyte porphyrins in CEP consist mostly of uroporphyrin I and coproporphyrin I. These porphyrins are also increased in bone marrow, spleen, plasma, and, to a lesser extent, liver. The porphyrin pattern in erythrocytes is influenced by rates of erythropoiesis and erythroid maturation. A predominance of protoporphyrin has been noted in some CEP patients, and in 1 such patient, uroporphyrin and coproporphyrin increased when erythropoiesis was stimulated by blood removal.

Diagnosis and Differential Diagnosis

The diagnosis of CEP should be documented by full characterization of porphyrin patterns and identification of the underlying mutations. In later-onset cases, an underlying myeloproliferative disorder and a UROS somatic mutation should be suspected and studied in detail.

The clinical picture in hepatoerythropoietic porphyria (HEP) may be very similar, but the porphyrin patterns in urine and feces in HEP resemble PCT. A predominant increase in erythrocyte protoporphyrin is unusual in CEP but is characteristic of HEP, and rare homozygous cases of AIP, HCP, and VP. EPP is also distinguished by normal urinary porphyrins and by increases in erythrocyte metal-free protoporphyrin, whereas the increased protoporphyrin in other conditions is complexed with zinc.

CEP should be suspected as a cause of nonimmune hydrops or hemolytic anemia in utero. With recognition of the disease at this stage, intrauterine transfusion can be considered, and severe, scarring photosensitivity from phototherapy for hyperbilirubinemia avoided. Prenatal diagnosis is feasible by finding red-brown discoloration and increased porphyrins in amniotic fluid, and measuring porphyrins in fetal erythrocytes and plasma. UROS activity can be measured in cultured amniotic fluid cells, or *UROS* mutations identified in chorionic villi or cultured amniotic cells.

Treatment

Protection from sunlight exposure, minimizing skin trauma, and prompt treatment of any cutaneous infections are highly important in managing CEP. Sunscreen lotions and beta-carotene are sometimes beneficial. Transfusions to achieve a level of hemoglobin sufficient to suppress erythropoiesis significantly can be quite effective in reducing porphyrin levels and photosensitivity. Concurrent deferoxamine to reduce iron overload, and hydroxyurea to suppress erythropoiesis further may provide additional benefit. Splenectomy reduces hemolysis and transfusion requirements in some patients. Oral charcoal may increase fecal loss of porphyrins, but may contribute little in more severe cases. Intravenous hemin may be somewhat effective, but has not been extensively studied and seems unlikely to provide long-term benefit.

The most effective treatment is bone marrow or stem cell transplantation in early childhood, which has markedly reduced porphyrin levels and photosensitivity and increased long-term survival.

Prognosis

The outlook is favorable in milder cases and in patients with more severe disease especially after successful bone marrow or stem cell transplantation.

Prevention and Genetic Counseling

Genetic counseling is important for affected families, because CEP can be recognized before birth and a severe phenotype can often be predicted by identifying the nature of the UROS mutations.

PORPHYRIA CUTANEA TARDA

PCT is the most common and readily treated human porphyria (see Table 91-2). It occurs in mid or late adult life, and is rare in children. Previous terms include *symptomatic porphyria, PCT symptomatica,* and *idiosyncratic porphyria.* The underlying cause is a liver-specific, acquired deficiency of uroporphyrinogen decarboxylase (UROD) with contributions by several types of genetic and acquired factors. Heterozygous *UROD* mutations are found in familial PCT. HEP, the homozygous form of familial PCT, usually has a more severe presentation in childhood, resembling CEP clinically.

Etiology

PCT is caused by a reduction of hepatic UROD activity to 20% of normal activity or less. An inhibitor of hepatic UROD has been characterized as uroporphomethene, which is derived from partial oxidation of the enzyme substrate uroporphyrinogen. CYPs, such as CYP1A2, as well as iron, are involved in its formation (Fig. 91-5). Although enzyme activity is inhibited, the amount of hepatic enzyme protein measured immunochemically remains at its genetically determined level.

UROD catalyzes the decarboxylation of the 4 acetic acid side chains of uroporphyrinogen (an octacarboxyl porphyrinogen) to form

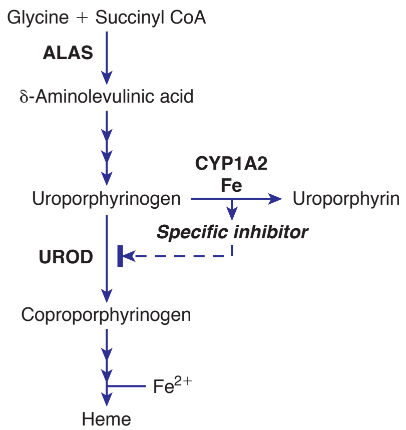

Figure 91-5 Formation of a specific inhibitor of uroporphyrinogen decarboxylase in the liver in porphyria cutanea tarda. ALAS, δ-aminolevulinic acid synthase; CYP1A2, cytochrome P450 1A2; UROD, uroporphyrinogen decarboxylase.

coproporphyrinogen (a tetracarboxyl porphyrinogen) (see Fig. 91-1). The enzyme reaction occurs in a sequential, clockwise fashion, with the intermediate formation of hepta-, hexa-, and pentacarboxyl porphyrinogens. Uroporphyrinogen III, as compared with other uroporphyrinogen isomers, is the preferred substrate. Human UROD is a dimer with the 2 active site clefts juxtaposed. The UROD gene is on chromosome 1p34 and contains 10 exons, with only 1 promoter. Therefore, the gene is transcribed as a single mRNA in all tissues.

The majority of PCT patients (i.e., ≈80%) have no *UROD* mutations and are said to have sporadic (type 1) disease. Some are heterozygous for *UROD* mutations and are said to have familial (type 2) PCT. Described mutations include missense, nonsense, and splice-site mutations, several small and large deletions, and small insertions, with only a few identified in more than 1 family. A few of these mutations may be located near the active site cleft, but most appear to involve regions with important structural roles. Being heterozygous for a *UROD* mutation is insufficient to cause PCT unless a UROD inhibitor is also generated. Because penetrance of the genetic trait is low, many patients with familial PCT have no family history of the disease.

Induction of hepatic ALAS1 is not a prominent feature in PCT, although alcohol may increase this enzyme slightly. Iron and estrogens are also not potent inducers of ALAS1 and drugs that are potent inducers of ALAS1 and CYPs are much less commonly implicated in PCT than in acute porphyrias.

Blistering skin lesions result from porphyrins that are released from the liver. Sunlight exposure leads to generation of reactive oxygen species in the skin, complement activation, and lysosomal damage.

Epidemiology

Differences in prevalence probably relate to geographic variations in susceptibility factors such as hepatitis C and ethanol use. The yearly incidence in the United Kingdom was estimated at 2-5 in 1,000,000 in the general population, and the prevalence in the United States and Czechoslovakia was estimated at approximately 1 in 25,000 and 1 in 5,000 in the general population, respectively. The disease was reported to be prevalent in the Bantus of South Africa in association with iron overload. PCT is more common in males, possible because of greater alcohol intake, and in women it is commonly associated with estrogen use.

A massive outbreak of PCT occurred in eastern Turkey in the 1950s. Wheat intended for planting and treated with hexachlorobenzene as a fungicide was consumed by many at a time of food shortage. Cases and small outbreaks of PCT after exposure to other chemicals including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, dioxin) have been reported. The manifestations improved in most cases when the exposure was stopped. There are reported cases of delayed onset many years after chemical exposure.

Pathology and Pathogenesis

PCT is currently classified into 3 clinically similar types. Generation of a UROD inhibitor in the liver plays an important role in all 3 types. The 80% of patients with **type 1 (sporadic)** PCT have no UROD mutations, and UROD activity is normal in nonhepatic tissues such as erythrocytes. In **familial (type 2)** PCT, a heterozygous *UROD* mutation results in a partial (approximately 50%) deficiency of UROD in all tissues from birth, and the disease becomes active in some heterozygotes when other susceptibility factors are present and a UROD inhibitor is generated in the liver, reducing hepatic UROD activity to 20% of normal or less. HEP results from inheritance of a *UROD* mutation from each parent and typically cause severe photosensitivity resembling CEP starting in early childhood. Some compound heterozygotes have developed symptoms in childhood more typical of PCT. **Type 3** is rare, and describes PCT with normal erythrocyte UROD activity occurring in more than 1 family member. Another genetic basis, such as *HFE* mutations, may be identified in type 3.

CYPs, especially CYP1A2, can catalyze the oxidation of uroporphyrinogen to uroporphyrin. This uroporphyrinogen oxidase activity is

enhanced by iron, and leads to formation of a UROD inhibitor (see Fig. 91-5). CYP1a2 seems essential for development of uroporphyria in rodents, because experimental uroporphyria does not develop in *CYP1a2* knockout mice.

Susceptibility Factors

The following factors are implicated in the development of PCT, and these occur in various combinations in individual patients.

Iron

A normal or increased amount of iron in the liver is essential for developing PCT, and treatment by phlebotomy to reduce hepatic iron leads to remission. Serum ferritin levels are usually in the upper part of the normal range or moderately increased and liver histology commonly shows increased iron staining. Prevalence of the C282Y mutation of the *HFE* gene, which is the major cause of hemochromatosis in people of northern European ancestry, is increased in both type 1 and type 2 PCT, and approximately 10% of patients are C282Y homozygotes. In southern Europe, the H63D mutation is more commonly associated. PCT may develop in patients with secondary iron overload. Reduced hepatic expression of the hormone hepcidin occurs in hemochromatosis and also in PCT, regardless of *HFE* genotype, which may explain hepatic siderosis in this condition.

Hepatitis C

This viral infection is highly prevalent in PCT in most geographic locations; in the United States, for example, it is present in 56-74% of cases, which is similar to rates in southern Europe. Prevalence of hepatitis C in PCT is lower in northern Europe (<20%). Steatosis and oxidative stress in hepatitis C may favor iron-mediated generation of reactive oxygen species and a UROD inhibitor. Dysregulation of hepcidin occurs in hepatitis C and may lead to increased iron absorption.

HIV

Many reports suggest that HIV infection can contribute to the development of PCT, although less commonly than does hepatitis C.

Ethanol

The long-recognized association between alcohol and PCT may be explained by the generation of active oxygen species, which may cause oxidative damage, mitochondrial injury, depletion of reduced glutathione and other antioxidant defenses, increased production of endotoxin, and activation of Kupffer cells. Alcohol may contribute to iron overload by impairing hepcidin production.

Smoking and Cytochrome P450 Enzymes

Smoking has not been extensively studied as a susceptibility factor but is commonly associated with alcohol use in PCT. It may act to induce hepatic CYPs and oxidative stress. Hepatic CYPs are thought to be important in oxidizing uroporphyrinogen and generating a UROD inhibitor (see Fig. 91-5). Genetic polymorphisms of *CYP1A2* and *1A1* have been implicated in human PCT. The frequency of an inducible *CYP1A2* genotype was more common in PCT patients than in controls in several studies.

Antioxidant Status

Ascorbic acid deficiency contributes to uroporphyria in laboratory models and perhaps in human PCT. In 1 series, plasma ascorbate levels were substantially reduced in 84% of patients with PCT. Low levels of serum carotenoids were also described, further suggesting that oxidant stress in hepatocytes is important in PCT.

Estrogens

Use of estrogen-containing oral contraceptives or postmenopausal estrogen replacement is very commonly associated with PCT (type 1 or 2) in women. PCT sometimes occurs during pregnancy, although it is not clear whether the risk is increased.

Clinical Manifestations

Cutaneous Manifestations

PCT is readily recognized by blistering and crusted skin lesions on the backs of the hands, which are the most sun-exposed areas of the body, and somewhat less commonly on the forearms, face, ears, neck, legs, and feet. The fluid-filled vesicles commonly rupture and become crusted or denuded areas, heal slowly, and are subject to infection. The skin on the backs of the hands is characteristically friable, and minor trauma may cause blisters or denudation of skin. Small white plaques, termed milia, may precede or follow vesicle formation. Facial hypertrichosis and hyperpigmentation are also common. Severe scarring and thickening of sun-exposed skin may resemble scleroderma. Skin biopsy findings include subepidermal blistering and deposition of periodic acid–Schiff-positive material around blood vessels and fine fibrillar material at the dermoepithelial junction, which may relate to excessive skin fragility. Immunoglobulin G, other immunoglobulins, and complement are also deposited at the dermoepithelial junction and around dermal blood vessels. The skin lesions and histologic changes are not specific for PCT. The same findings occur in VP and HCP, and resemble those of CEP and HEP, but are usually less severe. PCT usually develops in mid or late adult life. Earlier onset may be seen in those with UROD or *HFE* mutations. Childhood onset is rare, and suggests heterozygosity or even compound heterozygosity for UROD mutations.

Liver Abnormalities

PCT is almost always associated with nonspecific liver abnormalities, especially increased serum transaminases and γ-glutamyltranspeptidase, even in the absence of heavy alcohol intake or hepatitis C. Most histologic findings, such as necrosis, inflammation, increased iron, and increased fat, are nonspecific. Specific findings include red fluorescence of liver tissue, and fluorescent, birefringent, needle-like inclusions presumably consisting of porphyrins. Electron microscopy shows these inclusions are in lysosomes, and paracrystalline inclusions are found in mitochondria. Distorted lobular architecture and cirrhosis are more common with long-standing disease.

The risk of developing hepatocellular carcinoma is increased, with reported incidences ranging from 4-47% in PCT. These tumors seldom contain large amounts of porphyrins.

Other Findings and Associations

Mild or moderate erythrocytosis in some adult patients is not well understood, but chronic lung disease from smoking may contribute. An earlier onset of symptoms may be noted in patients with genetic predisposing factors, such as an inherited partial deficiency of UROD or the C282Y/C282Y *HFE* genotype. Iron overload secondary to conditions such as myelofibrosis and end-stage renal disease may be associated with PCT. The disease can be especially severe in patients with end-stage renal disease, because the lack of urinary excretion leads to much higher concentrations of porphyrins in plasma, and the excess porphyrins are poorly dialyzable. PCT occurs more frequently in patients with systemic lupus erythematosus and other immunologic disorders than would have been expected by chance.

Laboratory Findings

Porphyrins accumulate in the liver mostly as the oxidized porphyrins rather than porphyrinogens in PCT, as indicated by the immediate red fluorescence observed in liver tissue. This develops over weeks or months before porphyrins appear in plasma and are transported to the skin, causing photosensitivity. In contrast to the acute hepatic porphyrias, only a very small increase in synthesis of heme pathway intermediates and little or no increase in hepatic ALAS1 are required to account for the excess porphyrins excreted in PCT.

Hepatic UROD deficiency leads to a complex pattern of excess porphyrins, which initially accumulate as porphyrinogens, and then undergo nonenzymatic oxidation to the corresponding porphyrins (uro-, hepta-, hexa-, and pentacarboxyl porphyrins, and isocoproporphyrins). Uroporphyrin and heptacarboxyl porphyrin predominate in

urine, with lesser amounts of coproporphyrin and penta- and hexacarboxyl porphyrin. A normally minor pathway is accentuated by UROD deficiency, whereby pentacarboxyl porphyrinogen is oxidized by coproporphyrinogen oxidase (CPOX; the next enzyme in the pathway), forming isocoproporphyrinogen, an atypical tetracarboxyl porphyrinogen. Relative to normal values, urinary porphyrins are increased to a greater extent than fecal porphyrins. However, the total amount of porphyrins excreted in feces in PCT exceeds that in urine, and total excretion of type III isomers (including isocoproporphyrins, which are mostly derived from the type III series) exceeds that of type I isomers. Perhaps because uroporphyrinogen III is the preferred substrate for UROD, more uroporphyrinogen I than III accumulates and is excreted in PCT. Hepta- and hexacarboxyl porphyrin are mostly isomer III; and pentacarboxyl porphyrin and coproporphyrin are approximately equal mixtures of isomers I and III.

Diagnosis and Differential Diagnosis

Plasma porphyrins are always increased in clinically manifest PCT, and a total plasma porphyrin determination is most useful for screening. A normal value rules out PCT and other porphyrias that produce blistering skin lesions. If increased, it is useful to determine the plasma fluorescence emission maximum at neutral pH, because a maximum near 619 nm is characteristic of PCT (as well as CEP and HCP) and, most important, excludes VP, which has a distinctly different fluorescence maximum. Increased urinary porphyrins, with a predominance of uroporphyrin and heptacarboxyl porphyrin, is confirmatory. Urine porphyrins are less useful for initial screening because nonspecific increases, especially of coproporphyrin, occur in liver disease and other medical conditions. Urinary ALA may be increased slightly, and PBG is normal.

Familial (type 2) can be distinguished from sporadic (type 1) PCT by finding decreased erythrocyte UROD activity (in type 2), or more reliably by finding a disease-related *UROD* mutation. Type 3 is distinguished from type 1 only by occurrence of PCT in a relative. Biochemical findings in HEP are similar to those in PCT, but with an additional marked increase in erythrocyte zinc protoporphyrin.

Pseudoporphyria (also known as pseudo-PCT) presents with skin lesions that closely resemble PCT, but without significant increases in plasma porphyrins. A photosensitizing drug such as a nonsteroidal antiinflammatory agent is sometimes implicated. Both PCT and pseudoporphyria may occur in patients with end-stage renal disease.

Complications

Cutaneous blisters may rupture and become infected, sometimes leading to cellulitis. In more-severe disease in patients with end-stage renal disease, repeated infections can be mutilating, as in CEP. Pseudoscleroderma, with scarring, contraction, and calcification of skin and subcutaneous tissue, is a rare complication. Other complications include advanced liver disease and hepatocellular carcinoma.

Treatment

Two specific and effective forms of treatment, namely phlebotomy or low-dose hydroxychloroquine, are available. Susceptibility factors should be removed when possible. The diagnosis of PCT must be firmly established, because conditions that produce identical cutaneous lesions do not respond to these treatments. Treatment can usually be started after demonstrating an increase in plasma total porphyrins and excluding VP by analysis of the fluorescence spectrum at neutral pH, while urine and fecal studies are still pending. Use of alcohol, estrogens (in women), and smoking should be stopped, and patients tested for hepatitis C, HIV, and *HFE* mutations. Some susceptibility factors and the degree of iron overload as assessed by the serum ferritin concentration, influence the choice of treatment.

Phlebotomy is considered standard therapy, and is effective both in children and adults with PCT because it reduces hepatic iron content. Treatment is guided by plasma (or serum) ferritin and porphyrin levels. Hemoglobin or hematocrit levels should be followed to prevent symptomatic anemia. For adults, a unit of blood (≈450 mL) is removed at about 2 wk intervals until a target serum ferritin near the lower limit of normal (≈15 ng/mL) is achieved. A total of 6-8 phlebotomies is often sufficient. After this, plasma porphyrin concentrations continue to fall from pretreatment levels (generally 10-25 µg/dL) to below the upper limit of normal (≈1 µg/dL), usually after several more weeks. This is followed by gradual clearing of skin lesions, sometimes including pseudoscleroderma. Liver function abnormalities may improve, and hepatic siderosis, needle-like inclusions, and red fluorescence of liver tissue will disappear. Although remission usually persists even if ferritin levels later return to normal, it is advisable to follow porphyrin levels and reinstitute phlebotomies if these begin to rise. Infusions of deferoxamine, an iron chelator, may be used when phlebotomy is contraindicated.

An alternative when phlebotomy is contraindicated or poorly tolerated is a low-dose regimen of hydroxychloroquine (or chloroquine). Normal doses of these 4-aminoquinoline antimalarials increase plasma and urinary porphyrin levels and increase photosensitivity in PCT, reflecting an outpouring of porphyrins from the liver. This is accompanied by acute hepatocellular damage, with fever, malaise, nausea, and increased serum transaminases, but is followed by complete remission of the porphyria. These adverse consequences of normal doses are largely avoided by a low-dose regimen (hydroxychloroquine 100 mg or chloroquine 125 mg, of a normal tablet, twice weekly), which can be continued until plasma or urine porphyrins are normalized. There is at least some risk of retinopathy, which may be lower with hydroxychloroquine. The mechanism of action of 4-aminoquinolines in PCT is not known but is quite specific, because these drugs are not useful in other porphyrias. Recent studies indicate that low-dose hydroxychloroquine is as safe and effective as phlebotomy in PCT.

In patients with PCT and hepatitis C, PCT should be treated first because this condition is more symptomatic and can be treated more quickly and effectively. Treatment of PCT by phlebotomy may not be possible once interferon-ribavirin treatment is complicated by anemia. Moreover, treatment of hepatitis C may be more effective after iron reduction.

PCT in patients with end-stage renal disease is often more severe and difficult to treat. However, erythropoietin administration can correct anemia, mobilize iron, and support phlebotomy in many cases. Improvement after renal transplantation may be partly from resumption of endogenous erythropoietic production.

Liver imaging and a serum α-fetoprotein determination may be advisable in all PCT patients, perhaps at 6-12 mo intervals, for early detection of hepatocellular carcinoma. Finding low-erythrocyte UROD activity or a *UROD* mutation identifies those with an underlying genetic predisposition, which does not alter treatment but is useful for genetic counseling.

Prognosis

PCT is the most readily treated form of porphyria, and complete remission is expected with treatment either by phlebotomy or low-dose hydroxychloroquine. There is little information on rates of recurrence and long-term outlook. Risk for hepatocellular carcinoma is increased, and some susceptibility factors such as hepatitis C can lead to complications even after PCT is in remission.

Prevention and Genetic Counseling

Patients with PCT may have concerns about risk to other family members. A heritable *UROD* mutation can usually be detected or excluded by measuring erythrocyte UROD activity, although DNA studies are more sensitive. Relatives of patients with *UROD* mutations have an increased risk for developing PCT, and may have increased motivation to avoid adverse behaviors such as ethanol and tobacco use and exposures to hepatitis C and HIV. Such counseling would be given to anyone, however. The finding of *HFE* mutations, and especially C282Y, should prompt screening of relatives, some of whom may be C282Y homozygotes and warrant lifelong monitoring of serum ferritin.

HEPATOERYTHROPOIETIC PORPHYRIA

HEP, which is the homozygous form of familial (type 2) PCT, resembles CEP clinically. Excess porphyrins originate mostly from liver, with

a pattern consistent with severe UROD deficiency. This rare disorder has no particular racial predominance.

Etiology
HEP is an autosomal recessive disorder, although most patients have inherited a different mutation from unrelated parents. In contrast to most mutations in familial (type 2) PCT, most causing HEP are associated with expression of some residual enzyme activity. At least 1 genotype is associated with the predominant excretion of pentacarboxyl porphyrin.

Pathology and Pathogenesis
Excess porphyrins originate primarily from the liver in HEP, although the substantial increase in erythrocyte zinc protoporphyrin indicates that the heme biosynthetic pathway is also impaired in bone marrow erythroid cells. Apparently, porphyrinogens accumulate in the marrow while hemoglobin synthesis is most active, and are metabolized to protoporphyrin after hemoglobin synthesis is complete. The cutaneous lesions are a result of photoactivation of porphyrins in skin, as in other cutaneous porphyrias.

Clinical Manifestations
Like CEP, this disease usually presents with blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood. Sclerodermoid skin changes are sometimes prominent. Unusually mild cases have been described. Concurrent conditions that affect liver function can alter disease severity. For example, the disease became manifest because of hepatitis A in a 2 yr old child, and then improved with recovery of liver function.

Laboratory Findings
Biochemical findings resemble those in PCT with accumulation and excretion of uroporphyrin, heptacarboxyl porphyrin, and isocoproporphyrin. But in addition, erythrocyte zinc protoporphyrin is substantially increased.

Diagnosis and Differential Diagnosis
HEP is distinguished from CEP by increases in both uroporphyrin and heptacarboxyl porphyrin, and isocoproporphyrins. In CEP, the excess erythrocyte porphyrins are predominantly uroporphyrin and coproporphyrin rather than protoporphyrin. Blistering skin lesions are unusual in EPP, the excess erythrocyte protoporphyrin in that disease is free and not complexed with zinc, and urinary porphyrins are normal.

Treatment and Prognosis
Avoiding sunlight exposure is most important in managing this disease, as in CEP. Oral charcoal was helpful in a severe case associated with dyserythropoiesis. Phlebotomy has shown little or no benefit. The outlook depends on the severity of the enzyme deficiency and may be favorable if sunlight can be avoided.

Prevention and Genetic Counseling
As part of genetic counseling in affected families, it is feasible to diagnose HEP in utero, either by analysis of porphyrins in amniotic fluid or DNA studies.

HEREDITARY COPROPORPHYRIA
This autosomal dominant hepatic porphyria is caused by a deficiency of CPOX. The disease presents with acute attacks, as in AIP. Cutaneous photosensitivity may occur, but much less commonly than in VP. Rare homozygous cases present in childhood.

Etiology
A partial (50%) deficiency in CPOX activity has been found in all cells studied from patients with HCP. A much more profound deficiency is found in homozygous cases. Human CPOX is a homodimer composed of 39 kDa subunits, and contains no metals or prosthetic groups. The enzyme requires molecular oxygen, and is localized in the mitochondrial intermembrane space. A single active site on the enzyme catalyzes the oxidative decarboxylation of 2 of the 4 propionic acid groups of coproporphyrinogen III to form the 2 vinyl groups at positions 2 and 4, on rings A and B, respectively, of protoporphyrinogen IX (see Fig. 91-1). Most of the intermediate tricarboxyl porphyrinogen, termed *harderoporphyrinogen,* is not released before undergoing the second decarboxylation to protoporphyrinogen IX. Coproporphyrinogen I is not a substrate for this enzyme.

The human *CPOX* gene contains 7 exons and is located on chromosome 3q12.1. A single promoter contains elements for both housekeeping and erythroid-specific expression. A variety of *CPOX* gene mutations have been described in HCP, with a predominance of missense mutations and no genotype-phenotype correlations. Harderoporphyria, an autosomal recessive biochemical variant form of HCP, is caused by *CPOX* mutations that impair substrate binding, leading to premature release of harderoporphyrinogen.

Epidemiology
HCP is less common than AIP and VP, but its prevalence has not been carefully estimated. There is no obvious racial predominance. Homozygous HCP is rare and presents during childhood. Harderoporphyria, a biochemically distinguishable variant of HCP, has been recognized in heteroallelic and homoallelic forms.

Pathology and Pathogenesis
Increased ALA and PBG during acute attacks of HCP may be explained by induction of ALAS1 and by the normally relatively low activity of PBGD in the liver. Hepatic ALAS1 is increased during acute attacks, but is normal when the disease is latent and porphyrin precursor excretion is normal. Because coproporphyrinogen III concentration in the liver is probably less than the K_m for CPOX, the reaction rate is likely to be determined in part by substrate concentration. The substrate coproporphyrinogen appears to be lost more readily from the liver cell than, for example, uroporphyrinogen, especially when heme synthesis is stimulated. Coproporphyrin and coproporphyrinogen are both transported into bile and excreted in urine, and do not appear to accumulate in the liver in HCP.

Clinical Manifestations
Symptoms are identical to those of AIP except that attacks are generally milder, and cutaneous lesions that resemble those in PCT develop occasionally. Severe motor neuropathy and respiratory paralysis can occur. Like other acute porphyrias, HCP is almost always latent before puberty, and symptoms are most common in adult women. Attacks are precipitated by the same factors that cause attacks in AIP, including fasting, oral contraceptive steroids, and hormone increases during the luteal phase of the menstrual cycle. Concomitant liver diseases may increase porphyrin retention and photosensitivity. The risk of hepatocellular carcinoma is increased, as in other acute porphyrias.

The clinical features of homozygous HCP or harderoporphyria, which begin in early childhood, may include jaundice, hemolytic anemia, hepatosplenomegaly, and skin photosensitivity. These symptoms are generally quite distinct from those seen in heterozygotes.

Laboratory Findings
The porphyrin precursors ALA and PBG are increased during acute attacks, but may decrease more rapidly than in AIP. Marked increases in coproporphyrin III in urine and feces are more persistent. In homozygous cases, porphyrin excretion may be more markedly increased and is accompanied by substantial increases in erythrocyte zinc protoporphyrin. Harderoporphyria is characterized by a marked increase in fecal excretion of harderoporphyrin (tricarboxyl porphyrin) as well as coproporphyrin. Plasma porphyrins are usually normal or only slightly increased.

Diagnosis and Differential Diagnosis
The diagnosis of HCP is readily established in patients with clinically manifest disease, although urinary ALA, PBG, and uroporphyrin may revert to normal more quickly than in AIP. Urinary coproporphyrin

III is increased. Urinary porphyrins, especially coproporphyrin, can be increased in many medical conditions such as liver disease, and small increases may not be clinically significant and lead to an incorrect diagnosis of HCP. Fecal porphyrins are mostly coproporphyrin (isomer III) in HCP, whereas in VP, coproporphyrin III and protoporphyrin are often increased approximately equally. Plasma porphyrins are usually normal in HCP and increased in VP.

The ratio of fecal coproporphyrin III to coproporphyrin I is especially sensitive for detecting latent heterozygotes (especially adults). Assays for CPOX, a mitochondrial enzyme, require cells such as lymphocytes and are not widely available. Identification of a *CPOX* mutation in an index case greatly facilitates screening family members.

Treatment and Prognosis

Acute attacks of HCP are treated as in AIP, which includes intravenous hemin and identifying and avoiding precipitating factors. Cholestyramine may be of some value for photosensitivity occurring with liver dysfunction. Phlebotomy and chloroquine are not effective. Gonadotropin-releasing hormone analogs can be effective for prevention of cyclic attacks. The prognosis is generally better than in AIP.

Prevention and Genetic Counseling

These are the same as in other acute porphyrias.

Variegate Porphyria

This hepatic porphyria is caused by a deficiency of protoporphyrinogen oxidase (PPOX), which is inherited as an autosomal dominant trait. The disorder is termed *variegate* because it can present with neurologic or cutaneous manifestations. Other terms have included *porphyria variegata, protocoproporphyria,* and *South African genetic porphyria.* Rare cases of homozygous VP are symptomatic in childhood.

Etiology

PPOX is approximately half normal in all cells studied in patients with VP. The enzyme is more markedly deficient in rare cases of homozygous VP, with approximately half-normal enzyme activity in parents.

Human PPOX is a homodimer that contains flavin adenine dinucleotide and is localized to the cytosolic side of the inner mitochondrial membrane. Membrane-binding domains may be docked onto human FECH, the next enzyme in the pathway, which is embedded in the opposite side of the membrane. PPOX catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX by the removal of 6 hydrogen atoms (see Fig. 91-1). The enzyme requires molecular oxygen. The substrate is readily oxidized nonenzymatically to protoporphyrin under aerobic conditions, or if exported into the cytosol. PPOX is highly specific for protoporphyrinogen IX, and is inhibited by tetrapyrroles such as heme, biliverdin, and bilirubin and by certain herbicides that cause protoporphyrin to accumulate and induce phototoxicity in plants. Inhibition by bilirubin may account for decreased PPOX activity in Gilbert disease.

The human *PPOX* gene on chromosome 1q22-q23 consists of 1 noncoding and 12 coding exons. A single PPOX transcript is produced in a variety of tissues, but putative transcriptional element binding sequences may allow for erythroid-specific expression. Many *PPOX* mutations have been reported in VP families. A missense mutation, R59W, is prevalent in South Africa. No convincing genotype–phenotype correlations have been identified. Mutations in homozygous cases of VP are more likely to encode enzyme proteins with residual activity.

Epidemiology

VP is less common than AIP in most countries. The R59W mutation is highly prevalent in South African whites (3 in 1,000 in this population). This example of genetic drift or "founder effect" has been traced to a man or his wife who emigrated from Holland to South Africa in 1688. In Finland, the prevalence is 1.3 in 100,000 people and is about as common as AIP.

Pathology and Pathogenesis

Acute attacks develop in a minority (approximately 25%) of heterozygotes for PPOX deficiency, and are often attributable to drugs, steroids, and nutritional factors that play a role in other acute porphyrias. Protoporphyrinogen IX accumulates and undergoes autoxidation to protoporphyrin IX. Coproporphyrinogen III may accumulate as the result of a close functional association between PPOX in the inner mitochondrial membrane and CPOX in the intermembrane space. Liver porphyrin content is not increased. The increased porphyrin content in plasma consists of porphyrin–peptide conjugates, which may be formed from protoporphyrinogen. Increased ALA and PBG during acute attacks may be explained, as in HCP, by induction of ALAS1 by exacerbating factors, and by the normally relatively low activity of PBGD in liver. Furthermore, PBGD is inhibited by protoporphyrinogen, the substrate for PPOX.

Clinical Manifestations

Symptoms develop in some heterozygotes after puberty. Neurovisceral symptoms occurring as acute attacks are identical to AIP but are generally milder and less often fatal. Drugs, steroids, and nutritional alterations such as fasting, which are harmful in AIP, can also induce attacks of VP. Attacks occur equally in males and females, at least in South Africa. Cutaneous fragility, vesicles, bullae, hyperpigmentation, and hypertrichosis of sun-exposed areas are much more common than in HCP. They are likely to occur apart from and be more long lasting than the neurovisceral symptoms. Oral contraceptives can precipitate cutaneous manifestations. Acute attacks have become less common, and skin manifestations are more frequently the initial presentation; this may be due to earlier diagnosis and counseling. The risk of hepatocellular carcinoma is increased.

Symptoms of homozygous VP begin in infancy or childhood. These children generally have severe photosensitivity, neurologic symptoms, convulsions, developmental disturbances, and sometimes growth retardation, but do not have acute attacks.

Laboratory Findings

Urinary ALA, PBG, and uroporphyrin are increased during acute attacks but often less so than in AIP, and may be normal or only slightly increased during remission. Plasma porphyrins, urinary coproporphyrin III, and fecal coproporphyrin III and protoporphyrin are more persistently increased between attacks. Erythrocyte zinc protoporphyrin levels are markedly increased in homozygous VP, and may be modestly increased in heterozygous cases.

Diagnosis and Differential Diagnosis

VP is readily distinguished from AIP and HCP, which also present with acute attacks and increases in PBG. Plasma porphyrin analysis is especially useful, because the plasma porphyrins in VP are tightly protein bound, resulting in a characteristic fluorescence emission spectrum at neutral pH. Fecal porphyrins are increased, with approximately equal amounts of coproporphyrin III and protoporphyrin. Fluorometric detection of plasma porphyrins is more sensitive than stool porphyrin analysis in asymptomatic VP. PPOX assays using cells that contain mitochondria, such as lymphocytes, are sensitive for identifying asymptomatic carriers but are not widely available. Knowing the *PPOX* mutation in an index case enables the identification of relatives who carry the same mutation.

Treatment

Acute attacks are treated as in AIP. Hemin is beneficial for acute attacks but not for cutaneous symptoms. Light protection is important in patients with skin manifestations, using long-sleeved clothing, gloves, a broad-brimmed hat, and opaque sunscreen preparations. Exposure to short-wavelength UV light, which does not excite porphyrins, may increase skin pigmentation and provide some protection. Phlebotomy and chloroquine are not effective. Surprisingly, oral activated charcoal was reported to increase porphyrin levels and worsen skin manifestations.

Prognosis and Prevention

The outlook of patients with VP has improved, which may be attributed to improved treatment, earlier diagnosis, and detection of latent cases. Cyclic acute attacks in women can be prevented with a gonadotropin-releasing hormone analog, as in AIP. A diagnosis of VP or any other acute porphyria should not lead to difficulty obtaining insurance, because the prognosis is usually good once the diagnosis is established.

Genetic Counseling

This is the same as in other acute porphyrias.

ERYTHROPOIETIC PROTOPORPHYRIA

In this autosomal recessive disorder, protoporphyrin accumulates as the result of a marked deficiency of FECH, the last enzyme in the heme biosynthetic pathway, because of *FECH* mutations. EPP is sometimes termed *protoporphyria* or *erythrohepatic protoporphyria,* although the liver does not contribute substantially to production of excess protoporphyrin in uncomplicated cases. XLP is a genetically distinct form of porphyria that is less common than EPP but with the same phenotype, and is a result of gain of function *ALAS2* mutations.

Etiology

FECH, the enzyme that is deficient in EPP, catalyzes the final step in heme synthesis, which is insertion of ferrous iron (Fe^{2+}) into protoporphyrin IX (see Fig. 91-1). The enzyme is also termed *heme synthetase* or *protoheme ferrolyase.* The human enzyme is a dimer, and each homodimer contains a [2Fe-2S] cluster, which may have a role in bridging homodimers. FECH is found in the mitochondrial inner membrane where its active site faces the mitochondrial matrix. It may be associated with complex I of the mitochondrial electron transport chain, and the ferrous iron substrate may be produced upon nicotinamide adenine dinucleotide oxidation. FECH is specific for the reduced form of iron, but can utilize other metals such as Zn^{2+} and Co^{2+} and other dicarboxyl porphyrins. Accumulation of free protoporphyrin rather than zinc protoporphyrin in EPP indicates that formation of the latter is dependent on FECH activity in vivo.

The human *FECH* gene is located on chromosome 18q21.3, has a single promoter sequence, and contains 11 exons. Two mRNAs of 1.6 and 2.5 kb were described, which may be explained by the use of 2 alternative polyadenylation signals. The larger transcript is more abundant in murine erythroid cells, suggesting erythroid-specific regulation of FECH. A variety of *FECH* mutations have been reported in EPP, including missense, nonsense, and splicing mutations, small and large deletions, and an insertion.

The inheritance of 2 alleles associated with reduced FECH activity is required for disease expression. This is consistent with FECH activities as low as 15-25% of normal in EPP patients. In most patients, a disabling mutation on 1 *FECH* allele is combined with a common variant affecting the other allele. This common variant *FECH* allele (IVS3-48T > C) produces less-than-normal amounts of enzyme because it expresses an aberrantly spliced mRNA that is degraded by a nonsense-mediated RNA decay mechanism. The IVS3-48T > C *FECH* variant by itself does not cause disease, even when homozygous. In a few families, 2 severe *FECH* mutations have been found, without the IVS3-48T > C allele. EPP with autosomal recessive inheritance occurs naturally in cattle and in mouse models.

XLP is associated with gain-of-function deletions in the last exon of *ALAS2*. These lesions delete the last 10-20 amino acids of the ALAS2 polypeptide and apparently make the enzyme more stable. Free protoporphyrin predominates in erythrocytes in these cases, but because FECH activity is normal the proportion of zinc protoporphyrin is greater than in classic EPP. XLP accounts for approximately 2% of cases with the EPP phenotype in Europe and approximately 10% of cases in North America.

EPP is sometimes associated with myelodysplastic syndromes and expansion of a clone of hematopoietic cells with deletion of one *FECH* allele or other *FECH* mutations. In such cases, there is late onset of the disease.

Epidemiology

EPP is the most common porphyria to cause symptoms in children, but is often not diagnosed until adult life. Overall it is the third most common porphyria, although its prevalence is not precisely known (see Table 91-2). It is described mostly in white people, but occurs in other races. The IVS3-48T > C splice variant is common in whites and East Asians, but rare in Africans, which explains lower disease prevalence in populations of African origin.

Pathology and Pathogenesis

FECH is deficient in all tissues in EPP, but bone marrow reticulocytes are thought to be the primary source of the excess protoporphyrin, some of which enters plasma and circulates to the skin. Circulating erythrocytes are no longer synthesizing heme and hemoglobin, but they contain excess free protoporphyrin, which also contributes. In XLP caused by terminal deletions in exon 11 of ALAS2, all intermediates of the heme pathway are overproduced and ultimately accumulate in bone marrow erythroblasts as protoporphyrin. FECH is not deficient in the variant form, and this enzyme chelates some of the excess protoporphyrin with zinc. An aberrantly spliced mitoferrin transcript, which limits iron transport into mitochondria, has also been described in this condition. The liver functions as an excretory organ rather than a major source for excess protoporphyrin. But FECH deficiency in the skin and liver may be important, as tissue transplantation studies in mice suggest that skin photosensitivity and liver damage occur only when FECH is deficient in these tissues.

Patients with EPP and XLP are maximally sensitive to light in the 400 nm range, which corresponds to the so-called Soret band (the narrow peak absorption maximum that is characteristic for protoporphyrin and other porphyrins). Having absorbed light, porphyrins enter an excited energy state and release energy as fluorescence, singlet oxygen, and other reactive oxygen species. Tissue damage is accompanied by lipid peroxidation, oxidation of amino acids, crosslinking of proteins in cell membranes, and damage to capillary endothelial cells. Such damage may be mediated by photoactivation of the complement system and release of histamine, kinins, and chemotactic factors. Repeated acute damage leads to thickening of the vessel walls and perivascular deposits from accumulation of serum components. Deposition of amorphous material containing immunoglobulin, complement components, glycoproteins, acid glycosaminoglycans, and lipids around blood vessels occurs in the upper dermis.

There is little evidence for impaired erythropoiesis or hemolysis in EPP. However, mild anemia with microcytosis, hypochromia and reticulocytosis is common. Iron accumulation in erythroblasts and ring sideroblasts have been noted in bone marrow in some patients. Decreased transferrin saturation and low or low-normal serum ferritin suggest iron deficiency. Iron status should be carefully evaluated in EPP patients, keeping in mind that iron deficiency may lead to further increases in protoporphyrin and increase the risk for cholestasis. Oral iron supplements are often poorly absorbed in EPP, which is unexplained. Some patients report increased photosensitivity when given iron supplements, but whether this is from transient increases in porphyrins when iron deficiency is corrected and erythropoiesis increases is not known.

Liver damage that develops in a small proportion of EPP and XLP patients is attributed to excess protoporphyrin, which is cholestatic, insoluble in water and excreted only by hepatic uptake and biliary excretion. Some may be reabsorbed by the intestine and undergo enterohepatic circulation. With cholestasis the excess protoporphyrin that accumulates in the liver can form crystalline structures in hepatocytes, and impair mitochondrial function.

Clinical Manifestations

Symptoms of cutaneous photosensitivity begin in childhood, and consist of pain, redness, and itching occurring within minutes of sunlight exposure. Swelling may resemble angioneurotic edema, and *solar urticaria.* Symptoms are usually worse in the spring and summer. Petechiae and purpuric lesions may be seen, but blisters are usually absent. Chronic changes may include lichenification, leathery pseudovesicles,

labial grooving, and nail changes, but changes in pigmentation and pronounced scarring are unusual. Although physical findings in EPP and XLP may not be impressive, the symptoms significantly impair quality of life to a greater extent than in PCT and VP. An association between autosomal recessive EPP and seasonal palmar keratoderma is unexplained. Neuropathy develops only in some patients with severe hepatic decompensation.

Unless hepatic or other complications develop, protoporphyrin levels and symptoms of photosensitivity remain remarkably stable for many years in most patients. Factors that exacerbate hepatic porphyrias play little or no role in EPP or XLP. Mild, unexplained hypertriglyceridemia has been described. Erythrocyte protoporphyrin levels may decrease and sunlight tolerance may improve during pregnancy, which is unexplained.

Laboratory Findings

Protoporphyrin is substantially increased in circulating erythrocytes in EPP, and consists almost entirely of free protoporphyrin. In a variant form of EPP caused by ALAS2 exon 11 deletions, both zinc protoporphyrin and free protoporphyrin are increased, although the latter still predominates. Protoporphyrin is also increased in bone marrow, plasma, bile, and feces. Other porphyrins and porphyrin precursors are normal in uncomplicated EPP.

Diagnosis and Differential Diagnosis

A diagnosis of EPP is confirmed primarily by finding a substantially elevated concentration of erythrocyte protoporphyrin, which is predominantly metal-free and not complexed with zinc. In XLP, both free and zinc complexed protoporphyrins are elevated. Erythrocyte total protoporphyrin levels are on average higher in XLP more variable in EPP, possible reflecting differences in severity of the many reported *FECH* mutations. Erythrocyte zinc protoporphyrin concentration is increased in some homozygous porphyrias, iron deficiency, lead poisoning, anemia of chronic disease, hemolytic conditions, and many other erythrocytic disorders. Many assays for erythrocyte protoporphyrin or "free erythrocyte protoporphyrin" measure only zinc protoporphyrin (i.e., iron-free rather than metal-free protoporphyrin). Therefore, reports must be interpreted with care, and confirmation obtained from a laboratory that reliably fractionates metal-free and zinc protoporphyrin.

Plasma total porphyrin concentration is often less increased in EPP than in other cutaneous porphyrias, and may be normal. Great care must be taken to avoid light exposure during sample processing, because plasma porphyrins in EPP are particularly subject to photodegradation. Urinary porphyrin precursors and porphyrins are not increased.

Measurement of FECH activity requires cells containing mitochondria and is not widely available. A greater than expected proportion of zinc protoporphyrin (more than ~15% of the total) in erythrocytes is important in identifying XLP. DNA studies are increasingly important for confirming *FECH* or *ALAS2* mutations and for genetic counseling.

Life-threatening protoporphyric hepatopathy is heralded by increasingly abnormal liver function tests, increasing erythrocyte and plasma protoporphyrin levels, and worsening photosensitivity. Increases in urinary porphyrins, especially coproporphyrin, in this setting are attributable to liver dysfunction.

Complications

Biliary stones containing protoporphyrin are sometimes symptomatic and require cholecystectomy. Protoporphyric hepatopathy occurs in less than 5% of EPP patients, including children, and may be chronic or progress rapidly to death from liver failure. This liver disease is sometimes the major presenting feature of EPP. In XLP, liver disease may be more frequent and in 1 report of 8 families, 17% of patients had overt liver dysfunction. Protoporphyric hepatopathy can cause acute upper abdominal pain suggesting biliary obstruction, and unnecessary laparotomy to exclude this possibility can be detrimental. Concurrent conditions that impair liver function, such as viral hepatitis, alcohol intake, iron deficiency, fasting, or oral contraceptive steroids, may contribute. Liver histology shows marked deposition of protoporphyrin in liver cells and bile canaliculi. Patients with protoporphyric liver failure most often have *FECH* "null mutations" and the IVS3–48T>C hypoexpression allele, but some may have 2 severe mutant *FECH* alleles or XLP caused by *ALAS2* exon 11 deletions. The bone marrow is probably the major source of protoporphyrin, even in EPP patients with hepatic failure.

Treatment

Exposure to sunlight should be avoided, which is aided by wearing closely woven clothing. Oral beta-carotene leads to clinical improvement and greater tolerance to light in some patients, usually 1-3 mo after starting treatment. In most adults, doses of 120-180 mg daily will maintain serum carotene levels in the recommended range of 600-800 mg/dL, but doses up to 300 mg daily may be needed. Mild skin discoloration from carotenemia is expected. The recommended product is Lumitene, which was initially developed as a drug for treating this disease, rather than nutritional products that are less standardized. Beta-carotene may quench singlet oxygen or free radicals, but does not substantially alter circulating porphyrin levels. Better tolerance of sunlight may result in tanning, which provides additional protection. Oral cysteine may also quench excited oxygen species and was found to increase tolerance to sunlight in EPP.

Measures to darken the skin may also be helpful. This may be accomplished by narrow-band UV-B phototherapy or with topical products such as dihydroxyacetone and lawsone (naphthoquinone). Afamelanotide, a synthetic analog of melanocyte-stimulating hormone shows promise for increasing sunlight tolerance in EPP and XLP and is currently in Phase 3 trials in the United States. Caloric restriction and drugs or hormone preparations that impair hepatic excretory function should be avoided, and iron deficiency should be corrected if present. Vitamin D supplementation and hepatitides A and B vaccination are recommended.

Treatment of protoporphyric hepatopathy must be individualized and results are unpredictable. Ursodeoxycholic acid may be of some value in early stages. Cholestyramine or activated charcoal may interrupt the enterohepatic circulation of protoporphyrin, promote its fecal excretion, and reduce liver protoporphyrin content. Spontaneous resolution may occur, especially if another reversible cause of liver dysfunction, such as viral hepatitis or alcohol abuse, is contributing. In patients with severe hepatic decompensation, combined treatment with plasmapheresis, transfusion to suppress erythropoiesis, intravenous hemin to suppress erythroid and hepatic protoporphyrin production, ursodeoxycholic acid, vitamin E, and cholestyramine may be beneficial.

Motor neuropathy resembling that seen in acute porphyrias sometimes develops in EPP patients with liver disease before or after transfusion or liver transplantation and is sometimes reversible. Artificial lights, such as operating room lights during liver transplantation or other surgery, may cause severe photosensitivity, with extensive burns of the skin and peritoneum and photodamage of circulating erythrocytes.

With continued progression of liver disease, liver transplantation may be considered. Although liver disease may recur in the transplanted liver as a result of continued bone marrow production of excess protoporphyrin, outcomes are comparable to transplantation for other types of liver disease. Bone marrow transplantation should also be considered after liver transplantation if a suitable donor is available.

Prognosis

Typical EPP patients have lifelong photosensitivity but can otherwise expect normal longevity. Protoporphyric liver disease is often life-threatening; however, the incidence is low.

Prevention

Symptoms can be prevented by avoiding sunlight. Avoiding agents that may cause liver damage may help prevent liver complications.

Genetic Counseling

DNA studies to identify *FECH* mutations, the common IVS3–48T>C *FECH* hypoexpression allele, or ALAS2 exon 11 deletions are increasingly important for genetic counseling. EPP may improve during pregnancy. In classic EPP, DNA studies in both parents can predict the risk for EPP occurring in an offspring.

Dual Porphyria

Dual porphyria refers to patients with porphyria who have deficiencies of more than 1 enzyme of the heme biosynthetic pathway. An unusual pattern of porphyrin precursors and porphyrins may suggest the presence of 2 enzyme deficiencies. Mutations of 2 heme pathway enzymes have been documented in only 2 patients with porphyria. One presented with acute porphyria and had heterozygous mutations in both the *CPOX* and *ALAD* genes. The other had symptoms of AIP and PCT and was documented to have both *PBGD* and *UROD* mutations. In other reported cases, 1 or both enzyme deficiencies were based on enzyme measurements.

Porphyria Resulting from Tumors

Very rarely, hepatocellular tumors contain and presumably produce excess porphyrins, but such cases have not been studied carefully. Hepatocellular carcinomas complicating PCT and acute hepatic porphyrias usually are not described as containing large amounts of porphyrins. Erythropoietic porphyrias can develop late in life from clonal expansion of erythroid cells containing a specific enzyme deficiency in patients who have developed myelodysplastic or myeloproliferative syndromes.

Chapter 92

Hypoglycemia

Mark A. Sperling

Glucose has a central role in fuel economy and is a source of energy storage in the form of glycogen, fat, and protein (see Chapter 87). As an immediate source of energy, glucose provides 38 mol of adenosine triphosphate (ATP) per mole of glucose oxidized. Glucose is essential for energy metabolism in the brain where it is usually the preferred substrate and where its utilization accounts for nearly all of the brain's oxygen consumption. Cerebral glucose uptake occurs through a glucose transporter molecule or molecules that are not regulated by insulin. Cerebral transport of glucose is a Glut1, carrier-mediated, facilitated diffusion process that is dependent on blood glucose concentration. Hence, low concentrations of blood glucose result in cerebral glucopenia. Deficiency of brain glucose transporters can result in seizures because of low cerebral and cerebrospinal fluid (CSF) glucose concentrations (hypoglycorrhachia) despite normal blood glucose levels. To maintain the blood glucose concentration and prevent it from falling precipitously to levels that impair brain function, an elaborate regulatory system has evolved.

The defense against hypoglycemia is integrated by the autonomic nervous system and by hormones that act in concert to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis, while simultaneously limiting peripheral glucose utilization which conserves glucose for cerebral metabolism. Hypoglycemia represents a defect in one or several of the complex interactions that normally integrate glucose homeostasis during feeding and fasting. This process is particularly important for neonates, in whom there is an abrupt transition from intrauterine life, characterized by dependence on transplacental glucose supply, to extrauterine life, characterized ultimately by the autonomous ability to maintain euglycemia. Because prematurity or placental insufficiency may limit tissue nutrient deposits, and genetic abnormalities in enzymes or hormones may become evident in the neonate, hypoglycemia is common in the neonatal period.

DEFINITION

In neonates, there is not always an obvious correlation between blood glucose concentration and the classic clinical manifestations of hypoglycemia. The absence of symptoms does not indicate that glucose concentration is normal and has not fallen to less than some optimal level for maintaining brain metabolism. There is evidence that hypoxemia and ischemia may potentiate the role of hypoglycemia in causing permanent brain damage. Consequently, the lower limit of accepted normality of the blood glucose level in newborn infants with associated illness that already impairs cerebral metabolism has not been determined (see Chapter 107). Out of concern for possible neurologic, intellectual, or psychologic sequelae in later life, most authorities recommend that any value of blood glucose <55 mg/dL in neonates be viewed with suspicion and vigorously treated. This is particularly applicable after the initial 2-3 hr of life, when glucose normally has reached its nadir; subsequently, blood glucose levels begin to rise and achieve values of 50 mg/dL or higher after 12-24 hr. By day 3 of life in normal full-term newborns, blood glucose averages approximately 60 mg/dL. In older infants and children, a whole blood glucose concentration of <55 mg/dL (10-15% higher for serum or plasma) represents hypoglycemia, because counterregulatory mechanisms are activated at these glucose concentrations.

SIGNIFICANCE AND SEQUELAE

Most of the endogenous hepatic glucose production in infants and young children, which occurs several hours after feeding and during fasting, can be accounted for by brain metabolism.

Because the brain grows most rapidly in the 1st yr of life and because the larger proportion of glucose turnover is used for brain metabolism, sustained or repetitive hypoglycemia in infants and children can retard brain development and function. Transient isolated and asymptomatic hypoglycemia of short duration does not appear to be associated with these severe sequelae. In the rapidly growing brain, glucose may also be a source of membrane lipids and, together with protein synthesis it can provide structural proteins and myelination that are important for normal brain maturation. Under conditions of severe and sustained hypoglycemia, these cerebral structural substrates may become degraded to energy-usable intermediates such as lactate, pyruvate, amino acids, and ketoacids, which can support brain metabolism at the expense of brain growth. The capacity of the newborn brain to take up and oxidize ketone bodies is about 5-fold greater than that of the adult brain. However, the capacity of the liver to produce ketone bodies is limited in the immediate newborn period, especially in the presence of hyperinsulinism, which acutely inhibits hepatic glucose output, lipolysis, and ketogenesis, thereby depriving the brain of any alternate fuel sources. Although the brain may metabolize ketones, these alternate fuels cannot completely replace glucose as an essential central nervous system (CNS) fuel. The deprivation of the brain's major energy source during hypoglycemia and the limited availability of alternate fuel sources during hyperinsulinism have predictable adverse consequences on brain metabolism and growth: decreased brain oxygen consumption and increased breakdown of endogenous structural components with destruction of functional membrane integrity.

The major long-term sequelae of severe, prolonged hypoglycemia are cognitive impairment, recurrent seizure activity, cerebral palsy and autonomic dysregulation. Subtle effects on personality are also possible but have not been clearly defined. Permanent neurologic sequelae are present in 25-50% of patients with severe recurrent symptomatic hypoglycemia who are younger than 6 mo of age. These sequelae may be reflected in pathologic changes characterized by reduced myelination in cerebral white matter and atrophy of the cerebral cortex, reflected in enlargement of the sulci and thinning of the gyri of the brain. These sequelae also are more likely when alternative fuel sources are limited,

as occurs with hyperinsulinism, when the episodes of hypoglycemia are repetitive or prolonged, or when they are compounded by hypoxia. There is no precise knowledge relating the duration or severity of hypoglycemia to subsequent neurologic development of children in a predictable manner. Although less common, hypoglycemia in older children may also produce long-term neurologic defects through neuronal death mediated, in part, by cerebral excitotoxins released during hypoglycemia.

SUBSTRATE, ENZYME, AND HORMONAL INTEGRATION OF GLUCOSE HOMEOSTASIS

In the Newborn

See Chapter 107.

Under nonstressed conditions, fetal glucose is derived entirely from the mother through placental transfer. Therefore, fetal glucose concentration usually reflects, but is slightly lower than, maternal glucose levels. Catecholamine release, which occurs with fetal stress such as hypoxia, mobilizes fetal glucose and free fatty acids (FFAs) through β-adrenergic mechanisms, reflecting β-adrenergic activity in fetal liver and adipose tissue. Catecholamines may also inhibit fetal insulin and stimulate glucagon release.

The acute interruption of maternal glucose transfer to the fetus at delivery imposes an immediate need to mobilize endogenous glucose. Three related events facilitate this transition: changes in hormones, changes in their receptors, and changes in key enzyme activity. There is a 3-5–fold abrupt increase in glucagon concentration within minutes to hours of birth. The level of insulin usually falls initially and remains in the basal range for several days without demonstrating the usual brisk response to physiologic stimuli such as glucose. A dramatic surge in spontaneous catecholamine secretion is also characteristic. Epinephrine can also augment growth hormone secretion by α-adrenergic mechanisms; growth hormone levels are elevated at birth. Acting in concert, these hormonal changes at birth mobilize glucose via glycogenolysis and gluconeogenesis, activate lipolysis, and promote ketogenesis. As a result of these processes, plasma glucose concentration stabilizes after a transient decrease immediately after birth, liver glycogen stores become rapidly depleted within hours of birth, and gluconeogenesis from alanine, a major gluconeogenic amino acid, can account for approximately 10% of glucose turnover in the human newborn infant by several hours of age. FFA concentrations also increase sharply in concert with the surges in glucagon and epinephrine, and are followed later by rises in ketone bodies. Glucose is thus partially spared for brain utilization while FFAs and ketones provide alternative fuel sources for muscle as well as essential gluconeogenic factors such as acetyl coenzyme A (CoA) and the reduced form of nicotinamide adenine dinucleotide from hepatic fatty acid oxidation, which is required to drive gluconeogenesis.

In the early postnatal period, responses of the endocrine pancreas favor glucagon secretion so that blood glucose concentration can be maintained. These adaptive changes in hormone secretion are paralleled by similarly striking adaptive changes in hormone receptors. Key enzymes involved in glucose production also change dramatically in the perinatal period. Thus, there is a rapid fall in glycogen synthase activity and a sharp rise in phosphorylase activity after delivery. Similarly, the amount of the rate-limiting enzyme for gluconeogenesis, phosphoenolpyruvate carboxykinase, rises dramatically after birth, activated in part by the surge in glucagon and the fall in insulin. This framework can explain several causes of neonatal hypoglycemia based on inappropriate changes in hormone secretion and unavailability of adequate reserves of substrates in the form of hepatic glycogen, muscle as a source of amino acids for gluconeogenesis, and lipid stores for the release of fatty acids. In addition, appropriate activities of key enzymes governing glucose homeostasis are required (see Fig. 87-1 in Chapter 87).

In Older Infants and Children

Hypoglycemia in older infants and children is analogous to that of adults, in whom glucose homeostasis is maintained by glycogenolysis in the immediate postfeeding period and by gluconeogenesis several hours after meals. The liver of a 10 kg child contains 20-25 g of glycogen, which is sufficient to meet normal glucose requirements of 4-6 mg/kg/min for only 6-12 hr. Beyond this period, hepatic gluconeogenesis must be activated. Both glycogenolysis and gluconeogenesis depend on the metabolic pathway summarized in Figure 87-1. Defects in glycogenolysis or gluconeogenesis may not be manifested in infants until the frequent feeding at 3-4 hr intervals ceases and infants sleep through the night, a situation usually present by 3-6 mo of age. The source of gluconeogenic precursors is derived primarily from muscle protein. The muscle bulk of infants and small children is substantially smaller relative to body mass than that of adults, whereas glucose requirements/unit of body mass are greater in children, so the ability to compensate for glucose deprivation by gluconeogenesis is more limited in infants and young children, as is the ability to withstand fasting for prolonged periods. The ability of muscle to generate alanine, the principal gluconeogenic amino acid, may also be limited. Thus, in normal young children, the blood glucose level falls after 24 hr of fasting, insulin concentrations fall appropriately to levels of <5-10 µU/mL, lipolysis and ketogenesis are activated, and ketones may appear in the urine.

The switch from glycogen synthesis during and immediately after meals to glycogen breakdown and later gluconeogenesis is governed by hormones, of which insulin is of central importance. Plasma insulin concentrations increase to peak levels of 5-10–fold greater than their baseline of approximately 5-10 µU/mL after meals, which serve to lower the blood glucose concentration through the activation of glycogen synthesis, enhancement of peripheral glucose uptake, and inhibition of glucose production. In addition, lipogenesis is stimulated, whereas lipolysis and ketogenesis are curtailed. During fasting, plasma insulin concentrations fall to ≤5-10 µU/mL, and together with the rise of counterregulatory hormones, this fall in insulin results in activation of gluconeogenic pathways (see Fig. 87-1). Fasting glucose concentrations are maintained through the activation of glycogenolysis and gluconeogenesis, inhibition of glycogen synthesis, and activation of lipolysis and ketogenesis. It should be emphasized that a plasma insulin concentration of >5 µU/mL, in association with a blood glucose concentration of ≤50-55 mg/dL (2.8-3.0 mM), is abnormal, indicating a **state** of excessive insulin action, here termed **hyperinsulinism,** because of failure of the mechanisms that normally result in suppression of insulin secretion during fasting or hypoglycemia.

The hypoglycemic effects of insulin are opposed by the actions of several hormones whose concentration in plasma increases as blood glucose falls. These **counterregulatory hormones**—glucagon, growth hormone, cortisol, and epinephrine—act in concert by increasing blood glucose concentrations via activating glycogenolytic enzymes (glucagon, epinephrine); inducing gluconeogenic enzymes (glucagon, cortisol); inhibiting glucose uptake by muscle (epinephrine, growth hormone, cortisol); mobilizing amino acids from muscle for gluconeogenesis (cortisol); activating lipolysis and thereby providing glycerol for gluconeogenesis and fatty acids for ketogenesis (epinephrine, cortisol, growth hormone, glucagon); and inhibiting insulin release and promoting growth hormone and glucagon secretion (epinephrine).

Congenital or acquired deficiency of any one of these hormones is uncommon but will result in hypoglycemia, which occurs when endogenous glucose production cannot be mobilized to meet energy needs in the postabsorptive state, that is, 8-12 hr after meals or during fasting. Concurrent deficiency of several hormones (**hypopituitarism**) may result in hypoglycemia that is more severe or appears earlier during fasting than that seen with isolated hormone deficiencies. Most of the causes of hypoglycemia in neonates, infants and children reflect inappropriate adaptation to fasting as a result of excess insulin action, or inadequate counter-regulatory hormone response primarily of cortisol and growth hormone, or enzymatic defects in the mechanisms for glycogen storage and release, or defects in gluconeogenesis.

CLINICAL MANIFESTATIONS

See Chapter 107.

Clinical features generally fall into 2 categories. The first includes symptoms associated with the activation of the autonomic nervous system and epinephrine release, usually seen with a rapid decline in blood glucose concentration (Table 92-1). The second category includes

Table 92-1	Manifestations of Hypoglycemia in Childhood

†Common.
‡Most common manifestations in the newborn.

symptoms caused by decreased cerebral glucose utilization (cerebral glycopenia), usually associated with a slow decline in blood glucose level or prolonged hypoglycemia (Table 92-1). Although these classic symptoms occur in older children, the symptoms of hypoglycemia in newborns and infants may be subtler and include cyanosis, apnea, hypothermia, hypotonia, poor feeding, lethargy, and seizures. Some of these symptoms may be so mild that they are missed. Occasionally, hypoglycemia may be asymptomatic in the immediate newborn period. Newborns with hyperinsulinism are often large for gestational age; older infants with hyperinsulinism may eat excessively because of chronic hypoglycemia and become obese. In childhood, hypoglycemia may present as behavior problems, inattention, ravenous appetite, or seizures. It may be misdiagnosed as epilepsy, inebriation, personality disorders, headache, hysteria, and developmental delay. A blood glucose determination should always be performed in sick neonates, who should be vigorously treated if concentrations are <50 mg/dL. At any age, hypoglycemia should be considered a cause of an initial episode of convulsions or a sudden deterioration in psychobehavioral functioning or level of consciousness.

Many neonates have asymptomatic (chemical) hypoglycemia. The incidence of symptomatic hypoglycemia is highest in small for gestational age infants (Fig. 92-1). The exact incidence of symptomatic hypoglycemia has been difficult to establish because many of the symptoms in neonates occur **together** with other conditions such as infections, especially sepsis and meningitis; CNS anomalies, hemorrhage, or edema; hypocalcemia and hypomagnesemia; asphyxia; drug withdrawal; apnea of prematurity; congenital heart disease; or polycythemia.

The onset of symptoms in neonates varies from a few hours to a week after birth. In approximate order of frequency, symptoms include jitteriness or tremors, apathy, episodes of cyanosis, convulsions, intermittent apneic spells or tachypnea, weak or high-pitched cry, limpness or lethargy, difficulty feeding, and eye rolling. Episodes of sweating, sudden pallor, hypothermia, and cardiac arrest and failure also occur.

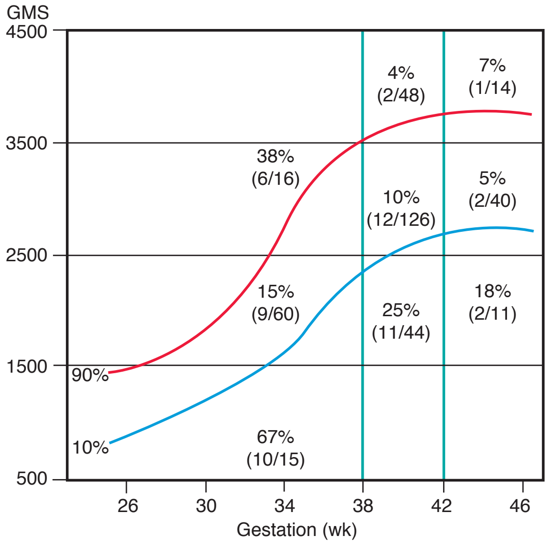

Figure 92-1 Incidence of hypoglycemia by birthweight, gestational age, and intrauterine growth. *(From Lubchenco LO, Bard H: Incidence of hypoglycemia in newborn infants classified by birthweight and gestational age,* Pediatrics *47:831–838, 1971.)*

Frequently, a clustering of episodic symptoms may be noted. Because these clinical manifestations may result from various causes, it is critical to measure serum glucose levels and determine whether symptoms disappear with the administration of sufficient glucose to raise the blood glucose to normal levels; if they do not, other diagnoses must be considered.

CLASSIFICATION OF HYPOGLYCEMIA IN INFANTS AND CHILDREN

Classification is based on knowledge of the control of glucose homeostasis in infants and children (Table 92-2).

Neonatal, Transient, Small for Gestational Age, and Premature Infants

See Chapter 107.

The estimated incidence of symptomatic hypoglycemia in newborns is 1-3 in 1,000 live births. This incidence is increased severalfold in certain high-risk neonatal groups (see Table 92-2 and Fig. 92-1). The premature and small for gestational age (SGA) infants are vulnerable to the development of hypoglycemia. The factors responsible for the high frequency of hypoglycemia in this group, as well as in other groups outlined in Table 92-2, are related to the inadequate stores of liver glycogen, muscle protein, and body fat needed to sustain the substrates required to meet energy needs. These infants are small by virtue of prematurity or impaired placental transfer of nutrients. Their enzyme systems for gluconeogenesis may not be fully developed. **Transient hyperinsulinism** responsive to diazoxide has also been reported as contributing to hypoglycemia in asphyxiated, SGA, and premature newborn infants. This form of hyperinsulinism associated with perinatal asphyxia, intrauterine growth restriction, maternal toxemia and other perinatal stressors, is probably the most common cause of hyperinsulinemic hypoglycemia in neonates and may be quite severe. In most cases, the condition resolves quickly, but it may persist to 7 mo of life or longer.

In contrast to deficiency of substrates or enzymes, the hormonal system appears to be functioning normally at birth in most low-risk neonates. Despite hypoglycemia, plasma concentrations of alanine, lactate, and pyruvate are higher, implying their diminished rate of utilization as substrates for gluconeogenesis. Infusion of alanine elicits further glucagon secretion but causes no significant rise in glucose. During the initial 24 hr of life, plasma concentrations of acetoacetate and β-hydroxybutyrate are lower in SGA infants than in full-term infants, implying diminished lipid stores, diminished fatty acid mobilization, impaired ketogenesis, or a combination of these

Table 92-2 Classification of Hypoglycemia in Infants and Children

NEONATAL TRANSITIONAL (ADAPTIVE) HYPOGLYCEMIA
Associated with Inadequate Substrate or Immature Enzyme Function in Otherwise Normal Neonates
Prematurity
Small for gestational age
Normal newborn
Transient Neonatal Hyperinsulinism
Infant of diabetic mother
Small for gestational age
Discordant twin
Birth asphyxia
Infant of toxemic mother

NEONATAL, INFANTILE, OR CHILDHOOD PERSISTENT HYPOGLYCEMIAS
Hyperinsulinism
Recessive K_{ATP} channel HI
Recessive HADH (hydroxyl acyl-CoA dehydrogenase) mutation HI
Recessive UCP2 (mitochondrial uncoupling protein 2) mutation HI
Focal K_{ATP} channel HI
Dominant K_{ATP} channel HI
Atypical congenital hyperinsulinemia (no mutations in *ABCC8* or *KCN11* genes)
Dominant glucokinase HI
Dominant glutamate dehydrogenase HI (hyperinsulinism/hyperammonemia syndrome)
Dominant mutations in HNF-4A and HNF-1A (hepatic nuclear factors 4α and 1α) HI with monogenic diabetes of youth later in life
Dominant mutation in SLC16A1(the pyruvate transporter)—exercise-induced hypoglycemia
Acquired islet adenoma
Beckwith-Wiedemann syndrome
Insulin administration (Munchausen syndrome by proxy)
Oral sulfonylurea drugs
Congenital disorders of glycosylation
Counterregulatory Hormone Deficiency
Panhypopituitarism
Isolated growth hormone deficiency
Adrenocorticotropic hormone deficiency
Addison disease
Epinephrine deficiency
Glycogenolysis and Gluconeogenesis Disorders
Glucose-6-phosphatase deficiency (GSD 1a)
Glucose-6-phosphate translocase deficiency (GSD 1b)
Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD 3)
Liver phosphorylase deficiency (GSD 6)
Phosphorylase kinase deficiency (GSD 9)
Glycogen synthetase deficiency (GSD 0)
Fructose-1,6-diphosphatase deficiency
Pyruvate carboxylase deficiency
Galactosemia
Hereditary fructose intolerance

Lipolysis Disorders
Fatty Acid Oxidation Disorders
Carnitine transporter deficiency (primary carnitine deficiency)
Carnitine palmitoyltransferase-1 deficiency
Carnitine translocase deficiency
Carnitine palmitoyltransferase-2 deficiency
Secondary carnitine deficiencies
Very-long-, long-, medium-, short-chain acyl-CoA dehydrogenase deficiency

OTHER ETIOLOGIES
Substrate-Limited
Ketotic hypoglycemia
Poisoning—drugs
Salicylates
Alcohol
Oral hypoglycemic agents
Insulin
Propranolol

Factitious
Nissen fundoplication (dumping syndrome)
Falciparum malaria

GSD, glycogen storage disease; HI, hyperinsulinemia; K_{ATP}, regulated potassium channel.

conditions. Diminished lipid stores are most likely because fat (triglyceride) feeding of newborns results in a rise in the plasma levels of glucose, ketones such as β OH butyrate and FFA. For infants with perinatal asphyxia, and some SGA newborns who have transient hyperinsulinism, hypoglycemia and diminished concentrations of β OH butyrate and FFAs are the hallmark of hyperinsulinism.

The role of FFAs and their oxidation in stimulating neonatal gluconeogenesis is essential. The provision of FFAs as triglyceride feedings from formula or human milk together with gluconeogenic precursors may prevent the hypoglycemia that usually ensues after neonatal fasting. For these and other reasons, milk feedings are introduced early (at birth or within 2-4 hr) after delivery. In the hospital setting, when feeding is precluded by virtue of respiratory distress or when feedings alone cannot maintain blood glucose concentrations at levels >50 mg/dL, intravenous glucose at a rate that supplies 4-8 mg/kg/min should be started. Infants with transient neonatal hypoglycemia can usually maintain the blood glucose level spontaneously after 2-3 days of life, but some require longer periods of support. In these latter infants,

insulin values >5 μU/mL at the time of hypoglycemia should be treated with diazoxide.

Infants Born to Diabetic Mothers

See Chapter 107.1.

Of the transient hyperinsulinemic states, infants born to diabetic mothers are the most common. Gestational diabetes affects some 2% of pregnant women, and ≈1 in 1,000 pregnant women have insulin-dependent diabetes. At birth, infants born to these mothers may be large and plethoric, and their body stores of glycogen, protein, and fat are replete.

Hypoglycemia in infants of diabetic mothers is mostly related to hyperinsulinemia and partly related to diminished glucagon secretion. Hypertrophy and hyperplasia of the islets is present, as is a brisk, biphasic, and typically mature insulin response to glucose; this brisk insulin response is absent in normal infants. Infants born to diabetic mothers also have a subnormal surge in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli, and, initially, excessive sympathetic activity that may lead to adrenomedullary exhaustion as reflected by decreased urinary excretion of epinephrine. The normal plasma hormonal pattern of low insulin, high glucagon, and high catecholamines is reversed to a pattern of high insulin, low glucagon, and low epinephrine. As a consequence of this abnormal hormonal profile, endogenous glucose production is significantly inhibited compared with that in normal infants, thus predisposing them to hypoglycemia.

Mothers whose diabetes has been well controlled during pregnancy, labor, and delivery generally have infants near normal size who are less likely to develop neonatal hypoglycemia and other complications formerly considered typical of such infants (see Chapter 107.1). In supplying exogenous glucose to these hypoglycemic infants, it is important to avoid hyperglycemia that evokes a prompt exuberant insulin release, which may result in rebound hypoglycemia. When needed, glucose should be provided at continuous infusion rates of 4-8 mg/kg/min, but the appropriate dose for each patient must be individually adjusted. During labor and delivery, maternal hyperglycemia should be avoided because it results in fetal hyperglycemia, which predisposes to hypoglycemia when the glucose supply is interrupted at birth. Hypoglycemia persisting or occurring after 1 wk of life requires an evaluation for the causes listed in Table 92-2.

Infants born with **erythroblastosis fetalis** may also have hyperinsulinemia and share many physical features, such as large body size, with infants born to diabetic mothers. The cause of the hyperinsulinemia in infants with erythroblastosis is not clear.

PERSISTENT OR RECURRENT HYPOGLYCEMIA IN INFANTS AND CHILDREN

Hyperinsulinism

Most children with hyperinsulinism that causes hypoglycemia present in the neonatal period or later in infancy; hyperinsulinism is the most common cause of persistent hypoglycemia in early infancy. Infants who have hyperinsulinism may be macrosomic at birth, reflecting the anabolic effects of insulin in utero. There is no history or biochemical evidence of maternal diabetes. The onset of symptoms is from birth to 18 mo of age, but occasionally it only becomes evident in older children. Insulin concentrations are inappropriately elevated at the time of documented hypoglycemia; with nonhyperinsulinemic hypoglycemia, plasma insulin concentrations should be <5 μU/mL and no higher than 10 μU/mL. In affected infants, plasma insulin concentrations at the time of hypoglycemia are commonly >5-10 μU/mL. Some authorities set more stringent criteria, arguing that any value of insulin >2 μU/mL with hypoglycemia is abnormal. The insulin (μU/mL):glucose (mg/dL) ratio is commonly >0.4; plasma insulin-like growth factor binding protein-1 (IGFBP-1), β OH butyrate, and FFA levels are low with hyperinsulinism. Rare instances of activating mutations in the insulin receptor signaling pathway have been reported where the clinical and biochemical features are similar to states of excessive insulin secretion, yet insulin concentrations are low to the point of being undetectable. Hence, the preferred term is **hyperinsulinism**, to describe a state of increased insulin action. Macrosomic infants may present with hypoglycemia from the first days of life. Infants with lesser degrees of hyperinsulinism may manifest hypoglycemia only after the first few weeks to months, when the frequency of feedings has been decreased to permit the infant to sleep through the night, and hyperinsulinism prevents the mobilization of endogenous glucose. Increasing appetite and demands for feeding, wilting spells, jitteriness, and frank seizures are the most common presenting features. Additional clues include the rapid development of fasting hypoglycemia within 4-8 hr of food deprivation compared with other causes of hypoglycemia (Tables 92-3 and 92-4); the need for high rates of exogenous glucose infusion to prevent hypoglycemia, often at rates >10-15 mg/kg/min; the absence of ketonemia or acidosis; and elevated C-peptide or proinsulin levels at the time of hypoglycemia. The latter insulin-related products are absent in **factitious hypoglycemia** from exogenous administration of insulin as a form of child abuse (Munchausen by proxy syndrome; see Chapter 40.2). Hypoglycemia is invariably provoked by withholding feedings for several hours, permitting simultaneous measurement of glucose, insulin, ketones, and FFAs in the same sample at the time of clinically manifested hypoglycemia. This is termed the **critical sample.** The glycemic response to glucagon at the time of hypoglycemia reveals a brisk increment in glucose concentration of at least 40 mg/dL, which implies that glucose mobilization has been restrained by insulin but that glycogenolytic mechanisms are intact (Tables 92-5, 92-6, and 92-7).

The measurement of serum IGFBP-1 concentration may help diagnose hyperinsulinism. The secretion of IGFBP-1 is acutely inhibited by insulin action; IGFBP-1 concentrations are low during hyperinsulinism-induced hypoglycemia. In patients with spontaneous or fasting-induced hypoglycemia with a low insulin level (ketotic hypoglycemia, normal fasting), IGFBP-1 concentrations are significantly higher.

The differential diagnosis of endogenous hyperinsulinism includes **diffuse β-cell hyperplasia** or **focal β-cell microadenoma.**

The distinction between these 2 major entities is important because the former, if unresponsive to medical therapy, requires near total pancreatectomy, despite which hypoglycemia may persist or diabetes mellitus may ensue at some later time. Some affected infants may respond to sirolimus. By contrast, focal adenomas diagnosed

Table 92-3 Hypoglycemia in Infants and Children: Clinical and Laboratory Features

GROUP	AGE AT DIAGNOSIS (mo)	GLUCOSE* (mg/dL)	INSULIN (μU/mL)	FASTING TIME TO HYPOGLYCEMIA (hr)
HYPERINSULINEMIA (*N* = 12)				
Mean	7.4	23.1	22.4	2.1[†]
SEM	2.0	2.7	3.2	0.6
NONHYPERINSULINEMIA (*N* = 16)				
Mean	41.8	36.1	5.8	18.2
SEM	7.3	2.4	0.9	2.9

*In hypoglycemia caused by hyperinsulinism β OH butyrate and FFA are low compared with normal at same duration of fasting.
[†]Milder forms of hyperinsulinism may require up to 18 hr of fasting to provoke hypoglycemia.
SEM, standard error of mean.

Table 92-4 Correlation of Clinical Features with Molecular Defects in Persistent Hyperinsulinemic Hypoglycemia in Infancy

TYPE	MACROSOMIA	HYPOGLYCEMIA/ HYPERINSULINEMIA	FAMILY HISTORY	MOLECULAR DEFECTS	ASSOCIATED CLINICAL, BIOCHEMICAL, OR MOLECULAR FEATURES	RESPONSE TO MEDICAL MANAGEMENT	RECOMMENDED SURGICAL APPROACH	PROGNOSIS
Sporadic	Present at birth	Moderate/severe in first days to weeks of life	Negative	? *SUR1*/K_{IR} 6.2 Mutations not always identified in diffuse hyperplasia	Loss of heterozygosity in microadenomatous tissue	Generally poor; may respond better to somatostatin than to diazoxide	Partial pancreatectomy if frozen section shows β-cell crowding with small nuclei—suggests microadenoma Subtotal >95% pancreatectomy if frozen section shows giant nuclei in β-cells—suggests diffuse hyperplasia	Excellent if focal adenoma is removed, thereby curing hypoglycemia and retaining sufficient pancreas to avoid diabetes Guarded if subtotal (>95%) pancreatectomy is performed because diabetes develops in, and hypoglycemia persists in
Autosomal recessive	Present at birth	Severe in first days to weeks of life	Positive	*SUR*/K_{IR} 6.2	Consanguinity a feature in some populations	Poor	Subtotal pancreatectomy	Guarded
Autosomal dominant	Unusual	Moderate onset usually post 6 mo of age	Positive	Glucokinase (activating) Some cases gene unknown	None	Very good to excellent	Surgery usually not required Partial pancreatectomy only if medical management fails	Excellent
Autosomal dominant	Unusual	Moderate onset usually post 6 mo of age	Positive	Glutamate dehydrogenase (activating)	Modest hyperammonemia	Very good to excellent	Surgery usually not required	Excellent
Beckwith-Wiedemann syndrome	Present at birth	Moderate, spontaneously resolves post 6 mo of age	Negative	Duplicating/ imprinting in chromosome 11p15.1	Macroglossia, omphalocele, hemihypertrophy	Good	Not recommended	Excellent for hypoglycemia; guarded for possible development of embryonal tumors (Wilms hepatoblastoma)
Congenital disorders of glycosylation	Not usual	Moderate/onset post 3 mo of age	Negative	Phosphomannose isomerase deficiency	Hepatomegaly, vomiting, intractable diarrhea	Good with mannose supplement	Not recommended	Fair

*Glucagon 50 μg/kg with maximum of 1 mg IV or IM.
†Measure once only before or after glucagon administration. Rise in glucose of ≥40 mg/dL after glucagon given at the time of hypoglycemia strongly suggests a hyperinsulinemic state with adequate hepatic glycogen stores and intact glycogenolytic enzymes. If ammonia is elevated to 100-200 μM, consider activating mutation of glutamate dehydrogenase.

Table 92-6 Criteria for Diagnosing Hyperinsulinism Based on "Critical" Samples (Drawn at a Time of Fasting Hypoglycemia: Plasma Glucose <50 mg/dL)

1. Hyperinsulinemia (plasma insulin >2 μU/mL)*
2. Hypofatty acidemia (plasma free fatty acids <1.5 mmol/L)
3. Hypoketonemia (plasma β-hydroxybutyrate: <2.0 mmol/L)
4. Inappropriate glycemic response to glucagon, 1 mg IV (change in glucose >40 mg/dL)

*Depends on sensitivity of insulin assay.

Table 92-7 Diagnosis of Acute Hypoglycemia in Infants and Children

ACUTE SYMPTOMS PRESENT
1. Obtain blood sample before and 30 min after glucagon administration.
2. Obtain urine as soon as possible. Examine for ketones; if not present and hypoglycemia confirmed, suspect hyperinsulinemia or fatty acid oxidation defect; if present, suspect ketotic, hormone deficiency, inborn error of glycogen metabolism, or defective gluconeogenesis.
3. Measure glucose in the original blood sample. If hypoglycemia is confirmed, proceed with substrate-hormone measurement as in Table 92-5.
4. If glycemic increment after glucagon exceeds 40 mg/dL above basal, suspect hyperinsulinemia.
5. If insulin level at time of confirmed hypoglycemia is >5 μU/mL, suspect endogenous hyperinsulinemia; if >100 μU/mL, suspect factitious hyperinsulinemia (exogenous insulin injection). Admit to hospital for supervised fast.
6. If cortisol is <10 μg/dL or growth hormone is <5 ng/mL, or both, suspect adrenal insufficiency or pituitary disease, or both. Admit to hospital for hormonal testing and neuroimaging.

HISTORY SUGGESTIVE: ACUTE SYMPTOMS NOT PRESENT
1. Careful history for relation of symptoms to time and type of food intake, bearing in mind age of patient. Exclude possibility of alcohol or drug ingestion. Assess possibility of insulin injection, salt craving, growth velocity, intracranial pathology.
2. Careful examination for hepatomegaly (glycogen storage disease; defect in gluconeogenesis); pigmentation (adrenal failure); stature and neurologic status (pituitary disease).
3. Admit to hospital for provocative testing:
   a. 24 hr fast under careful observation; when symptoms provoked, proceed with steps 1-4 as when acute symptoms present.
   b. Pituitary–adrenal function using arginine-insulin stimulation test if indicated.
4. Consider molecular diagnostic test before liver biopsy for histologic and enzyme determinations.
5. Oral glucose tolerance test (1.75 g/kg; max 75 g) if reactive hypoglycemia suspected (dumping syndrome, etc.).

preoperatively or intraoperatively permit localized curative resection with subsequent normal glucose metabolism. Approximately 50% of the autosomal recessive or sporadic forms of neonatal/infantile hyperinsulinism are caused by focal microadenomas, which may be distinguished from the diffuse form by the pattern of insulin response to selective insulin secretagogues infused into an arterial branch supplying the pancreas, with sampling via the hepatic vein. However, these invasive and technically difficult procedures have been largely abandoned in favor of positron emission tomography using 18-fluoro-L-dopa. This technique can distinguish the diffuse form (uniform fluorescence throughout the pancreas) from the focal form (focal uptake of 18-fluoro-L-dopa and localized fluorescence) with an extremely high degree of reliability, success, specificity, and sensitivity (see Fig. 92-3 and below).

Insulin-secreting macroadenomas are rare in childhood and may be diagnosed preoperatively via CT or MRI. The plasma levels of insulin alone, however, cannot distinguish the aforementioned entities. The diffuse or microadenomatous forms of islet cell hyperplasia represent a variety of genetic defects responsible for abnormalities in the endocrine pancreas characterized by autonomous insulin secretion that is not appropriately reduced when blood glucose declines spontaneously or in response to provocative maneuvers such as fasting (see Tables 92-4, 92-7, and 92-8 and Fig. 92-2). Clinical, biochemical, and molecular genetic approaches now permit classification of congenital hyperinsulinism, formerly termed **nesidioblastosis,** into distinct entities. **Persistent hyperinsulinemic hypoglycemia of infancy (PHHI)** may be inherited or sporadic, is severe, and is caused by mutations that affect the regulation of the potassium channel intimately involved in insulin secretion by the pancreatic β cell (Fig. 92-2). Normally, glucose entry into the β cell is enabled by the non–insulin-responsive glucose transporter GLUT-2. On entry, glucose is phosphorylated to glucose-6-phosphate by the enzyme glucokinase, enabling glucose metabolism to generate ATP. The rise in the molar ratio of ATP relative to adenosine diphosphate closes the ATP-sensitive potassium channel in the cell membrane (K_{ATP} channel). This channel is composed of 2 subunits, the K_{IR} 6.2 channel, part of the family of inward-rectifier potassium channels, and a regulatory component in intimate association with K_{IR} 6.2 known as the sulfonylurea receptor (SUR1). Together, K_{IR} 6.2 and SUR1 constitute the potassium-sensitive ATP channel K_{ATP}. Normally, the K_{ATP} is open, but with the rise in ATP and closure of the channel, potassium accumulates intracellularly, causing depolarization of the membrane, opening of voltage-gated calcium channels, influx of calcium into the cytoplasm, and secretion of insulin via exocytosis. The genes for both SUR1 and K_{IR} 6.2 are located close together on the short arm of chromosome 11, the site of the insulin gene. **Inactivating** mutations in the gene for SUR1 or, less often, K_{IR} 6.2 prevent the potassium channel from opening; it remains variably closed with constant depolarization and, therefore, constant inward flux of calcium; hence, insulin secretion is continuous and not governed by the glucose concentration. A milder autosomal dominant form of these defects is also reported. Likewise, an **activating** mutation in glucokinase or glutamate dehydrogenase enzyme activity results in closure of the potassium channel through overproduction of ATP which causes hyperinsulinism. Genetic defects in fatty acid metabolism, in the insulin transcription factor HNF-4α and HNF-1α, and in the uncoupling protein UCP-2 of the mitochondrial gene complex also have been involved in

Table 92-8 Clinical Manifestations and Differential Diagnosis in Childhood Hypoglycemia

Details of each condition are discussed in the text.
0, absence; ↑ or ↓ indicates respectively small increase or decrease; ↑↑ or ↓↓ indicates respectively large increase or decrease.

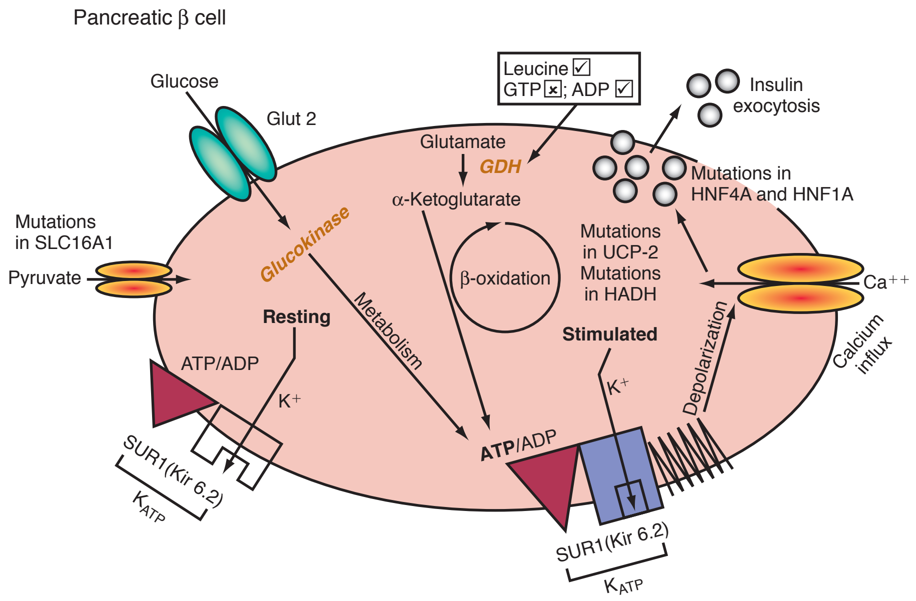

Figure 92-2 **Schematic of the pancreatic cell with some important steps in insulin secretion.** The membrane-spanning, adenosine triphosphate (ATP)-sensitive potassium (K^+) channel (K_{ATP}) consists of 2 subunits: the sulfonylurea receptor (SUR) and the inward rectifying K channel (K_{IR} 6.2). In the resting state, the ratio of ATP to adenosine diphosphate (ADP) maintains K_{ATP} in an open state, permitting efflux of intracellular K^+. When blood glucose concentration rises, its entry into the β cell is facilitated by the GLUT-2 glucose transporter, a process not regulated by insulin. Within the β cell, glucose is converted to glucose-6-phosphate by the enzyme glucokinase and then undergoes metabolism to generate energy. The resultant increase in ATP relative to ADP closes K_{ATP}, preventing efflux of K^+, and the rise of intracellular K^+ depolarizes the cell membrane and opens a calcium (Ca^{2+}) channel. The intracellular rise in Ca^{2+} triggers insulin secretion via exocytosis. Sulfonylureas trigger insulin secretion by reacting with their receptor (SUR) to close K_{ATP}; diazoxide inhibits this process, whereas somatostatin, or its analog octreotide, inhibits insulin secretion by interfering with calcium influx. Genetic mutations in SUR1 or K_{IR} 6.2 that prevent K_{ATP} from being open, tonically maintain inappropriate insulin secretion and are responsible for autosomal recessive forms of persistent hyperinsulinemic hypoglycemia of infancy (PHHI). One form of autosomal dominant PHHI is caused by an activating mutation in glucokinase. The amino acid leucine also triggers insulin secretion by closure of K_{ATP}. Metabolism of leucine is facilitated by the enzyme glutamate dehydrogenase (GDH), and overactivity of this enzyme in the pancreas leads to hyperinsulinemia with hypoglycemia, associated with hyperammonemia from overactivity of GDH in the liver. Mutations in the pyruvate channel SLC16A1 can cause ectopic expression in the β cell and permit pyruvate, accumulated during exercise, to induce insulin secretion and hence exercise-induced hypoglycemia. Mutations in the mitochondrial uncoupling protein 2 (UCP2) and hydroxyl acyl-CoA dehydrogenase (HADH) are associated with hyperinsulinism (HI) by mechanisms yet to be defined. Mutations in the transcription factors hepatic nuclear factors (HNF) 4α and 1α can be associated with neonatal macrosomia and HI, but progress to monogenic diabetes of youth (MODY) later in life. √, stimulation; GTP, guanosine triphosphate; X, inhibition.

hyperinsulinemic hypoglycemia. **Inactivating** mutations of the glucokinase gene or **activating** mutations of the ATP regulated potassium channel which prevent or limit closure of the channel, are responsible for inadequate insulin secretion and form the basis of some forms of maturity-onset diabetes of youth or of neonatal diabetes mellitus (see Chapter 589).

The familial forms of PHHI are more common in certain populations, notably Arabic and Ashkenazi Jewish communities, where it may reach an incidence of approximately 1 in 2,500, compared with the sporadic rates in the general population of approximately 1 in 50,000. These **autosomal recessive forms** of PHHI typically present in the immediate newborn period as macrosomic newborns with a weight frequently >4.0 kg and severe recurrent or persistent hypoglycemia manifesting in the initial hours or days of life. Glucose infusions as high as 15-20 mg/kg/min and frequent feedings fail to maintain euglycemia. Diazoxide, which acts by opening K_{ATP} channels (see Fig. 92-2) fails to control hypoglycemia adequately. Somatostatin (octreotide), which also opens K_{ATP} channels and inhibits calcium flux, may be partially effective in approximately 50% of patients (see Fig. 92-2). Calcium channel blocking agents have had inconsistent effects. Some affected infants have responded to sirolimus. When affected patients are unresponsive to these measures, pancreatectomy is strongly recommended to avoid the long-term neurologic sequelae of hypoglycemia. If surgery is undertaken, preoperative CT or MRI rarely reveals an isolated adenoma, which would then permit local resection. Intraoperative ultrasonography may identify a small impalpable adenoma, permitting local resection. Adenomas often present in late infancy or early childhood.

Distinguishing between **focal** and **diffuse** cases of **persistent hyperinsulinism** has been attempted in several ways. Preoperatively, transhepatic portal vein catheterization and selective pancreatic venous sampling to measure insulin may localize a focal lesion from the step-up in insulin concentration at a specific site. Selective catheterization of arterial branches supplying the pancreas, followed by infusion of a secretagogue such as calcium and portal vein sampling for insulin concentration (arterial stimulation-venous sampling) may localize a lesion. Both approaches are highly invasive, restricted to specialized centers, and not uniformly successful in distinguishing the focal from the diffuse forms, hence, these techniques are not recommended. 18F-labeled L-dopa combined with positron emission tomography scanning is a highly promising means to distinguish the focal from the diffuse lesions of hyperinsulinism unresponsive to medical management (Fig. 92-3). The "gold standard" remains intraoperative histologic characterization. Diffuse hyperinsulinism is characterized by large β cells with abnormally large nuclei, whereas focal adenomatous lesions display small and normal β cell nuclei. Although *SUR1* mutations are present in both types, the focal lesions arise by a random loss of a maternally imprinted growth-inhibitory gene on maternal chromosome 11p in association with paternal transmission of a mutated *SUR1* or K_{IR} 6.2 paternal chromosome 11p expressing the insulin-like growth factor 2 *(IGF2)* gene. Thus the focal form represents a double hit–loss of maternal repressor and transmission of a paternal mutation that contains a growth-promoting gene. Local excision of focal adenomatous islet cell hyperplasia results in a cure with little or no recurrence. For the diffuse form, near-total resection of 85-90% of the pancreas is recommended. The near-total pancreatectomy required for the diffuse

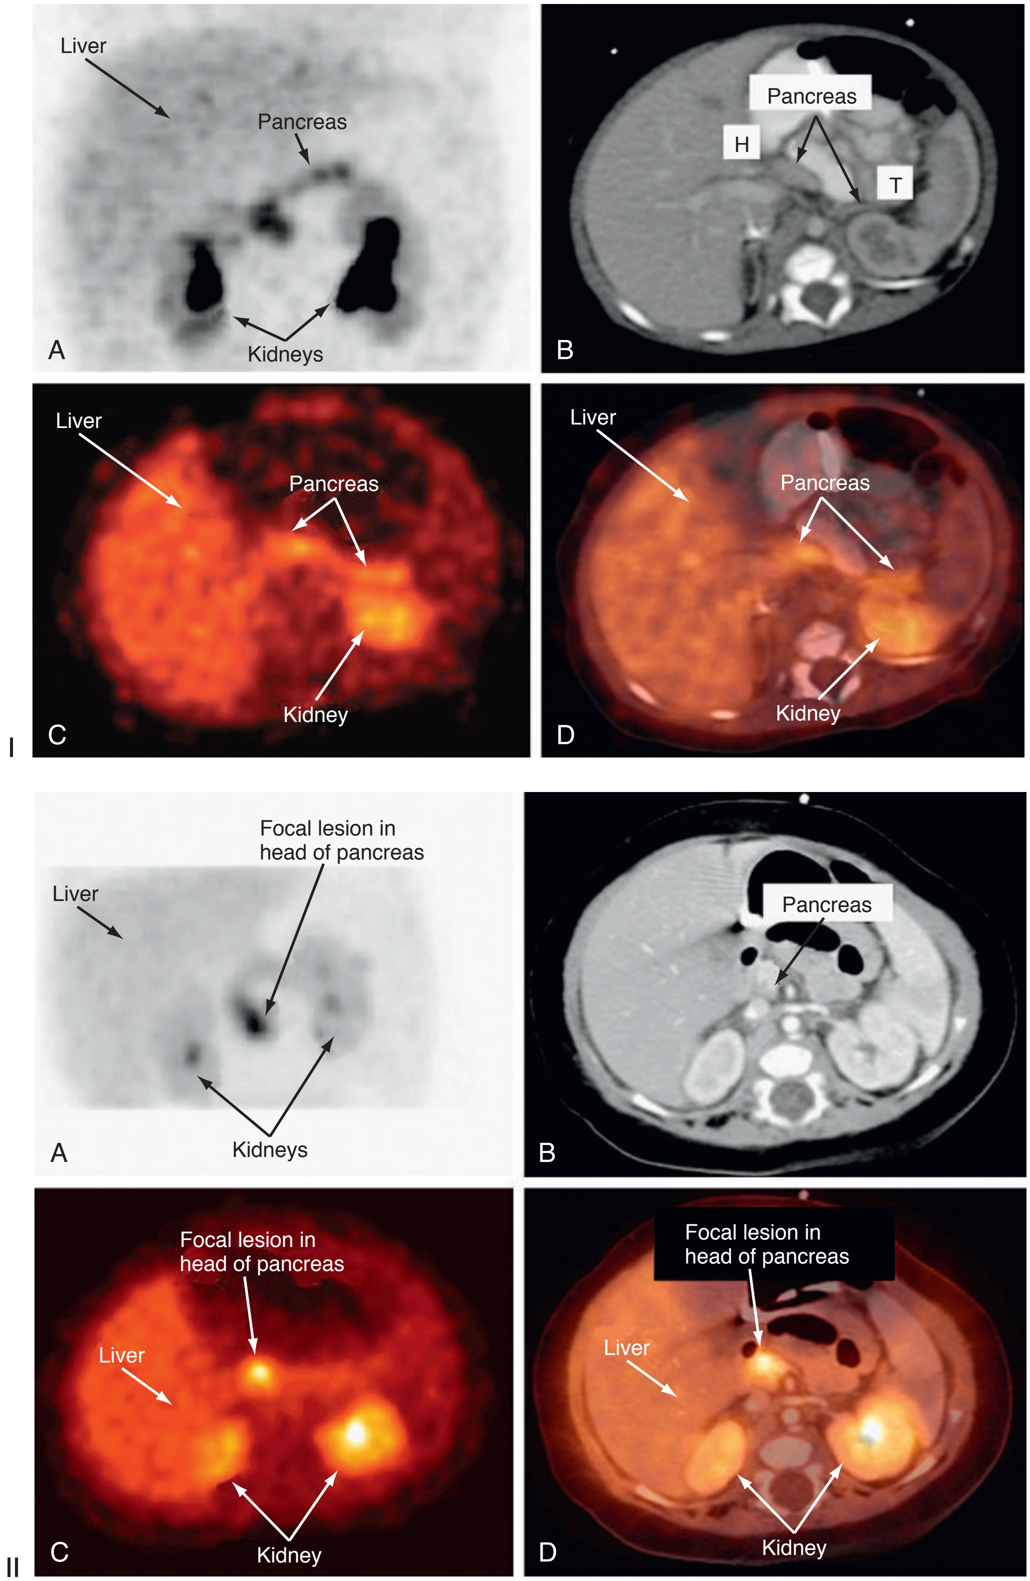

Figure 92-3 Congenital hyperinsulinism. **I** Panels (diffuse): [18F]-DOPA positron emission tomography (PET) of patient with diffuse form of congenital hyperinsulinism. **A,** Diffuse uptake of [18F]-DOPA is visualized throughout the pancreas. hyperplastic lesions is, however, often associated with persistent hypoglycemia with the later development of hyperglycemia or frank, insulin-requiring diabetes mellitus.

Further resection of the remaining pancreas may occasionally be necessary if hypoglycemia recurs and cannot be controlled by medical measures, such as the use of octreotide or diazoxide.

Experienced pediatric surgeons in medical centers equipped to provide the necessary preoperative and postoperative care, diagnostic evaluation, and management should perform surgery. In some patients who have been managed medically, hyperinsulinism and hypoglycemia regress over months. This is similar to what occurs in children with the hyperinsulinemic hypoglycemia seen in the epigenetic and genetic imprinting disorder **Beckwith-Wiedemann syndrome.**

If hypoglycemia first manifests between 3 and 6 mo of age or later, a therapeutic trial using medical approaches with diazoxide, octreotide, and frequent feedings can be attempted for up to 2-4 wk. Failure to maintain euglycemia without undesirable side effects from the drugs may prompt the need for surgery. Some success in suppressing insulin release and correcting hypoglycemia in patients with PHHI has been reported with the use of the long-acting somatostatin analog octreotide. Most cases of neonatal PHHI are sporadic; familial forms permit genetic counseling on the basis of anticipated autosomal recessive inheritance.

A second form of familial PHHI suggests **autosomal dominant inheritance.** The clinical features tend to be less severe, and onset of hypoglycemia is most likely, but not exclusively, to occur beyond the immediate newborn period and usually beyond the period of weaning at an average age at onset of about 1 yr. At birth, macrosomia is rarely observed, and response to diazoxide is almost uniform. The initial presentation may be delayed and rarely occur as late as 30 yr, unless provoked by fasting. The genetic basis for this autosomal dominant form has not been delineated; it is not always linked to K_{IR} 6.2/*SUR1*. The activating mutation in glucokinase is transmitted in an autosomal dominant manner. If a family history is present, genetic counseling for a 50% recurrence rate can be given for future offspring.

A third form of persistent PHHI is associated with **mild and asymptomatic hyperammonemia,** usually as a sporadic occurrence, although dominant inheritance occurs. Presentation is more like the autosomal dominant form than the autosomal recessive form. Diet and diazoxide control symptoms, but pancreatectomy may be necessary in some cases. The association of hyperinsulinism and hyperammonemia is caused by an inherited or de novo gain-of-function mutation in the enzyme glutamate dehydrogenase. The resulting increase in glutamate oxidation in the pancreatic β cell raises the ATP concentration and, hence, the ratio of ATP:adenosine diphosphate, which closes K_{ATP}, leading to membrane depolarization, calcium influx, and insulin secretion (see Fig. 92-2). In the liver, the excessive oxidation of glutamate to β-ketoglutarate may generate ammonia and divert glutamate from being processed to *N*-acetylglutamate, an essential cofactor for removal of ammonia through the urea cycle via activation of the enzyme carbamoyl phosphate synthetase. The hyperammonemia is mild, with concentrations of 100-200 μM/L, and produces no CNS symptoms or consequences, as seen in other hyperammonemic states. Leucine, a potent amino acid for stimulating insulin secretion and implicated in leucine-sensitive hypoglycemia, acts by allosterically stimulating glutamate dehydrogenase. Thus, **leucine-sensitive hypoglycemia** may be a form of the hyperinsulinemia–hyperammonemia syndrome or a potentiation of mild disorders of the K_{ATP} channel; it need not always be associated with a modest increase in serum ammonia.

Hypoglycemia associated with hyperinsulinemia is also seen in approximately 50% of patients with the **Beckwith-Wiedemann syndrome.** This syndrome is caused by an imprinting disorder (see Chapter 81) and characterized by omphalocele, gigantism, macroglossia, microcephaly, and visceromegaly (Fig. 92-4). Distinctive lateral earlobe fissures and facial nevus flammeus are present; hemihypertrophy occurs in many of these infants. Diffuse islet cell hyperplasia occurs in infants with hypoglycemia. The diagnostic and therapeutic approaches are the same as those discussed previously, although

Figure 92-4 Beckwith-Wiedemann syndrome. *(Courtesy of Dr. Michael Cohen, Dalhousie University, Halifax, Nova Scotia. From Jones KL:* Smith's recognizable patterns of human malformation, *ed 6, Philadelphia, 2006, WB Saunders.)*

microcephaly and slowing of brain development may occur independently of hypoglycemia. Patients with the Beckwith-Wiedemann syndrome may acquire tumors, including Wilms tumor, hepatoblastoma, adrenal carcinoma, gonadoblastoma, and rhabdomyosarcoma. This overgrowth syndrome is caused by mutations in the chromosome 11p15.5 region close to the genes for insulin, SUR1, K_{IR} 6.2, and IGF2. Duplications in this region and genetic imprinting from a defective or absent copy of the maternally derived gene are involved in the variable features and patterns of transmission. Hypoglycemia may resolve in weeks to months of medical therapy. Pancreatic resection may rarely be needed.

Hyperinsulinemic hypoglycemia in infancy is reported as a manifestation of one form of **congenital disorder of glycosylation**. Disorders of protein glycosylation usually present with neurologic symptoms but may also include liver dysfunction with hepatomegaly, intractable diarrhea, protein-losing enteropathy, and hypoglycemia (see Chapter 87.6). These disorders are often underdiagnosed. One entity associated with hyperinsulinemic hypoglycemia is caused by phosphomannose isomerase deficiency, and clinical improvement followed supplemental treatment with oral mannose at a dose of 0.17 g/kg 6 times per day.

After the first 12 mo of life, hyperinsulinemic states are uncommon until islet cell adenomas reappear as a cause after the patient is several years of age. Hyperinsulinemia as a result of **islet cell adenoma** should be considered in any child 5 yr or older who presents with hypoglycemia. Islet cell adenomas do not "light up" during scanning with L-dopa labeled with fluorine-18. An islet cell adenoma in a child should arouse suspicion of the possibility of **multiple endocrine neoplasia** type 1 (Wermer syndrome), which involves mutations in the menin gene and may be associated with hyperparathyroidism and with pituitary tumors. Tables 92-7 and 92-8 outline the diagnostic approach. Fasting for up to 24-36 hr usually provokes hypoglycemia; coexisting hyperinsulinemia confirms the diagnosis,

provided that factitious administration of insulin by the parents, a form of **Munchausen syndrome by proxy,** is excluded. Occasionally, provocative tests may be required. Exogenously administered insulin can be distinguished from endogenous insulin by simultaneous measurement of C-peptide concentration. If C-peptide levels are elevated, endogenous insulin secretion is responsible for the hypoglycemia; if C-peptide levels are low but insulin values are high, exogenous insulin has been administered, perhaps as a form of child abuse. Islet cell adenomas at this age are treated by surgical excision. Antibodies to insulin or the insulin receptor (**insulin mimetic action**) are also rarely associated with hypoglycemia. Activating mutations in the Akt2 signaling complex of the insulin receptor also can cause hyperinsulinism. Some **tumors** produce insulin-like growth factors, thereby provoking hypoglycemia by interacting with the insulin receptor. The astute clinician must also consider the possibility of deliberate or accidental ingestion of drugs such as a sulfonylurea or related compound that stimulates insulin secretion. In such cases, insulin and C-peptide concentrations in blood will be elevated. Inadvertent substitution of an insulin secretagogue by a dispensing error should be considered in those taking medications who suddenly develop documented hypoglycemia.

A rare form of hyperinsulinemic hypoglycemia has been reported after **exercise**. Whereas glucose and insulin remain unchanged in most people after moderate, short-term exercise, rare patients manifest severe hypoglycemia with hyperinsulinemia 15-50 min after the same standardized exercise. This form of exercise-induced hyperinsulinism is caused by an abnormal responsiveness of β-cell insulin release in response to pyruvate generated during exercise. The gene responsible for this syndrome, *SLC16A1,* regulates a transporter, MCT1R, that controls the entry of pyruvate into cells. Dominant mutations in *SLC16A1* that increase the ectopic expression of MCTR1 transporter in pancreatic β cells permit excessive entry of pyruvate into β cells and act to increase insulin secretion with resultant hypoglycemia during exercise.

Hypoglycemia with so-called nesidioblastosis has also rarely been reported after **bariatric surgery** for obesity. The mechanism for this form of hyperinsulinemic hypoglycemia remains to be defined.

Infants and children with **Nissen fundoplication,** a relatively common procedure used to ameliorate gastroesophageal reflux, frequently have an associated "dumping" syndrome with hypoglycemia. Characteristic features include significant hyperglycemia of 200 mg/dL and up to 500 mg/dL 30 min postprandially, and severe hypoglycemia (average 32 mg/dL in one series) 1.5-3.0 hr later. The early hyperglycemia phase is associated with brisk and excessive insulin release that causes the rebound hypoglycemia. A role for exaggerated GLP1 secretion has been proposed and glucagon responses have been reported to be inappropriately low in some cases. However, the physiologic mechanisms are not always clearly understood, and attempted treatments not always effective; **acarbose,** an inhibitor of glucose absorption, was reported to be successful in one small series.

Endocrine Deficiency

Hypoglycemia associated with endocrine deficiency is usually caused by adrenal insufficiency with or without associated growth hormone deficiency (see Chapters 557 and 575). In panhypopituitarism, isolated adrenocorticotropic hormone (ACTH) or growth hormone deficiency, or combined ACTH deficiency plus growth hormone deficiency, the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism; in males, a microphallus may provide a clue to a coexisting deficiency of gonadotropin. Newborns with hypopituitarism often have a form of "hepatitis" associated with cholestatic jaundice and hypoglycemia. The combination of hypoglycemia and cholestatic jaundice requires exclusion of hypopituitarism as a cause, as the jaundice resolves with replacement treatment of growth hormone, cortisol, and thyroid as required. This constellation is often associated with the syndrome of **septooptic dysplasia.** When adrenal disease is severe, as in congenital adrenal hyperplasia caused by enzyme defects in cortisol synthesis, adrenal hemorrhage, or congenital hypoplasia of the adrenal glands, disturbances in serum electrolytes with hyponatremia and hyperkalemia or ambiguous genitals may provide diagnostic clues (see Chapter 576). In older children, failure of growth should suggest growth hormone deficiency. Hyperpigmentation or salt-craving may provide the clue to Addison disease with increased ACTH levels or adrenal unresponsiveness to ACTH owing to a defect in the adrenal receptor for ACTH, congenital adrenal hypoplasia, adrenoleukodystrophy, or the Allgrove triple A syndrome. The frequent association of Addison disease in childhood with hypoparathyroidism (hypocalcemia), chronic mucocutaneous candidiasis, and other endocrinopathies which constitute the autoimmune polyendocrinopathy syndrome type 1 should be considered. Adrenoleukodystrophy, and congenital adrenal hypoplasia are sex-linked conditions and should be considered in the differential diagnosis of primary Addison disease in male children (see Chapter 86.2).

Hypoglycemia in cortisol–growth hormone deficiency may be caused by decreased gluconeogenic enzymes with cortisol deficiency, increased glucose utilization because of a lack of the antagonistic effects of growth hormone on insulin action, or failure to supply endogenous gluconeogenic substrate in the form of alanine and lactate with compensatory breakdown of fat and generation of ketones. Deficiency of these hormones results in reduced gluconeogenic substrate, which resembles the syndrome of ketotic hypoglycemia. Investigation of a child with hypoglycemia, therefore, requires exclusion of ACTH-cortisol or growth hormone deficiency and, if diagnosed, its appropriate replacement with cortisol or growth hormone.

Epinephrine deficiency could theoretically be responsible for hypoglycemia. Urinary excretion of epinephrine has been diminished in some patients with spontaneous or insulin-induced hypoglycemia in whom absence of pallor and tachycardia was also noted, suggesting that failure of catecholamine release, as the result of a defect anywhere along the hypothalamic–autonomic–adrenomedullary axis, might be responsible for the hypoglycemia. This possibility has been challenged, owing to the rarity of hypoglycemia in patients with bilateral adrenalectomy, provided that they receive adequate glucocorticoid replacement, and because diminished epinephrine excretion is found in normal patients with repeated insulin-induced hypoglycemia. Many of the patients described as having hypoglycemia with failure of epinephrine excretion fit the criteria for ketotic hypoglycemia. Also, repetitive hypoglycemia leads to diminished cortisol plus epinephrine responses, as seen most commonly in insulin-treated diabetes mellitus and the syndrome of hypoglycemia unawareness, associated with autonomic failure.

Glucagon deficiency in infants or children may theoretically be associated with hypoglycemia but has never been documented.

Substrate Limited

Ketotic Hypoglycemia

Ketotic hypoglycemia is the **most common** form of *childhood* hypoglycemia. This condition usually presents between the ages of 18 mo and 5 yr and commonly remits spontaneously by the age of 8-9 yr. Hypoglycemic episodes typically occur during periods of intercurrent illness when food intake is limited. The classic history is of a child who eats poorly or completely avoids the evening meal, is difficult to arouse from sleep the following morning and hence eats poorly again, and may have a seizure or be comatose by mid-morning. Another common presentation occurs when parents sleep late and the affected child is unable to eat breakfast, thus prolonging the overnight fast.

At the time of documented hypoglycemia, there is associated ketonuria and ketonemia; plasma insulin concentrations are appropriately low, ≤5-10 μU/mL, thus excluding hyperinsulinemia. A ketogenic provocative diet, formerly used as a diagnostic test, is no longer used to establish the diagnosis because fasting alone provokes a hypoglycemic episode with ketonemia and ketonuria within 12-18 hr in susceptible individuals. Normal children of similar age can withstand fasting without hypoglycemia developing during the same period, although

even normal children may acquire these features by 36 hr of fasting.

Children with ketotic hypoglycemia have plasma alanine concentrations that are markedly reduced in the basal state after an overnight fast and decline even further with prolonged fasting. Alanine, produced in muscle, is a major gluconeogenic precursor. Alanine is the only amino acid that is significantly lower in these children, and infusions of alanine (250 mg/kg) produce a rapid rise in plasma glucose without causing significant changes in blood lactate or pyruvate levels, indicating that the entire gluconeogenic pathway from the level of pyruvate is intact, but that there is a deficiency of substrate. Glycogenolytic pathways are also intact because glucagon induces a normal glycemic response in affected children in the fed state. The levels of hormones that counter hypoglycemia are appropriately elevated, and insulin is appropriately low.

The etiology of ketotic hypoglycemia may be a defect in any of the complex steps involved in protein catabolism, oxidative deamination of amino acids, transamination, alanine synthesis, or alanine efflux from muscle. Children with ketotic hypoglycemia are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia. Any decrease in muscle mass may compromise the supply of gluconeogenic substrate at a time when glucose demands per unit of body weight are already relatively high, thus predisposing the patient to the rapid development of hypoglycemia, with ketosis representing the attempt to switch to an alternative fuel supply. Children with ketotic hypoglycemia may represent the low end of the spectrum of children's capacity to tolerate fasting. Similar relative intolerance to fasting is present in normal children, who cannot maintain blood glucose after 30-36 hr of fasting, compared with the adult's capacity for prolonged fasting. Although the defect may be present at birth, it may not be evident until the child is stressed by more prolonged periods of calorie restriction. Moreover, the spontaneous remission observed in children at age 8-9 yr might be explained by the increase in muscle bulk with its resultant increase in supply of endogenous substrate and the relative decrease in glucose requirement per unit of body mass with increasing age.

In anticipation of spontaneous resolution of this syndrome, treatment of ketotic hypoglycemia consists of frequent feedings of a high-protein, high-carbohydrate diet. During intercurrent illnesses, parents should be taught to test the child's urine for the presence of ketones, the appearance of which precedes hypoglycemia by several hours. In the presence of ketonuria, liquids of high carbohydrate content should be offered to the child. If these cannot be tolerated, the child should be treated with intravenous glucose administration in a hospital.

Branched-Chain Ketonuria (Maple Syrup Urine Disease)

See Chapter 85.6.

The hypoglycemic episodes were once attributed to high levels of leucine, but evidence indicates that interference with the production of alanine and its availability as a gluconeogenic substrate during calorie deprivation is responsible for hypoglycemia.

Glycogen Storage Disease

See Chapter 87.1.

Glucose-6-Phosphatase Deficiency (Type I Glycogen Storage Disease)

Affected children usually display a remarkable tolerance to their chronic hypoglycemia; blood glucose values in the range of 20-50 mg/dL are not associated with the classic symptoms of hypoglycemia, possibly reflecting the adaptation of the CNS to ketone bodies and lactate as alternative fuels. Hepatomegaly and poor growth are consistent physical features. Hypoglycemia is associated with acidosis (HCO_3 <18 mEq/L), increased β O-B and lactate; hyperuricemia also is frequent. Management is discussed in detail in Chapter 87.

Amylo-1,6-Glucosidase Deficiency (Debrancher Enzyme Deficiency; Type III Glycogen Storage Disease)

See Chapter 87.

Liver Phosphorylase Deficiency (Type VI Glycogen Storage Disease)

See Chapter 87.

Low hepatic phosphorylase activity may result from a defect in any of the steps of activation; a variety of defects have been described. Hepatomegaly, excessive deposition of glycogen in liver, growth retardation, and occasional symptomatic hypoglycemia occur. A diet high in protein and reduced in carbohydrate usually prevents hypoglycemia.

Glycogen Synthetase Deficiency

See Chapter 87.

The inability to synthesize glycogen is rare. There is hypoglycemia and hyperketonemia after fasting because glycogen reserves are markedly diminished or absent. After feeding, however, hyperglycemia with glucosuria may occur because of the inability to assimilate some of the glucose load into glycogen. During fasting hypoglycemia, levels of the counterregulatory hormones, including catecholamines, are appropriately elevated or normal, and insulin levels are appropriately low. The liver is not enlarged. Protein-rich feedings at frequent intervals result in dramatic clinical improvement, including growth velocity. This condition mimics the syndrome of ketotic hypoglycemia and should be considered in the differential diagnosis of that syndrome.

Disorders of Gluconeogenesis

Fructose-1,6-Diphosphatase Deficiency

See Chapter 87.3.

A deficiency of this enzyme results in a block of gluconeogenesis from all possible precursors below the level of fructose-1,6-diphosphate. Infusion of these gluconeogenic precursors results in lactic acidosis without a rise in glucose; acute hypoglycemia may be provoked by inhibition of glycogenolysis. Glycogenolysis remains intact, and glucagon elicits a normal glycemic response in the fed, but not in the fasted, state. Accordingly, affected individuals have hypoglycemia only during caloric deprivation, as in fasting, or during intercurrent illness. As long as glycogen stores remain normal, hypoglycemia does not develop. In affected families, there may be a history of siblings with known hepatomegaly who died in infancy with unexplained metabolic acidosis.

Defects in Fatty Acid Oxidation

See Chapter 86.

The important role of fatty acid oxidation in maintaining gluconeogenesis is underscored by examples of congenital or drug-induced defects in fatty acid metabolism that may be associated with fasting hypoglycemia.

Various congenital enzymatic deficiencies causing defective carnitine or fatty acid metabolism occur. A severe and relatively common form of fasting hypoglycemia with hepatomegaly, cardiomyopathy, and hypotonia occurs with long- and medium-chain fatty acid CoA dehydrogenase deficiency. Plasma carnitine levels are low, ketones are not present, but dicarboxylic aciduria is present in urine. Clinically, patients with **acyl-CoA dehydrogenase deficiency** present with a Reye-like syndrome (see Chapter 361), recurrent episodes of severe fasting hypoglycemic coma, and cardiorespiratory arrest (sudden infant death syndrome-like events). Severe hypoglycemia and metabolic acidosis without ketosis also occur in patients with multiple acyl-CoA dehydrogenase disorders. Hypotonia, seizures, and acrid odor are other clinical clues. Survival depends on whether the defects are severe or mild; diagnosis is established from studies of enzyme activity in liver biopsy tissue or in cultured fibroblasts from affected patients. Tandem mass spectrometry can be employed for blood samples, even those on filter paper, for screening of congenital inborn errors. Molecular diagnosis also is available for most entities. The frequency of this disorder

is at least 1 in 10,000-15,000 births. Avoidance of fasting and supplementation with carnitine may be lifesaving in these patients who generally present in infancy.

Interference with fatty acid metabolism also underlies the fasting hypoglycemia associated with Jamaican vomiting sickness, with atractyloside, and with the drug valproate. In **Jamaican vomiting sickness,** the unripe ackee fruit contains a water-soluble toxin, hypoglycin, which produces vomiting, CNS depression, and severe hypoglycemia. The hypoglycemic activity of hypoglycin derives from its inhibition of gluconeogenesis secondary to its interference with the acyl-CoA and carnitine metabolism essential for the oxidation of long-chain fatty acids. The disease is almost totally confined to Jamaica, where ackee forms a staple of the diet for the poor. The ripe ackee fruit no longer contains this toxin. *Atractyloside* is a reagent that inhibits oxidative phosphorylation in mitochondria by preventing the translocation of adenine nucleotides, such as ATP, across the mitochondrial membrane. Atractyloside is a perhydrophenanthrenic glycoside derived from *Atractylis gummifera.* This plant is found in the Mediterranean basin; ingestion of this "thistle" is associated with hypoglycemia and a syndrome similar to Jamaican vomiting sickness. The anticonvulsant drug **valproate** is associated with side effects, predominantly in young infants, which include a Reye-like syndrome, low serum carnitine levels, and the potential for fasting hypoglycemia. In all these conditions, hypoglycemia *is not associated with ketonuria.*

Acute Alcohol Intoxication

The liver metabolizes alcohol as a preferred fuel, and generation of reducing equivalents during the oxidation of ethanol alters the reduced form of nicotinamide adenine dinucleotide : nicotinamide adenine dinucleotide ratio, which is essential for certain gluconeogenic steps. As a result, gluconeogenesis is impaired and hypoglycemia may ensue if glycogen stores are depleted by starvation or by preexisting abnormalities in glycogen metabolism. In toddlers who have been unfed for some time, even the consumption of small quantities of alcohol can precipitate these events. The hypoglycemia promptly responds to intravenous glucose, which should always be considered in a child who presents initially with coma or seizure, after taking a blood sample to determine glucose concentration. The possibility of the child's ingesting alcoholic drinks must also be considered if there was a preceding adult evening party. A careful history allows the diagnosis to be made and may avoid needless and expensive hospitalization and investigation.

Salicylate Intoxication

See Chapter 63.

Both hyperglycemia and hypoglycemia occur in children with salicylate intoxication. Accelerated utilization of glucose, resulting from augmentation of insulin secretion by salicylates, and possible interference with gluconeogenesis may contribute to hypoglycemia. Infants are more susceptible than are older children. Monitoring of blood glucose levels with appropriate glucose infusion in the event of hypoglycemia should form part of the therapeutic approach to salicylate intoxication in childhood. Ketosis may occur.

Phosphoenolpyruvate Carboxykinase Deficiency

Deficiency of this rate-limiting gluconeogenic enzyme is associated with severe fasting hypoglycemia and variable onset after birth. Hypoglycemia may occur within 24 hr after birth, and defective gluconeogenesis from alanine can be documented in vivo. Liver, kidney, and myocardium demonstrate fatty infiltration, and atrophy of the optic nerve and visual cortex may occur. Hypoglycemia may be profound. Lactate and pyruvate levels in plasma have been normal, but a mild metabolic acidosis may be present. The fatty infiltration of various organs is caused by increased formation of acetyl-CoA, which becomes available for fatty acid synthesis. Diagnosis of this rare entity can be made with certainty only through appropriate enzymatic determinations in liver biopsy material or molecular diagnosis. Avoidance of periods of fasting through frequent feedings rich in carbohydrate should be helpful because glycogen synthesis and breakdown are intact.

Pyruvate Carboxylase Deficiency

See Chapter 87.

Other Enzyme Defects

Galactosemia (Galactose-1-Phosphate Uridyl Transferase Deficiency)

See Chapter 87.

Fructose Intolerance (Fructose-1-Phosphate Aldolase Deficiency)

See Chapter 87.

Acute hypoglycemia is caused by the inhibition by fructose-1-phosphate of glycogenolysis via the phosphorylase system and of gluconeogenesis at the level of fructose-1,6-diphosphate aldolase. Affected individuals usually learn spontaneously to eliminate fructose from their diet.

Defects in Glucose Transporters

Glut-1 Deficiency

Rarely infants with a seizure disorder are found to have low CSF glucose concentrations despite normal plasma glucose. Lactate concentrations in CSF are low, suggesting decreased glycolysis rather than bacterial infection, which causes low CSF glucose with high lactate. The erythrocyte glucose transporter is defective, suggesting a similar defect in the brain glucose transporter responsible for the clinical features. A ketogenic diet reduces the severity of seizures by supplying an alternate source of brain fuel that bypassed the defect in glucose transport.

Glut-2 Deficiency

Children with hepatomegaly, galactose intolerance, and renal tubular dysfunction **(Fanconi-Bickel syndrome)** have a deficiency of the GLUT-2 glucose transporter of plasma membranes. In addition to liver and kidney tubules, GLUT-2 is also expressed in pancreatic β cells. Hence, the clinical manifestations reflect impaired glucose release from liver and defective tubular reabsorption of glucose plus phosphaturia and aminoaciduria**.**

Systemic Disorders

Several systemic disorders are associated with hypoglycemia in infants and children. Neonatal sepsis is often associated with hypoglycemia, possibly as a result of diminished caloric intake with impaired gluconeogenesis. Similar mechanisms may apply to the hypoglycemia found in severely malnourished infants or those with severe malabsorption. Hyperviscosity with a central hematocrit of >65% is associated with hypoglycemia in at least 10-15% of affected infants. **Falciparum malaria** is associated with hyperinsulinemia and hypoglycemia. Heart and renal failure are also associated with hypoglycemia, but the mechanism is obscure.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Table 92-8 and Figure 92-5 list the pertinent clinical and biochemical findings in the common childhood disorders associated with hypoglycemia. A careful and detailed history is essential in every suspected or documented case of hypoglycemia (see Table 92-7). Specific points to be noted include age at onset, temporal relation to meals or caloric deprivation, and a family history of prior infants known to have had hypoglycemia or of unexplained infant deaths. In the 1st wk of life, the majority of infants have the transient form of neonatal hypoglycemia either as a result of prematurity/intrauterine growth restriction or by virtue of being born to diabetic mothers. The absence of a history of maternal diabetes, but the presence of macrosomia and the characteristic large plethoric appearance of an "infant of a diabetic mother" should arouse the possibility of hyperinsulinemic hypoglycemia of infancy, probably resulting from a K_{ATP} channel defect that is familial (autosomal recessive) or sporadic; decreased β OH butyrate, low FFAs, and plasma insulin concentrations >5-10 μU/mL in the presence of documented hypoglycemia confirm this diagnosis. The presence of

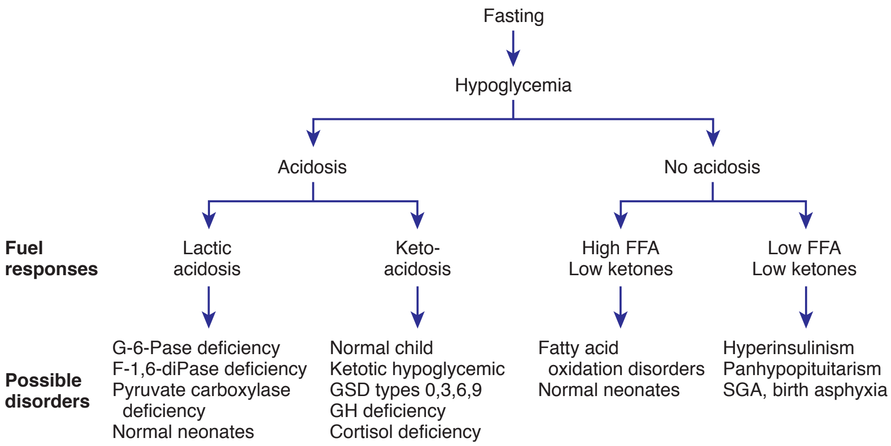

Figure 92-5 Algorithm for diagnosis of hypoglycemia based on fasting fuel responses. F1,6-diPase, fructose-1,6-diphosphatase; FFA, free fatty acid; G-6Pase, glucose-6-phosphatase; GH, growth hormone; GSD, glycogen storage disease; SGA, small for gestational age. *(From Kliegman RM, Greenbaum LA, Lye PS, editors:* Practical strategies in pediatric diagnosis and therapy, *ed 2, Philadelphia, 2004, Elsevier Saunders.)*

hepatomegaly should arouse suspicion of an enzyme deficiency such as glucose-6-phosphate in glycogen storage disease-1 or other glycogen storage diseases; if a non–glucose-reducing sugar is present in the urine (e.g., Clinitest positive but Clinistix negative), galactosemia is most likely. In males, the presence of a microphallus suggests the possibility of hypopituitarism, which also may be associated with cholestatic jaundice in both sexes; evidence of a midline facial defect such as cleft palate also suggests possible hypopituitarism as the cause of hypoglycemia via deficiency in growth hormone and/or cortisol. A high index of suspicion and awareness of hypoglycemia as the cause for unusual behavior of any "sick" newborn should prompt a **bedside glucose determination**. However, because glucose meters have an accuracy of only ±20%, any blood glucose value <60 mg/dL must be confirmed by a formal laboratory measurement that is performed without delay on a blood sample preserved in a tube that prevents glycolysis, which can cause spurious low values.

Past the newborn period, clues to the cause of persistent or recurrent hypoglycemia may be obtained through a careful history, physical examination, and initial laboratory findings. The temporal relation of the hypoglycemia to food intake may suggest that the defect is one of gluconeogenesis, if symptoms occur 6 hr or more after meals. If hypoglycemia occurs shortly after meals, hyperinsulinism should be suspected and confirmed or excluded via measurement of β OH butyrate, insulin, and FFA in a sample in which blood glucose is <50 mg/dL. The autosomal dominant forms of hyperinsulinemic hypoglycemia need to be considered, with measurement of glucose, insulin, and ammonia, and careful history for other affected family members of any age. Measurement of IGFBP-1 may be useful; it is low in states of hyperinsulinism and high in other forms of hypoglycemia. The presence of hepatomegaly suggests one of the enzyme deficiencies in glycogen breakdown or in gluconeogenesis, as outlined in Table 92-8. The absence of ketonemia or ketonuria at the time of initial presentation strongly suggests hyperinsulinism or a defect in fatty acid oxidation. In most other causes of hypoglycemia, with the exception of galactosemia and fructose intolerance, ketonemia and ketonuria are present at the time of fasting hypoglycemia. At the time of the hypoglycemia, serum should be obtained for determination of substrates especially β OH butyrate, lactate and FFA as well as hormones especially insulin, cortisol, ACTH, and growth hormone, followed by repeated measurement after an intramuscular or intravenous injection of glucagon, as outlined in Table 92-7. Table 92-8 summarizes the interpretation of the findings. Hypoglycemia with ketonuria in children between ages 18 mo and 5 yr is most likely to be ketotic hypoglycemia, especially if hepatomegaly is absent. The ingestion of a toxin, including alcohol or salicylate, can usually be excluded rapidly by the history. Inadvertent or deliberate drug ingestion and errors in dispensing medicines should also be considered. Munchhausen by proxy should be considered when parents or other caregivers have access to insulin or insulin secretagogues—high insulin concentrations in the sample with low concentrations of C-peptide confirm exogenous insulin administration. Deliberate or accidental ingestion of drugs that stimulate endogenous insulin secretion will result in both high insulin and C-peptide concentrations and may require specialized laboratory methods that identify the offending substance.

When the history is suggestive, but acute symptoms are not present, a 24 hr supervised fast can usually provoke hypoglycemia and resolve the question of hyperinsulinism or other conditions (see Table 92-8). Rarely, such a fast needs to be extended to 36 hr, but only in older children. Such a fast is contraindicated if a fatty acid oxidation defect is suspected; other approaches such as mass tandem spectrometry or molecular diagnosis, or both, should be considered. Because adrenal insufficiency may mimic ketotic hypoglycemia, plasma cortisol and ACTH levels should be determined at the time of documented hypoglycemia; increased buccal or skin pigmentation may provide the clue to primary adrenal insufficiency with elevated ACTH (melanocyte-stimulating hormone) activity. Short stature or a decrease in the growth rate may provide the clue to pituitary insufficiency involving growth hormone as well as ACTH. Definitive tests of pituitary–adrenal function, such as the arginine-insulin stimulation test for growth hormone insulin-like growth factor-1, IGFBP-1, and cortisol release, may be necessary.

In the presence of hepatomegaly and hypoglycemia, a presumptive diagnosis of the enzyme defect can often be made through the clinical manifestations, presence of hyperlipidemia, acidosis, hyperuricemia, response to glucagon in the fed and fasted states, and response to infusion of various appropriate precursors (see Tables 92-7 and 92-8). Table 92-8 summarizes these clinical findings and investigative approaches. Definitive diagnosis of the glycogen storage disease may require molecular diagnosis (see Chapter 87). Occasional patients with all the manifestations of glycogen storage disease are found to have normal enzyme activity. These definitive studies require special expertise available only in certain institutions.

TREATMENT

The prevention of hypoglycemia and its resultant effects on CNS development are critically important in the newborn period. For neonates with hyperinsulinism not associated with maternal diabetes, subtotal or focal pancreatectomy may be needed, unless hypoglycemia can be readily controlled with long-term diazoxide, somatostatin analogs (e.g., octreotide), or sirolimus.

Treatment of **acute symptomatic** neonatal or infant hypoglycemia includes intravenous administration of 2 mL/kg of 10% dextrose in water ($D_{10}W$), followed by a continuous infusion of glucose at 6-8 mg/kg/min, adjusting the rate to maintain blood glucose levels in the normal range. If hypoglycemic seizures are present, some recommend a 4 mL/kg bolus of $D_{10}W$.

Treatment of asymptomatic hyperglycemia in at risk infants usually includes enteral feedings rather than parenteral glucose. If symptoms develop or the hypoglycemia persists despite enteral feedings, intravenous glucose is indicated. Dextrose gel (40% at 400 mg/kg)

administered into the mouth may be an alternative to enteral feedings if breast milk or if formula is not available.

The management of **persistent** neonatal or infantile hypoglycemia includes increasing the rate of intravenous glucose infusion to 10-15 mg/kg/min or more, if needed. This may require a central venous or umbilical venous catheter to administer a hypertonic 15-25% glucose solution. If hyperinsulinism is present, it should be medically managed initially with diazoxide and then somatostatin analogs. If hypoglycemia is unresponsive to intravenous glucose plus diazoxide (maximal doses up to 15-20 mg/kg/day) and somatostatin analogs, surgery via partial or near-total pancreatectomy should be considered. Such surgery should be performed in centers with the requisite facilities, and trained staff experienced in the procedures. If possible, surgery should be preceded by [18F]-L-DOPA scanning to localize a lesion which can then provide guidance to the surgeon for curative resection before the operation is undertaken.

Oral diazoxide, 5-15 mg/kg/24 hr given in divided doses twice daily, may reverse hyperinsulinemic hypoglycemia but may also produce hirsutism, edema, nausea, hyperuricemia, electrolyte disturbances, advanced bone age, immunoglobulin G deficiency, and, rarely, hypotension with prolonged use. The long-acting somatostatin analog octreotide may be helpful in controlling hyperinsulinism causing hypoglycemia in patients with islet cell disorders, including genetic mutations in K_{ATP} channel and islet cell adenoma. Glucagon given by continuous IV infusion at 5 µg/kg/hr together with octreotide administered subcutaneously every 6-12 hr in doses of 20-50 µg/kg/day in neonates and young infants may maintain blood glucose, but generally these agents are used as a temporizing measure before surgery for partial or more complete pancreatectomy. Potential but unusual complications of octreotide include poor growth because of inhibition of growth hormone release, pain at the injection site, vomiting, diarrhea, and hepatic dysfunction (hepatitis, cholelithiasis), and necrotizing enterocolitis; tachyphylaxis to the drug's effects is more common. It may be particularly useful for the treatment of refractory hypoglycemia despite subtotal pancreatectomy. Total pancreatectomy is not optimal therapy, owing to the risks of surgery, permanent diabetes mellitus, and exocrine pancreatic insufficiency. Continued prolonged medical therapy without pancreatic resection if hypoglycemia is controllable is worthwhile, because over time some children have a spontaneous resolution of the hyperinsulinism-induced hypoglycemia. This should be balanced against the risk of hypoglycemia-induced CNS injury and the toxicity of drugs.

PROGNOSIS

The prognosis is good in asymptomatic neonates with hypoglycemia of short duration. Hypoglycemia recurs in 10-15% of infants after adequate treatment. Recurrence is more common if intravenous fluids are extravasated or discontinued too rapidly before oral feedings are well tolerated. Children who had transient neonatal hypoglycemia have an increased incidence of ketotic hypoglycemia later in life.

The prognosis for normal intellectual function must be guarded because prolonged, recurrent, and severe symptomatic hypoglycemia is associated with neurologic sequelae. Symptomatic infants with hypoglycemia, particularly low-birthweight infants, those with persistent hyperinsulinemic hypoglycemia, and severely hypoglycemic infants born to poorly controlled diabetic mothers, have a poorer prognosis for subsequent normal intellectual development than asymptomatic infants do.

The Fetus and the Neonatal Infant

PART XII

Chapter 93

Overview of Mortality and Morbidity

Waldemar A. Carlo

The risk for mortality in fetuses and neonates is very high around the time of birth. The perinatal period is most often defined as the period from the 28th wk of gestation through the 7th day after birth. The neonatal period is defined as the 1st 28 days after birth and may be further subdivided into the very early (birth to <24 hr), early (birth to <7 days), and late neonatal periods (7 days to <28 days). Infancy is defined as the 1st yr after birth.

Perinatal mortality is influenced by prenatal, maternal, and fetal conditions and by circumstances surrounding delivery. Perinatal deaths are associated with intrauterine growth restriction (IUGR); conditions that predispose the fetus to asphyxia, such as placental insufficiency; severe congenital malformations; and overwhelming early-onset neonatal infections (Table 93-1). The major causes of neonatal mortality are prematurity/low birthweight (LBW) and congenital anomalies (Fig. 93-1). Mortality is highest during the 1st 24 hr after birth. Neonatal mortality (4.04/1,000 in 2011) accounts for about two-thirds of all infant deaths (deaths before 1 yr of age). Neonatal and postneonatal mortality rates in the United States have declined slightly in the last decade (Fig. 93-2). Factors related to the decline in mortality include improved obstetric and neonatal intensive care management with a significant reduction in birthweight-specific neonatal mortality (Fig. 93-3). Further reduction in neonatal mortality will depend on prevention of preterm delivery and LBW, prenatal diagnosis and early management of congenital anomalies, and effective diagnosis and treatment of diseases that result from adverse factors during pregnancy, labor, and/or delivery (see Table 93-1). In the United States each year, approximately 6 million pregnancies, 4 million live births, 19,000 neonatal deaths, and 28,000 infant deaths occur. Approximately 10% of births are to teenage women between the ages of 15 and 19 yr, a proportion that has been decreasing for approximately 50 yr (Fig. 93-4). Births to girls 10-14 yr of age, very young mothers who are at great social and medical risk, declined substantially over this period.

Infant mortality rates (deaths occurring from birth to 12 mo per 1,000 live births) vary by country; in 2010, rates were lowest in Hong Kong (1.7/1,000 births), moderate in the United States (6.1/1,000), and highest in developing, resource-poor countries (30-150/1,000). Medical, socioeconomic, and cultural factors influence perinatal and neonatal mortality. Preventive variables such as health education, prenatal care, nutrition, social support, risk identification, and obstetric care can effectively reduce perinatal, neonatal, and infant mortality. A number of reasons can explain in part the relatively higher infant mortality in the United States than in other countries. There is evidence of differential reporting of live births versus fetal deaths or stillbirths among countries. Many countries do not report as live births those of infants as mature as up to 27 wk if they die early after birth. The reporting of vital events in the United States is more complete than in many countries, including developed countries. This situation in part explains the larger proportion of LBW/preterm infants in the United States than in other countries. Increases in recorded preterm live births, especially of the most immature infants (<500 g body weight) in the United States, result in increases in both neonatal and infant mortality rates. Nonetheless, continuing healthcare disparities in part account for the higher infant mortality rate in the United States. Infants of African-American women continue to have a high infant mortality rate (12.76/1,000), which is more than twice the rates of infants of white (5.52/1,000) and Hispanic mothers (4.76/1,000 Central and South American vs. 7.29/1,000 Puerto Rican).

In the United States, approximately 50% of infant deaths in 2011 were a consequence of 4 conditions (classified according to the *International Classification of Diseases*, 10th revision): congenital malformations (20.1%), disorders relating to prematurity and unspecified LBW (16.9%), sudden infant death syndrome (8.2%), and newborns affected by maternal complications of pregnancy (6.3%). LBW (as a result of preterm delivery and/or IUGR) is a major determinant of both neonatal and infant mortality rates and, together with congenital anomalies (cardiac, central nervous system, respiratory), contributes significantly to childhood morbidity. In developing countries, LBW/prematurity, birth asphyxia, and infections are the major causes of infant deaths.

The LBW rate (infants weighing ≤2,500 g at birth each year) in the United States increased from 6.6% to 8.2% between 1981 and 2008, whereas the very-low birthweight (VLBW) rate (infants weighing ≤1,500 g at birth) increased from 1.1% to 1.46% of all births. In the past decade, LBW has increased among white infants, mainly because of a rise in the number of multiple births (often associated with assisted reproduction). Nonetheless, LBW and VLBW rates remain highest among black infants. Reasons for the racial disparity in LBW remain unclear. Despite advances in prenatal and obstetric care, racial disparity in birthweight persists, thus suggesting the need for novel prevention programs. Furthermore, although preterm LBW survival is better among black neonates, overall neonatal and infant mortality rates remain highest among blacks (Fig. 93-5), even for infants born to extremely low-risk mothers (married, age 20-34 yr, ≥13 yr of education, adequate prenatal care, no medical risk factors, no alcohol or tobacco use during pregnancy). A reduction in the racial disparity in mortality is an important public health issue reflected in *Healthy People 2020*, the U.S. national health objectives for the year 2020.

LBW is caused by preterm birth, IUGR, or both. The predominant cause of LBW in the United States is preterm birth, whereas in developing countries, the cause is more often IUGR. Although IUGR does not appear to further increase the risk of mortality in preterm infants, both morbidity and mortality are increased in term growth-restricted infants. VLBW infants are most often premature (<37 wk of gestation), although IUGR may also complicate their early delivery. Even though VLBW occurs in only 1-2% of all infants in the United States, their births represent a large proportion of the neonatal and infant mortality, as well as of infants with both short- and long-term complications, including neurodevelopmental handicaps. The etiology of preterm birth is complex, multifactorial, and not completely understood. Causes include maternal diseases such as severe preeclampsia requiring elective delivery, premature rupture of membranes, uterine abnormalities, placental bleeding (abruptio, previa), multiple-fetus gestation, drug misuse, maternal chronic illnesses, fetal distress, and infection. A complex interaction can be noted among infection, inflammation, and both preterm premature rupture of membranes and preterm birth. Infectious antecedents include maternal urinary tract infection, chorioamnionitis, bacterial vaginosis, and upper and lower genitourinary tract infection with a variety of agents (*Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Gardnerella vaginalis,* and group B streptococcus). Preconceptional dietary folate supplementation may effectively reduce the rate of spontaneous

preterm birth. In many cases, the cause of preterm delivery is unknown. The number of late preterm births (34-36 wk) has increased owing in part to elective deliveries; late preterm neonates are also at increased risk for morbidity and mortality. If possible, elective delivery should be delayed until ≥39 wk.

Although 99% of births occur in hospitals, only 80-85% of pregnant women receive ideal prenatal care in the 1st trimester. Many women who receive inadequate prenatal care are at risk for perinatal complications. Barriers to prenatal care include lack or insufficiency of money or insurance to pay for care; poor coordination of services, including language and cultural issues; and inadequate effective education about the importance of prenatal care. Successful and adequate provision of high-quality prenatal care requires competent healthcare professionals and coordination of services among physicians' offices, clinics, community hospitals, specially regionalized programs for high-risk mothers and infants, and tertiary care centers. Regional perinatal programs should provide continuing education and consultation in both the community and the referral center and transportation for pregnant women and newborn infants to appropriate hospitals; they should also include a regional hospital with facilities, equipment, and personnel for obstetric and neonatal intensive care (Table 93-2).

Fetal deaths slightly exceed neonatal deaths in their contribution to perinatal mortality. The fetal mortality rate in the United States has been declining steadily during the last 2 decades and decreased to 6.2/1000 in 2004. Obstetricians and maternal–fetal medicine subspecialists have a central role in reducing perinatal mortality and

morbidity. The overall decrease in fetal death has been from a reduction in late fetal deaths (≥28 wk). Intrapartum fetal deaths have declined more than antepartum fetal deaths, reflecting improvements in care during labor and delivery. It is important to emphasize the ability to predict the maturity and functional reserve of a fetus both before and during labor so that fetuses and infants at greatest risk can be identified as early as possible. The obstetrician and pediatrician must interact effectively to anticipate perinatal problems and take prompt preventive and therapeutic measures.

Causes of intrauterine fetal demise include obstetric conditions (preeclampsia, others), placental and umbilical cord abnormalities, genetic and syndromic disorders, intrauterine infections, fetal growth restriction, and preexisting maternal diseases. In approximately 40% of intrauterine fetal demise, there is no identifiable etiology.

Table 93-1	Major Causes of Perinatal and Neonatal Mortality

Trauma	
Infection	
Meconium aspiration pneumonia	
Persistent pulmonary hypertension (PPHN)	

Postneonatal mortality refers to deaths between 28 days and 1 yr of life. Historically, these infant deaths were a result of causes outside the neonatal period, such as sudden infant death syndrome, infections (respiratory, enteric), and trauma. With the advent of modern neonatal care, many VLBW and preterm infants who would have died in the 1st mo of life now survive the neonatal period only to succumb to the sequelae listed in Table 93-3. This delayed neonatal mortality is an important contributor to postneonatal mortality and explains its lack of decline during the last years.

Late preterm infants are at risk for hypothermia, hypoglycemia, respiratory distress, apnea, jaundice, feeding difficulties, dehydration, and suspected sepsis. They are also at risk of having rehospitalizations. Even term infants born at 37 and 38 wk by cesarean section are at increased risk for respiratory distress syndrome, transient tachypnea of the newborn, suspected sepsis, hypoglycemia, need for ventilatory support, and admission to the neonatal intensive care unit (Table 93-4).

For the most immature infants at the limit of viability (22-25 wk gestation), decision making about care is a complex process that involves the physician, other health professionals, and the family. The challenge for all premature infants is not only to improve survival, but also to reduce short-term complications and improve long-term neurodevelopmental outcome. Adverse neurodevelopmental sequelae include cerebral palsy, seizures, hydrocephalus requiring a shunt, blindness, deafness, and cognitive impairment. The risk of an adverse outcome increases with decreasing gestational age at birth. Higher birthweight, female gender, singleton birth, and antenatal steroids reduce the risk of neurodevelopment impairment or death. Early morbidity and prognostic variables that contribute to adverse neurodevelopmental outcomes include intraventricular hemorrhage, periventricular leukomalacia, necrotizing enterocolitis requiring extensive bowel resection, neonatal infection, and bronchopulmonary dysplasia. Many studies have documented the impact of adverse social and family risk factors on poor outcome.

Table 93-2 Levels of In-Hospital Perinatal Care

MATERNAL	NEONATE
BASIC	
Monitor and care for low-risk patients	Resuscitation
	Stabilization
Triage for high risk for transfer	Well neonatal care
Detection and care of unanticipated labor problems	Nursery care
Emergency cesarean delivery within 30 min	Visitation
	General pediatrician staff (capable of neonatal resuscitation)
Blood bank, anesthesia, radiology, ultrasound, and laboratory support	
Care of postpartum problems	
Obstetrician, nurse, midwife staff	
SPECIAL CARE	
Basic services plus:	*Basic services plus:*
Care of high-risk pregnancies	Care of high-risk neonate with short-term problems
Triage, transfer of high-risk pregnancies (<32 wk, intrauterine growth retardation, preeclampsia, severe maternal medical illness)	Stabilization before transfer (<1,500 g, <32 wk, critically ill)
	Accept convalescing back (reverse) transfers
SUBSPECIALTY CARE	
Basic plus specialty care plus:	*Basic plus specialty care plus:*
Experienced perinatologist (24-hr coverage)	Experienced neonatologist (24-hr coverage)
Evaluation of high-risk therapies	Inborn plus transferred patients
Care for severe maternal medical or obstetric illnesses	Evaluation of high-risk therapies
	All pediatric medical, radiologic, and surgical subspecialties
High-risk fetal care (Rh disease, nonimmune hydrops, life-threatening anomalies)	Neonatal intensive care unit with operating room capabilities
	High-risk follow-up
Outcomes research	Outcomes research

Table 93-3 Morbidities and Sequelae of Perinatal and Neonatal Illness

MORBIDITIES	EXAMPLES
CENTRAL NERVOUS SYSTEM	
Spastic diplegic-quadriplegic cerebral palsy	Hypoxic–ischemic encephalopathy, periventricular leukomalacia, undetermined antenatal factors
Choreoathetotic cerebral palsy	Bilirubin encephalopathy (kernicterus)
Microcephaly	Hypoxic-ischemic encephalopathy, intrauterine infection (rubella, CMV)
Communicating hydrocephalus	Intraventricular hemorrhage, meningitis
Seizures	Hypoxic-ischemic encephalopathy, hypoglycemia
Encephalopathy	Congenital infections (rubella, CMV, HIV, toxoplasmosis)
Educational failure and/or mental retardation	Immaturity, hypoxia, hypoglycemia, cerebral palsy, intraventricular hemorrhage, low socioeconomic status
SENSATION—PERIPHERAL NERVES	
Reduced visual acuity (blindness)	Retinopathy of prematurity
Strabismus	Undetermined, prematurity
Hearing impairment (deafness)	Drug toxicity (furosemide, aminoglycosides), bilirubin encephalopathy, hypoxia ± hyperventilation
Poor speech	Immaturity, chronic illness, hypoxia, prolonged endotracheal intubation, hearing deficit
Paralysis–paresis	Birth trauma—brachial plexus, phrenic nerve, spinal cord
RESPIRATORY	
BPD	Oxygen toxicity, barotrauma
Subglottic stenosis	Endotracheal tube injury
Sudden infant death syndrome	Prematurity, BPD, infant of illicit drug user
Choanal stenosis, nasal septum destruction	Nasotracheal intubation
	Growth failure
CARDIOVASCULAR	
Cyanosis	Precorrective palliative care of congenital cyanotic heart disease, cor pulmonale from BPD, reactive airway
Heart failure	Precorrective palliative care of complex congenital heart disease, BPD, ventricular septal defect
GASTROINTESTINAL	
Short-gut syndrome	Necrotizing enterocolitis, gastroschisis, malrotation-volvulus, cystic fibrosis, intestinal atresia
Cholestatic liver disease (cirrhosis, hepatic failure)	Hyperalimentation toxicity, sepsis, short-gut syndrome
Failure to thrive	Short-gut syndrome, cholestasis, BPD, cerebral palsy, severe congenital heart disease
Inguinal hernia	Unknown
MISCELLANEOUS	
Cutaneous scars	Chest tube or intravenous catheter placement, hyperalimentation, subcutaneous infiltration, fetal puncture, intrauterine varicella, cutis aplasia
Absence of radial artery pulse	Frequent arterial puncture
Hypertension	Renal thrombi, repair of coarctation of aorta

BPD, bronchopulmonary dysplasia; CMV, cytomegalovirus.

Table 93-4 Incidence of Adverse Outcome According to Completed Week of Gestation at Delivery for Infants Born by Caesarean Section

OUTCOME	WK 37 (N = 934)	WK 38 (N = 3909)	WK 39 (N = 6512)	WK 40 (N = 1385)	WK 41 (N = 1385)	WK 42 (N = 113)
Respiratory distress syndrome	3.7	1.9	0.9	0.9	0.8	1.8

Admission to the neonatal intensive care unit	12.8	8.1	5.9	4.8	7.9	14.2
Suspected sepsis	6.6	3.9	2.4	2.6	3.6	10.6
Treated hypoglycemia	2.4	0.9	0.7	0.8	1.6	1.8
Ventilation	1.9	0.9	0.4	0.4	0.4	

From Tita AT, Landon MB, Spong CY, et al: Timing of elective repeat cesarean delivery at term and neonatal outcomes, N Engl J Med *360:111–120, 2009.*

High-risk infants must be monitored after discharge so that neurodevelopmental impairment is detected as early as possible and to ensure that children and families receive any interventions indicated and adequate support to optimize long-term outcome. At school age, former VLBW and preterm infants have poorer physical growth, cognitive function, and school performance. Although disadvantages may persist into adulthood, data now suggest that there may be cognitive improvement throughout childhood.

Chapter 94

The Newborn Infant

Waldemar A. Carlo

See also Chapter 9.

The neonatal period is a highly vulnerable time for infants as they are completing many of the physiologic adjustments required for extrauterine existence. The high neonatal morbidity and mortality rates attest to the fragility of life during this period; of all deaths occurring in the 1st yr of life in the United States, two-thirds are in the neonatal period. The annual rate of deaths during the 1st yr is unequaled by the rate in any other period of life until the 7th decade.

94.1 History in Neonatal Pediatrics

Waldemar A. Carlo

The perinatal history should include the following information:

- Demographic and social data: socioeconomic status, age, race
- Past medical illnesses in the mother and family, including previous siblings: cardiopulmonary disorders, infectious diseases, genetic disorders, anemia, jaundice, diabetes mellitus
- Previous maternal reproductive problems: stillbirth, prematurity, blood group sensitization
- Events occurring in the present pregnancy: preterm labor, fetal assessments, vaginal bleeding, medications, acute illness, duration of rupture of membranes
- Description of the labor (duration, fetal presentation, fetal distress, fever) and delivery (cesarean section, anesthesia or sedation, use of forceps, Apgar scores, need for resuscitation)

94.2 Physical Examination of the Newborn Infant

Waldemar A. Carlo

Many physical and behavioral characteristics of a normal newborn infant are described in Chapters 9 and 590.

The **initial examination** of a newborn infant should be performed as soon as possible after delivery. Temperature, pulse, respiratory rate, color, signs of respiratory distress, tone, activity, and level of consciousness of infants should be monitored frequently until stabilization. For high-risk deliveries, this examination should take place in the delivery room and should focus on congenital anomalies, maturation and growth, and pathophysiologic problems that may interfere with normal cardiopulmonary and metabolic adaptation to extrauterine life. Congenital anomalies of varying degrees of severity may be present in 3-5% of infants. After a stable delivery room course, a second and more detailed examination should be performed within 24 hr of birth. If an infant remains in the hospital longer than 48 hr, a **discharge examination** should be performed within 24 hr of discharge. For a healthy infant, the mother should be present during this examination; even minor, seemingly insignificant anatomic variations may worry the parents and should be explained. The explanation must be careful and skillful so that otherwise unworried parents are not unduly alarmed. Infants should not be discharged from the hospital without a final examination because certain abnormalities, particularly cyanosis and heart murmurs, often appear or disappear in the immediate neonatal period; in addition, evidence of disease that has just been acquired may be noted. The pulse (normal: 120-160 beats/min), respiratory rate (normal: 30-60 breaths/min), temperature, weight, length, head circumference, and dimensions of any visible or palpable structural abnormality should be assessed. Blood pressure is determined if a neonate appears ill or has a heart murmur. Pulse oximetry should be performed to screen for critical congenital heart disease and is part of the routine screening for newborn infants. An oxygen saturation ≥95% test after 24 hr after birth in otherwise healthy appearing term infants has >99% sensitivity and specificity to rule out critical congenital heart disease. Neonates with oxygen saturations <95% should be referred for evaluation and possible echocardiogram (see Chapter 425).

Examining a newborn requires patience, gentleness, and procedural flexibility. Thus, if the infant is quiet and relaxed at the beginning of the examination, palpation of the abdomen or auscultation of the heart should be performed first, before other, more disturbing manipulations are attempted.

GENERAL APPEARANCE

Physical activity may be absent during normal sleep, or it may be decreased by the effects of illness or drugs; an infant may be either lying with the extremities motionless, to conserve energy for the effort of difficult breathing, or vigorously crying, with accompanying activity of the arms and legs. Both active and passive muscle tone and any unusual posture should be noted. Coarse, tremulous movements with ankle or jaw **myoclonus** are more common and less significant in newborn infants than at any other age. Such movements tend to occur when an infant is active, whereas convulsive twitching usually occurs in a quiet state. **Edema** may produce a superficial appearance of good nutrition. Pitting after applied pressure may or may not be noted, but the skin of the fingers and toes lacks the normal fine wrinkles when filled with fluid. Edema of the eyelids commonly results from irritation caused by the administration of silver nitrate. Generalized edema may occur with prematurity, hypoproteinemia secondary to severe erythroblastosis fetalis, nonimmune hydrops, congenital nephrosis, Hurler syndrome, and from unknown causes. Localized edema suggests a congenital malformation of the lymphatic system; when confined to one or more extremities of a female infant, it may be the initial sign of Turner syndrome (see Chapters 81 and 586).

SKIN

Vasomotor instability and peripheral circulatory sluggishness are revealed by deep redness or purple lividity in a crying infant, whose color may darken profoundly with closure of the glottis preceding a vigorous cry, and by harmless cyanosis (**acrocyanosis**) of the hands and feet, especially when they are cool. Mottling, another example of general circulatory instability, may be associated with serious illness or related to a transient fluctuation in skin temperature. An extraordinary division of the body from the forehead to the pubis into red and pale halves is known as **harlequin color change**, a transient and harmless condition. Significant **cyanosis** may be masked by the pallor of circulatory failure or anemia; alternatively, the relatively high hemoglobin content of the 1st few days and the thin skin may combine to produce an appearance of cyanosis at a higher Pa_{O_2} (partial pressure arterial oxygen) than in older children. Localized cyanosis is differentiated from ecchymosis by the momentary blanching pallor (with cyanosis) that occurs after pressure. The same maneuver also helps in demonstrating icterus. **Pallor** may be caused by anemia, asphyxia, shock, or edema. Early recognition of anemia may lead to a diagnosis of fetomaternal blood transfusion, erythroblastosis fetalis, subcapsular hematoma of the liver or spleen, subdural hemorrhage, or fetal–maternal or twin–twin transfusion. Without being anemic, postmature infants tend to have paler and thicker skin than term or premature infants. The ruddy appearance of plethora is seen with polycythemia.

The vernix and common transitory macular capillary hemangiomas of the eyelids and neck are described in Chapter 647. Cavernous

hemangiomas are deeper, blue masses that, if large, may trap platelets and produce disseminated intravascular coagulation or interfere with local organ function. Scattered petechiae may be seen on the presenting part (usually the scalp or face) after a difficult delivery. Slate-blue, well-demarcated areas of pigmentation called **Mongolian spots** are seen over the buttocks, back, and sometimes other parts of the body in more than 50% of black, Native American, and Asian infants, and occasionally in white infants. These benign patches have no known anthropologic significance despite their name; they tend to disappear within the 1st year. The vernix, skin, and especially the cord may be stained brownish yellow if the amniotic fluid has been colored by the passage of meconium during or before birth.

The skin of premature infants is thin and delicate and tends to be deep red; in extremely premature infants, the skin appears almost gelatinous and translucent. Fine, soft, immature hair called **lanugo** frequently covers the scalp and brow and may also cover the face of premature infants. Lanugo has usually been lost or replaced by vellus hair in term infants. **Tufts of hair** over the lumbosacral spine suggest an underlying abnormality, such as occult spina bifida, a sinus tract, or a tumor. The nails are rudimentary in very premature infants, but they may protrude beyond the fingertips in infants born past term. Postterm infants may have a peeling, parchment-like skin (Fig. 94-1), a severe degree of which may mimic ichthyosis congenita (see Chapter 658).

In many neonates, small, white papules on an erythematous base develop 1-3 days after birth. This benign rash, **erythema toxicum**, persists for as long as 1 wk, contains eosinophils, and is usually distributed on the face, trunk, and extremities (see Chapter 647). **Pustular melanosis**, a benign lesion seen predominantly in black neonates, contains neutrophils and is present at birth as a vesiculopustular eruption around the chin, neck, back, extremities, and palms or soles; it lasts 2-3 days. Both lesions need to be distinguished from more dangerous vesicular eruptions such as herpes simplex (see Chapter 252) and staphylococcal disease of the skin (see Chapter 181.1).

Amniotic bands may disrupt the skin, extremities (amputation, ring constriction, syndactyly), face (clefts), or trunk (abdominal or thoracic wall defects). Their cause is uncertain but may be related to amniotic membrane rupture or vascular compromise with fibrous band formation. Excessive skin fragility and extensibility with joint hypermobility suggest Ehlers-Danlos syndrome, Marfan syndrome, congenital contractural arachnodactyly, and other disorders of collagen synthesis.

Figure 94-1 **Infant with intrauterine growth retardation as a result of placental insufficiency.** Note the long, thin appearance with peeling, parchment-like dry skin, alert expression, meconium staining of the skin, and long nails. *(From Clifford S:* Advances in pediatrics, *vol 9, Chicago, 1962, Year Book.)*

SKULL

The head circumference of all infants should be plotted on a growth chart to rule out **microcephalus** and **megalencephaly**. The skull may be molded, particularly if the infant is the first-born and if the head has been engaged in the pelvic canal for a considerable time. The parietal bones tend to override the occipital and frontal bones. The head of an infant born by cesarean section or from a breech presentation is characterized by its roundness. The suture lines and the size and fullness of the anterior and posterior fontanels should be determined digitally by palpation. Premature fusion of sutures (**cranial synostosis**) is identified as a hard nonmovable ridge over the suture and an abnormally shaped skull. Great variation in the size of the **fontanels** exists at birth; if small, the anterior fontanel usually tends to enlarge during the first few mo after birth. The persistence of excessively large anterior (normal: 20 ± 10 mm) and posterior fontanels has been associated with several disorders (Table 94-1). Persistently small fontanels suggest microcephaly, craniosynostosis, congenital hyperthyroidism, or wormian bones; presence of a third fontanel suggests trisomy 21, but is seen in preterm infants. Soft areas (**craniotabes**) are occasionally found in the parietal bones at the vertex near the sagittal suture; they are more common in preterm infants and in infants who have been exposed to uterine compression. Although such soft areas are usually insignificant, their possible pathologic cause should be investigated if they persist. Soft areas in the occipital region suggest the irregular calcification and wormian bone formation associated with osteogenesis imperfecta, cleidocranial dysostosis, lacunar skull, cretinism, and, occasionally, Down syndrome. Transillumination of an abnormal skull in a dark room followed by ultrasound or magnetic resonance imaging will rule out hydranencephaly and hydrocephaly (see Chapter 591). An excessively large head (megalencephaly) suggests hydrocephaly, storage disease, achondroplasia, cerebral gigantism, neurocutaneous syndromes, or inborn errors of metabolism, or may be familial. The skull of a premature infant may suggest hydrocephaly because of the relatively larger brain growth in comparison with growth of other organs. Depression of the skull (indentation, fracture, ping pong ball deformity) is usually of prenatal onset and a result of prolonged focal

Table 94-1 Disorders Associated with a Large Anterior Fontanel
Achondroplasia
Apert syndrome
Athyrotic hypothyroidism
Cleidocranial dysostosis
Congenital rubella syndrome
Hallermann-Streiff syndrome
Hydrocephaly
Hypophosphatasia
Intrauterine growth restriction
Kenny syndrome
Osteogenesis imperfecta
Prematurity
Pyknodysostosis
Russell-Silver syndrome
Trisomies 13-, 18-, and 21
Vitamin D deficiency rickets

pressure by the bony pelvis. Atrophic or alopecic scalp areas may represent aplasia cutis congenita, which may be sporadic, or autosomal dominant, or associated with trisomy 13, chromosome 4 deletion, or Johanson-Blizzard syndrome. Deformational plagiocephaly may be the result of in utero positioning forces on the skull and manifests as an asymmetric skull and face with ear malalignment (see Chapter 592). It is associated with torticollis and vertex positioning.

FACE

The general appearance of the face should be noted with regard to dysmorphic features, such as epicanthal folds, widely or narrowly spaced eyes, microphthalmos, asymmetry, long philtrum, and low-set ears, which are often associated with congenital syndromes. The face may be asymmetric as a result of a 7th nerve palsy, hypoplasia of the depressor muscle at the angle of the mouth, or an abnormal fetal posture (see Chapter 108); when the jaw has been held against a shoulder or an extremity during the intrauterine period, the mandible may deviate strikingly from the midline. Symmetric facial palsy suggests absence or hypoplasia of the 7th nerve nucleus (**Möbius syndrome**).

Eyes

The eyes often open spontaneously if the infant is held up and tipped gently forward and backward. This maneuver, a result of labyrinthine and neck reflexes, is more successful for inspecting the eyes than is forcing the lids apart. Conjunctival and retinal hemorrhages are usually benign. Retinal hemorrhages are more common with vacuum- or forceps-assisted deliveries, than spontaneous vaginal delivery, and least common after cesarean section. They are usually bilateral, intraretinal, and in the posterior pole. They resolve in most infants by 2 wk of age (85%) and in all infants by 4 wk. **Pupillary reflexes** are present after 28-30 wk of gestation. The iris should be inspected for colobomas and heterochromia. A cornea >1 cm in diameter in a term infant (with photophobia and tearing) suggests congenital glaucoma and requires prompt ophthalmologic consultation. The presence of bilateral red reflexes suggests the absence of cataracts and intraocular pathology (see Chapters 619, 627-633). **Leukokoria** (white pupillary reflex) suggests cataracts, tumor, chorioretinitis, retinopathy of prematurity, or a persistent hyperplastic primary vitreous and warrants an immediate ophthalmologic consultation.

Ears

Deformities of the pinnae are occasionally seen. Unilateral or bilateral preauricular skin tags occur frequently; if pedunculated, they can be tightly ligated at the base, resulting in dry gangrene and sloughing. The tympanic membrane, easily seen otoscopically through the short and straight external auditory canal, normally appears dull gray.

Nose

The nose may be slightly obstructed by mucus accumulated in the narrow nostrils. The nares should be symmetric and patent. Dislocation of the nasal cartilage from the vomerian groove results in asymmetric nares. Anatomic obstruction of the nasal passages secondary to unilateral or bilateral choanal atresia results in respiratory distress.

Mouth

A normal mouth may rarely have precocious dentition, with natal (present at birth) or neonatal (eruption after birth) teeth in the lower incisor position or aberrantly placed; these teeth are shed before the deciduous ones erupt (see Chapter 307). Alternatively, such teeth occur in Ellis-van Creveld, Hallermann-Streiff, and other syndromes. Extraction is not usually indicated. Premature eruption of deciduous teeth is even more unusual. The soft and hard palate should be inspected and palpated for a complete or submucosal cleft, and the contour noted if the arch is excessively high or the uvula is bifid. On the hard palate on either side of the raphe, there may be temporary accumulations of epithelial cells called **Epstein pearls**. Retention cysts of similar appearance may also be seen on the gums. Both disappear spontaneously, usually within a few weeks of birth. Clusters of small white or yellow follicles or ulcers on erythematous bases may be found on the anterior tonsillar pillars, most frequently on the 2nd or 3rd day of life. Of unknown cause, they clear without treatment in 2-4 days.

Neonates do not have active salivation. The tongue appears relatively large; the frenulum may be short, but its shortness (**tongue-tied** or **ankyloglossia**) is rarely a reason for cutting it. If there are problems with feedings (breast or bottle) and the frenulum is short, frenulotomy (frenotomy) may be indicated. Frenotomy may reduce maternal nipple pain and improve breastfeeding scores more rapidly than no treatment, but over time neonates not treated with frenotomy also had successful feeding. The sublingual mucous membrane occasionally forms a prominent fold. The cheeks have fullness on both the buccal and the external aspects as a result of the accumulation of fat making up the sucking pads. These pads, as well as the labial tubercle on the upper lip (**sucking callus**), disappear when suckling ceases. A marble-sized buccal mass is usually caused by benign idiopathic fat necrosis.

The throat of a newborn infant is hard to see because of the low arch of the palate; it should be clearly viewed because posterior palatal or uvular clefts are easy to miss. The tonsils are small.

NECK

The neck appears relatively short. Abnormalities are not common but include goiter, cystic hygroma, branchial cleft rests, teratoma, hemangioma, and lesions of the sternocleidomastoid muscle that are presumably traumatic or due to a fixed positioning in utero that produces either a hematoma or fibrosis, respectively. Congenital **torticollis** causes the head to turn toward and the face to turn away from the affected side. Plagiocephaly, facial asymmetry, and hemihypoplasia may develop if it is untreated (see Chapter 592.1). Redundant skin or webbing in a female infant suggests intrauterine lymphedema and Turner syndrome (see Chapters 81 and 586). Both clavicles should be palpated for fractures.

CHEST

Breast hypertrophy is common, and milk may be present (but should not be expressed). Asymmetry, erythema, induration, and tenderness suggest mastitis or a breast abscess. Supernumerary nipples, inverted nipples, or widely spaced nipples with a shield-shaped chest may be seen; the last finding suggests Turner syndrome.

LUNGS

Much can be learned by observing breathing. Normal variations in rate and rhythm are characteristic and fluctuate according to the infant's physical activity, the state of wakefulness, or the presence of crying. Because fluctuations are rapid, the respiratory rate should be counted for a full minute with the infant in the resting state, preferably asleep. Under these circumstances, the usual rate for normal term infants is 30-60 breaths/min; in premature infants the rate is higher and fluctuates more widely. A rate consistently greater than 60 breaths/min during periods of regular breathing that persists for more than an hour after birth is an indication to rule out pulmonary, cardiac, or metabolic disease (acidosis) etiologies. Preterm infants may breathe with a Cheyne-Stokes rhythm, known as periodic respiration, or with complete irregularity. Irregular gasping, sometimes accompanied by spasmodic movements of the mouth and chin, strongly indicates serious impairment of the respiratory centers.

The breathing of newborn infants at rest is almost entirely diaphragmatic, so during inspiration, the soft front of the thorax is usually drawn inward while the abdomen protrudes. If the baby is quiet, relaxed, and with good color, this "paradoxic movement" does not necessarily signify insufficient ventilation. On the other hand, labored respiration with retractions is important evidence of respiratory distress syndrome, pneumonia, anomalies, or mechanical disturbance of the lungs. A weak persistent or intermittent groaning, whining cry, or **grunting** during expiration can signify potentially serious cardiopulmonary disease or sepsis and warrants immediate attention. When benign, the grunting resolves between 30 and 60 min after birth. Flaring of the alae nasi and retraction of the intercostal muscles and sternum are common signs of pulmonary pathology.

Normally, the breath sounds are bronchovesicular. Suspicion of pulmonary pathology because of diminished breath sounds, rhonchi, retractions, or cyanosis should always be verified with a chest radiograph.

HEART

Normal variation in the size and shape of the chest makes it difficult to estimate the size of the heart. The location of the heart should be determined to detect dextrocardia. Transitory murmurs usually represent a closing ductus arteriosus. Although congenital heart disease may not initially produce a murmur, a substantial portion of infants in whom persistent murmurs are detected during routine neonatal examination have underlying malformation. Evaluation of the heart by echocardiography is essential when the possibility of a significant lesion exists, particularly if oxygen saturations are below 95%.

The pulse is usually 110-140 beats/min at rest, but may vary normally from 90 beats/min in relaxed sleep to 180 beats/min during activity. The still higher rate of supraventricular tachycardia (>220 beats/min) may be determined better with a cardiac monitor or electrocardiogram than by auscultation. Preterm infants usually have a higher resting heart rate, up to about 160 beats/min, but may have a sudden onset of sinus bradycardia secondary to apnea. On both admission to and discharge from the nursery, the infant's pulses should be palpated in the upper and lower extremities to detect coarctation of the aorta.

Blood pressure measurements may be a valuable diagnostic aid in ill infants (see Chapter 425). The oscillometric method is the easiest and most accurate noninvasive method available. Continuous direct measurement of blood pressure with an umbilical artery catheter may be indicated in special circumstances for critically ill infants in an intensive care unit (Fig. 94-2).

ABDOMEN

The liver is usually palpable, sometimes as much as 2 cm below the rib margin. Less commonly, the tip of the spleen may be felt. The approximate size and location of each kidney can usually be determined on deep palpation. At no other period of life does the amount of air in the gastrointestinal tract vary so much, nor is it usually so great under normal circumstances. The intestinal tract is gasless at birth. Gas is swallowed soon after birth, and gas should normally be present in the rectum on roentgenogram by 24 hr of age. The abdominal wall is normally weak (especially in premature infants), and diastasis recti and umbilical hernias are common, particularly among black infants.

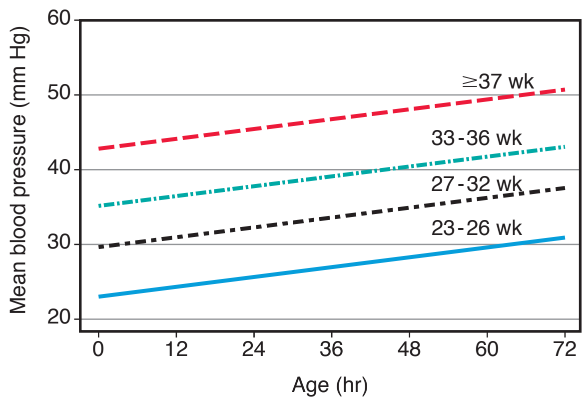

Figure 94-2 **Nomogram for mean blood pressure (BP) in neonates with gestational ages of 23-43 wk derived from continuous arterial BP measurements obtained from 103 infants admitted to the neonatal intensive care unit.** The graph shows the predicted mean BP of neonates of different gestational ages during the 1st 72 hr of life. Each line represents the lower limit of the 80% confidence interval (2-tail) of the mean BP for each gestational age group; 90% of infants for each gestational age group will be expected to have a mean BP value equal to or above the value indicated by the corresponding line, the lower limit of the confidence interval. *(From Nuntnarumit P, Yang W, Bada-Ellzey SB: Blood pressure measurements in the newborn,* Clin Perinatol *26:976–996, 1999.)*

Unusual masses should be investigated immediately with ultrasonography. Renal pathology is the cause of most neonatal abdominal masses. **Cystic abdominal masses** include hydronephrosis, multicystic-dysplastic kidneys, adrenal hemorrhage, hydrometrocolpos, intestinal duplication, and choledochal, ovarian, omental, or pancreatic cysts. **Solid masses** include neuroblastoma, congenital mesoblastic nephroma, hepatoblastoma, and teratoma. A solid flank mass may be caused by **renal vein thrombosis**, which becomes clinically apparent with hematuria, hypertension, and thrombocytopenia. Renal vein thrombosis in infants is associated with polycythemia, dehydration, maternal diabetes, asphyxia, sepsis, nephrosis, and hypercoagulable states such as antithrombin III and protein C deficiency.

Abdominal distention at birth or shortly afterward suggests either obstruction or perforation of the gastrointestinal tract, often as a result of meconium ileus; later distention suggests lower bowel obstruction, sepsis, or peritonitis. A scaphoid abdomen in a newborn suggests diaphragmatic hernia. Abdominal wall defects produce an omphalocele (see Chapter 105) when they occur through the umbilicus and gastroschisis when they occur lateral to the midline. Omphaloceles are associated with other anomalies and syndromes such as Beckwith-Wiedemann, conjoined twins, trisomy 18, meningomyelocele, and imperforate anus. **Omphalitis** is an acute local inflammation of the periumbilical tissue that may extend to the abdominal wall, the peritoneum, the umbilical vein or portal vessels, or the liver and may result in later portal hypertension. The umbilical cord should have 2 arteries and 1 vein. A single umbilical artery is associated with an increased risk for an occult renal anomaly.

GENITALS

The genitals and mammary glands normally respond to transplacentally acquired maternal hormones to produce enlargement and secretion of the breasts in both sexes and prominence of the genitals in females, often with considerable nonpurulent discharge. These transitory manifestations require no intervention.

An imperforate hymen or other causes of vaginal obstruction may result in **hydrometrocolpos** and a lower abdominal mass. A normal scrotum at term is relatively large; its size may be increased by the trauma of breech delivery or by a transitory hydrocele, which is distinguished from a hernia by palpation and transillumination. The testes should be in the scrotum or should be palpable in the canals in term infants. Black male infants usually have dark pigmentation of the scrotum before the rest of the skin assumes its permanent color. The scrotum may be ecchymotic from breech presentation or a retroperitoneal hemorrhage; it may contain meconium particles associated with meconium peritonitis.

The prepuce of a newborn infant is normally tight and adherent. Severe hypospadias or epispadias should always lead one to suspect either that abnormal sex chromosomes are present (see Chapter 81) or that the infant is actually a masculinized female with an enlarged clitoris, because this finding may be the first evidence of adrenogenital syndrome (see Chapter 576). Erection of the penis is common and has no significance. Urine is usually passed during or immediately after birth; a period without voiding may normally follow. Most neonates void by 12 hr, and approximately 95% of preterm and term infants void within 24 hr.

ANUS

Some passage of meconium usually occurs within the 1st 12 hr after birth; 99% of term infants and 95% of premature infants pass meconium within 48 hr of birth. Imperforate anus is not always visible and may require evidence obtained by gentle insertion of the examiner's little finger or a rectal tube. Radiographic study is required. Passage of meconium does not rule out an imperforate anus if a rectal–vaginal fistula is present. The dimple or irregularity in skinfold often normally

present in the sacrococcygeal midline may be mistaken for an actual or potential neurocutaneous sinus.

EXTREMITIES

During examination of the extremities, the effects of fetal posture (see Chapter 672) should be noted so that their cause and usual transitory nature can be explained to the mother. Such explanations are particularly important after breech presentations. A fracture or nerve injury associated with delivery can be detected more commonly by observation of the extremities in spontaneous or stimulated activity than by any other means. The hands and feet should be examined for polydactyly, syndactyly, and abnormal dermatoglyphic patterns such as a simian crease.

The hips of all infants should be examined with specific maneuvers to rule out congenital dislocation (see Chapter 678.1).

NEUROLOGIC EXAMINATION

See Chapters 9 and 590.

In utero neuromuscular diseases associated with limited fetal motion produce a constellation of signs and symptoms that are independent of the specific disease. Severe positional deformations and contractures produce arthrogryposis. Other manifestations of fetal neuromuscular disease include breech presentation, polyhydramnios, failure to breathe at birth, pulmonary hypoplasia, dislocated hips, undescended testes, thin ribs, and clubfoot. Many congenital disorders manifest as hypotonia, hypertonia, or seizures.

Bibliography is available at Expert Consult.

94.3 Routine Delivery Room and Initial Care

Waldemar A. Carlo

Low-risk infants may initially be placed on the mother's abdomen after delivery; clearing the mouth of secretions with gentle suction with a bulb syringe or soft catheter is indicated if there is an excessive (copious) amount of fluid in the mouth or nares. In resource-poor countries, gentle wiping of the face, nose, and mouth with a soft cloth may be equally effective as a bulb syringe. Nonetheless, spontaneously breathing neonates with no distress do not need any assisted method to clear their airway. Most healthy infants who appear to be in satisfactory condition should be given directly to their mothers for immediate bonding and nursing. Delayed clamping of the umbilical cord (~30 sec) has value in reducing the incidence of anemia in infancy. If respiratory distress is a concern, infants should be placed under warmers for observation.

The **Apgar score** is a practical method of systematically assessing newborn infants immediately after birth (Table 94-2). A low score may be the result of fetal distress but may also be caused by a number of factors, including prematurity and drugs given to the mother during labor (Table 94-3). The Apgar score was not designed to predict neurologic outcome. Indeed, the score is normal in most patients in whom cerebral palsy subsequently develops, and the incidence of cerebral palsy is low in infants with Apgar scores of 0-3 at 5 min (but higher than in infants with Apgar scores of 7-10). Low Apgar scores and umbilical artery blood pH predict neonatal death. An Apgar score of 0-3 at 5 min is uncommon but is a better predictor of neonatal death (in both term and preterm infants) than an umbilical artery pH ≤7.0; the presence of both variables increases the relative risk of neonatal mortality in term and preterm infants (Table 94-4). Infants who fail to initiate respiration should receive prompt resuscitation and close observation (see Chapter 100).

MAINTENANCE OF BODY HEAT

Newborn infants are at risk for heat loss and hypothermia for several reasons. Relative to body weight, the body surface area of a newborn infant is approximately 3 times that of an adult. Generation of body heat depends in large part on body weight, but heat loss depends on surface area. In low birthweight and preterm infants, the insulating layer of subcutaneous fat is thin. The estimated rate of heat loss in a newborn is approximately 4 times that of an adult. Under the usual delivery room conditions (20-25°C [68-77°F]), an infant's skin temperature falls approximately 0.3°C (0.54°F)/min and deep body temperature decreases approximately 0.1°C (0.18°F)/min during the period immediately after delivery; these rates generally result in a

Table 94-3 Factors Affecting the Apgar Score*

FALSE-POSITIVE (NO FETAL ACIDOSIS OR HYPOXIA; LOW APGAR SCORE)
Prematurity
Analgesics, narcotics, sedatives
Magnesium sulfate
Acute cerebral trauma
Precipitous delivery
Congenital myopathy
Congenital neuropathy
Spinal cord trauma
Central nervous system anomaly
Lung anomaly (diaphragmatic hernia)
Airway obstruction (choanal atresia)
Congenital pneumonia and sepsis
Previous episodes of fetal asphyxia (recovered)
Hemorrhage-hypovolemia
FALSE-NEGATIVE (ACIDOSIS; NORMAL APGAR SCORE)
Maternal acidosis
High fetal catecholamine levels
Some full-term infants

*Regardless of the etiology, a low Apgar score because of fetal asphyxia, immaturity, central nervous system depression, or airway obstruction identifies an infant needing immediate resuscitation.

Table 94-2 Apgar Evaluation of Newborn Infants*

SIGN	0	1	2
Heart rate	Absent	Below 100	Over 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Response to catheter in nostril (tested after oropharynx is clear)	No response	Grimace	Cough or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

*Sixty sec after complete birth of the infant (disregarding the cord and placenta), the 5 objective signs listed here are evaluated, and each is given a score of 0, 1, or 2. A total score of 10 indicates an infant in the best possible condition. An infant with a score of 0-3 requires immediate resuscitation.

Modified from Apgar V: A proposal for a new method of evaluation of the newborn infant, Curr Res Anesth Analg *32:260–267, 1953.*

cumulative loss of 2-3°C (3.6-5.4°F) in deep body temperature (corresponding to a heat loss of approximately 200 kcal/kg). The heat loss occurs by 4 mechanisms: (1) **convection** of heat energy to the cooler surrounding air, (2) **conduction** of heat to the colder materials touching the infant, (3) **heat radiation** from the infant to other nearby cooler objects, and (4) **evaporation** from skin and lungs.

Metabolic acidosis, hypoxemia, hypoglycemia, and increased renal excretion of water and solutes may develop in term infants exposed to cold after birth because of their effort to compensate for heat loss. Heat production is augmented by increasing the metabolic rate and oxygen consumption in part by releasing norepinephrine, which results in nonshivering thermo-genesis through oxidation of fat, particularly brown fat. In addition, muscular activity may increase. Hypoglycemic or hypoxic infants cannot increase their oxygen consumption when exposed to a cold environment, and their central temperature decreases. After labor and vaginal delivery, many newborn infants have mild to moderate metabolic acidosis, for which they may compensate by hyperventilating, a response that is more difficult for infants with central nervous system depression (asphyxia, drugs) and infants exposed to cold stress in the delivery room. Therefore, to reduce heat loss, it is desirable to ensure that infants are dried and either wrapped in blankets or placed with the mother or under radiant warmers. **Skin-to-skin contact** with the mother is the optimal method of maintaining temperature in the stable newborn. Because carrying out resuscitative measures on a covered infant or one enclosed in an incubator is difficult, a radiant heat source should be used to warm the baby during resuscitation.

ANTISEPTIC SKIN AND CORD CARE

Careful removal of the amniotic fluid and blood from the skin shortly after birth may reduce the risk of infection with bloodborne agents. Once a healthy infant's temperature has stabilized, the entire skin and cord should be cleansed with warm water or a mild nonmedicated soap solution and rinsed with water to reduce the incidence of skin and periumbilical colonization with pathogenic bacteria and subsequent infectious complications. To avoid heat loss, the infant is then dried and wrapped in clean blankets. To reduce colonization with *Staphylococcus aureus* and other pathogenic bacteria, the umbilical cord may be treated daily with a bactericidal or antimicrobial agents such as chlorhexidine, triple dye, or bacitracin. One application of triple dye followed by twice-daily alcohol swabbing (until the cord falls off) reduces colonization, exudates, and foul odor of the umbilicus in comparison with dry care (soap and water when soiled). On the rare occasion of *S. aureus* nursery epidemics, a single hexachlorophene bath may be used. Topical ointments should not be applied to preterm infants in neonatal intensive care units because this treatment increases the risk of bacterial sepsis. Routine or repeated total-body exposure to hexachlorophene may be neurotoxic, particularly in low-birthweight infants, and is thus contraindicated. Nursery personnel should use alcohol-based solutions or chlorhexidine or iodophor-containing antiseptic soaps for routine handwashing before caring for each infant. Rigid enforcement of hand-to-elbow washing for 2 min in the initial wash and 15-30 sec in subsequent washes is essential for staff and visitors entering the nursery.

OTHER MEASURES

The eyes of all infants, including those born by cesarean section, must be protected against gonococcal ophthalmia neonatorum by application of a 1-cm ribbon of erythromycin (0.5%) or tetracycline (1.0%) sterile ophthalmic ointments in each lower conjunctival sac. This procedure may be delayed during the initial short-alert period after birth to promote bonding, but once applied, drops should not be rinsed out (see Chapters 192 and 226.3). A 1% silver nitrate solution is an acceptable alternative, but leads to a transient chemical conjunctivitis in 10-20% of cases.

Although hemorrhage in newborn infants can be a result of factors other than vitamin K deficiency, an intramuscular injection of 0.5-1 mg of water-soluble vitamin K_1 (phytonadione) should be given to all infants shortly after birth to prevent hemorrhagic disease of the newborn (see Chapter 103.4). Oral vitamin K is not as effective as the parenteral dosage.

Hepatitis B immunization before discharge from the nursery is recommended for newborns with weight >2 kg irrespective of maternal hepatitis status.

Neonatal screening is available for various genetic, metabolic, hematologic, and endocrine disorders. All states in the United States have adopted the Advisory Committee on Heritable Disorders in Newborns and Children, although the specific tests performed vary by state based in part to disease prevalence, detection rates, and costs (see Chapter 84). The most commonly identified disorders (and their rates) include hypothyroidism (52/100,000 births), cystic fibrosis (30/100,000), hemoglobinopathies (26/100,000), medium-chain acyl–coenzyme A dehydrogenase deficiency (6/100,000), galactosemia (5/100,000), phenylketonuria (5/100,000), and adrenal hyperplasia (5/100,000). To be effective in the timely identification and prompt management of treatable diseases, screening programs must include not only high-quality laboratory tests but also follow-up of infants with abnormal test results; education, counseling, and psychologic support for families; and prompt referral of the identified neonate for accurate diagnosis and appropriate treatment.

Hearing impairment, a serious morbidity that affects speech and language development, may be severe in 2/1,000 births and overall affects 5/1,000 births. Universal screening of infants is recommended to ensure early detection of hearing loss and appropriate, timely intervention.

Universal screening with pulse oximetry provides early detection of ductal dependent cyanotic congenital heart disease (see Chapter 425).

Universal screening for hyperbilirubinemia should include risk assessment in all infants with measurement of serum or transcutaneous bilirubin levels before hospital discharge.

Universal screening for congenital hip dysplasia with physical examination with the Ortolani (sensation of the dislocated hip reducing) and Barlow (unstable hip dislocating from the acetabulum) tests is recommended but routine hip ultrasound is not indicated.

Routine measurement of the hematocrit or blood glucose value is not necessary in the absence of risk factors.

Bibliography is available at Expert Consult.

94.4 Nursery Care

Waldemar A. Carlo

Non–high-risk, healthy infants may be taken to the "regular" (normal) newborn nursery or may be placed in the mother's room if the hospital has rooming-in facilities.

The bassinet, preferably of clear plastic to allow for easy visibility and care, should be cleaned frequently. All professional care should be given to the infant in the bassinet, including the physical examination, clothing changes, temperature taking, skin cleansing, and other procedures that, if performed elsewhere, would establish a common contact point and possibly provide a channel for cross infection. The clothing and bedding should be minimal, only enough needed for an infant's comfort; the nursery temperature should be kept at approximately 22-26°C (72-78°F). The infant's temperature should be taken by axillary measurement. Although the interval between temperature measurements depends on many circumstances, it need not be shorter than 4 hr during the 1st 2-3 days and 8 hr thereafter. Axillary temperatures of 36.5-37.4°C (97.7-99.3°F) are within normal limits. Weighing at birth and daily thereafter is sufficient. Healthy infants should be placed supine to reduce the risk of sudden infant death syndrome.

Vernix is spontaneously shed within 2-3 days, much of it adhering to the clothing, which should be completely changed daily. The diaper should be checked before and after feeding and when the baby cries; it should be changed when wet or soiled. The perineal area can be cleaned with baby wipes or with mild soap and warm water. Meconium or feces should be cleansed from the buttocks with sterile cotton moistened with sterile water. The foreskin of a male infant should not be retracted.

Infants should meet minimum criteria before hospital discharge (Table 94-5). Late preterm infants (34-36 wk) and infants with early discharge (<48 hr) or very early discharge (<24 hr) are at increased risk of rehospitalization. Early discharge requires careful ambulatory follow-up at home (by a visiting nurse) or in the office within 48 hr of discharge.

Table 94-5 Criteria for Discharge from the Normal Newborn Nursery*

Criteria
Uncomplicated antepartum, intrapartum, postpartum courses
Vaginal delivery
Singleton at 38-42 wk: appropriate for gestational age
Normal vital signs including respiratory rate <60 breaths/min; axillary temperature 36.1-37°C (97.0-98.6°F) in open crib
Physical examination reveals no abnormalities requiring continued hospitalization
Urination; stool × 1
At least 2 uneventful, successful feedings
No excessive bleeding 2 hr after circumcision
No jaundice within 24 hr of birth; if jaundice, appropriate management and follow-up are in place
Evidence of parental knowledge, ability, and confidence to care for the baby at home:
Feeding
Cord, skin, genital care
Recognition of illness (jaundice, poor feeding, lethargy, fever, etc.)
Infant safety (car seat, supine sleep position, etc.)
Availability of family and physician support (physician follow-up)
Laboratory evaluation:
Syphilis
Hepatitis B surface antigen and vaccination or appointment for vaccination
Coombs test and blood type if clinically indicated
Expanded metabolic screening: phenylketonuria, thyroid, galactosemia, sickle cell
Hearing screening
No social risks:
Substance abuse
History of child abuse
Domestic violence
Mental illness
Teen mother
Homelessness
Barriers to follow-up
Source of continuing medical care is identified

*It is not likely that all these criteria will be met before 48 hr of age.
Adapted from American Academy of Pediatrics, American College of Obstetricians and Gynecologists: Guidelines for perinatal care, *ed 7, Elk Grove Village, IL, 2012, American Academy of Pediatrics.*

94.5 Parent–Infant Bonding

Waldemar A. Carlo

See also Chapter 9.

Normal infant development depends partly on a series of affectionate responses exchanged between a mother and her newborn infant that binds them psychologically and physiologically. This bonding is facilitated and reinforced by the emotional support of a loving family. The attachment process may be important in enabling some mothers to provide loving care during the neonatal period and subsequently during childhood. The power of this attachment is so great that it enables the mother and the father to make unusual sacrifices necessary for the day-to-day care of the infant, care night after night, giving feedings 24 hr a day, attending to crying, and so on. The sacrifices continue for many years as parents dedicate much of their lives to their children.

Parent–infant bonding is initiated before birth with the planning and confirmation of the pregnancy. Subsequently, there is a growing awareness of the baby as an individual, starting usually with the remarkably powerful event of "quickening" or sensation of fetal movements. After delivery and during the ensuing weeks, sensory (visual, auditory, olfactory) and physical contact between the mother and baby triggers various mutually rewarding and pleasurable interactions, such as the mother touching the infant's extremities and face with her fingertips and encompassing and gently massaging the infant's trunk with her hands. Touching an infant's cheek elicits responsive turning toward the mother's face or toward the breast with nuzzling and licking of the nipple, a powerful stimulus for prolactin secretion. An infant's initial quiet alert state provides the opportunity for eye-to-eye contact, which is particularly important in stimulating the loving and possessive feelings of many parents for their babies. An infant's crying elicits the maternal response of touching the infant and speaking in a soft, soothing, higher-toned voice. Initial contact between the mother and infant should take place in the delivery room, and opportunities for extended intimate contact and breastfeeding should be provided within the 1st hours after birth. Delayed or abnormal maternal–infant bonding, as occurs because of prematurity, infant or maternal illness, birth defects, or family stress, may harm infant development and maternal caretaking ability. Hospital routines should be designed to encourage parent–infant contact. Open nurseries, rooming-in arrangements, care by parents, and family-centered care increase the opportunities for better parent–infant interaction.

NURSERIES AND BREASTFEEDING

See Chapter 45 for full discussions of breastfeeding and formula feeding.

Ample evidence indicates that there are infant and maternal benefits to breastfeeding. Practices that encourage successful breastfeeding include antepartum education and encouragement, immediate postpartum mother–infant contact with suckling, rooming-in arrangements, demand feeding, inclusion of fathers in breastfeeding education, and support from experienced women. Nursing at first for least 5 min at each breast is reasonable, allows a baby to obtain most of the available breast contents, and provides effective stimulation for increasing the milk supply. Nursing episodes should then be extended according to the comfort and desire of the mother and infant. A confident and relaxed mother, supported by an encouraging home and hospital environment, is likely to nurse well. The Baby-Friendly Hospital Initiative, a global effort (sponsored by the World Health Organization and the United Nations Children's Fund) to promote breastfeeding, recommends 10 steps to successful breastfeeding (Table 94-6). Some hospital practices contribute to difficulties in breastfeeding by enforcing 4-hr feeding schedules, limiting nursing time, using only 1 breast at a

feeding, washing nipples with substances other than water, delaying the first feeding, providing formula supplements, and using heavy intrapartum sedation.

DRUGS AND BREASTFEEDING

Maternal medications may affect the production and safety of breast milk (Table 94-7). Although most commonly used medications are safe, the safety of any new drug to be used while a woman is breastfeeding must be confirmed before the drug is initiated and/or breastfeeding is continued. Maternal sedatives may result in sedation of the infant. Maternal drugs that are weak acids, composed of large molecules, plasma bound, or poorly absorbed from the maternal or neonatal intestine are less likely to affect a neonate.

CONTRAINDICATIONS TO BREASTFEEDING

Medical contraindications to breastfeeding in the United States include infants with galactosemia, maple syrup urine disease, and phenylketonuria. Maternal conditions that contraindicate breastfeeding include infection with HIV, human T-cell lymphotropic virus types 1 and 2, active tuberculosis (until appropriately treated ≥2 wk and not considered contagious), herpes virus infection on breast, and maternal treatment with some radioactive compounds (Table 94-8).

Table 94-6 Ten Steps to Successful Breastfeeding

Every facility providing maternity services and care for newborn infants should accomplish the following:

1. Have a written breastfeeding policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within a half hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk unless *medically* indicated.
7. Practice rooming-in (allow mothers and infants to remain together) 24 hr a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers (also called *dummies* or *soothers*) to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Chapter 95
High-Risk Pregnancies

Waldemar A. Carlo and Namasivayam Ambalavanan

High-risk pregnancies are those that increase the likelihood of abortion, fetal death, preterm delivery, intrauterine growth restriction, poor cardiopulmonary or metabolic transitioning at birth, fetal or neonatal disease, congenital malformations, or mental retardation and other handicaps (Table 95-1; see Chapter 96). Some factors, such as ingestion of a teratogenic drug in the 1st trimester, are causally related to the risk; others, such as hydramnios, are associations that alert a physician to determine the etiology and avoid the inherent risks associated with excessive amniotic fluid. On the basis of their history, 10-20% of pregnant women can be identified as being at high risk; nearly half of all perinatal mortality and morbidity is associated with these high-risk pregnancies. Although assessing antepartum risk is important in reducing perinatal mortality and morbidity, some pregnancies become high risk only during labor and delivery; therefore, careful monitoring is critical throughout the intrapartum course.

Identifying high-risk pregnancies is important not only because it is the first step toward prevention but also because therapeutic steps may often be taken to reduce the risks to the fetus or neonate if the physician knows of the potential for difficulty.

GENETIC FACTORS

The occurrence of chromosomal abnormalities, congenital anomalies, inborn errors of metabolism, mental retardation, or any familial disease in blood relatives increases the risk of the same condition in the infant. Because many parents recognize only obvious clinical manifestations of genetically determined diseases, specific inquiry should be made about any disease affecting 1 or more blood relatives.

MATERNAL FACTORS

The lowest neonatal mortality rate occurs in infants of mothers who receive adequate prenatal care and who are 20-30 yr of age. Pregnancies in both teenagers and women older than 40 yr, particularly primiparous women, are at increased risk for intrauterine growth restriction, fetal distress, and intrauterine death. Advanced maternal age increases the risk of both chromosomal and nonchromosomal fetal malformations (Fig. 95-1).

Maternal illness (Table 95-2), multiple pregnancies (particularly those involving monochorionic twinning), infections (Table 95-3), and certain drugs (see Chapter 96) increase the risk for the fetus. The use of assisted reproductive technology (in vitro fertilization, intracytoplasmic sperm injection) increases the risk of perinatal mortality, infant morbidity, prematurity, low and very-low birthweight, and cerebral palsy, largely because of the increase in multiple-fetus pregnancies with such technology; the risks for birth defects are also increased, in part, because of epigenetic effects on gene expression.

Table 95-1 Factors Associated with High-Risk Pregnancy
ECONOMIC
Poverty
Unemployment
Uninsured, underinsured health insurance
Poor access to prenatal care
CULTURAL–BEHAVIORAL
Low educational status
Poor healthcare attitudes
No care or inadequate prenatal care
Cigarette, alcohol, illicit drug use
Age <20 or >40 yr
Unmarried
Short interpregnancy interval
Lack of support group (husband, family, religion)
Stress (physical, psychologic)
Black race
BIOLOGIC–GENETIC
Previous low birthweight or preterm infant
Low weight for height
Poor weight gain during pregnancy
Short stature
Poor nutrition
Consanguinity
Intergenerational effects
Low maternal birthweight
Hereditary diseases (inborn error of metabolism)
REPRODUCTIVE
Previous cesarean section
Previous infertility
Conception by reproductive technology
Prolonged gestation
Prolonged labor
Previous infant with cerebral palsy, mental retardation, birth trauma, congenital anomalies
Abnormal lie (breech)
Multiple gestations
Premature rupture of membranes
Infection (systemic, amniotic, extra-amniotic, cervical)
Preeclampsia or eclampsia
Uterine bleeding (abruptio placentae, placenta previa)
Parity (0 or >5 previous deliveries)
Uterine or cervical anomalies
Fetal disease
Abnormal fetal growth
Idiopathic premature labor
Iatrogenic prematurity
High or low levels of maternal serum α-fetoprotein
MEDICAL
Diabetes mellitus
Hypertension
Congenital heart disease
Autoimmune disease
Sickle cell anemia
Intercurrent surgery or trauma
Sexually transmitted infection
Maternal hypercoagulable states
Exposure to prescription medications
TORCH (*t*oxoplasmosis, *o*ther agents, *r*ubella, *c*ytomegalovirus, *h*erpes simplex) infection

Preterm birth is common in high-risk pregnancies (see Chapter 97). Factors associated with prematurity, noted in Table 95-1, include biologic markers such as cervical shortening, genital infection, fetal fibronectin in cervicovaginal secretions, serum α-fetoprotein, and preterm premature rupture of membranes (PROM). PROM occurs in 30-40% of preterm deliveries, and it is a leading identifiable cause of prematurity. Preterm delivery is often difficult to predict.

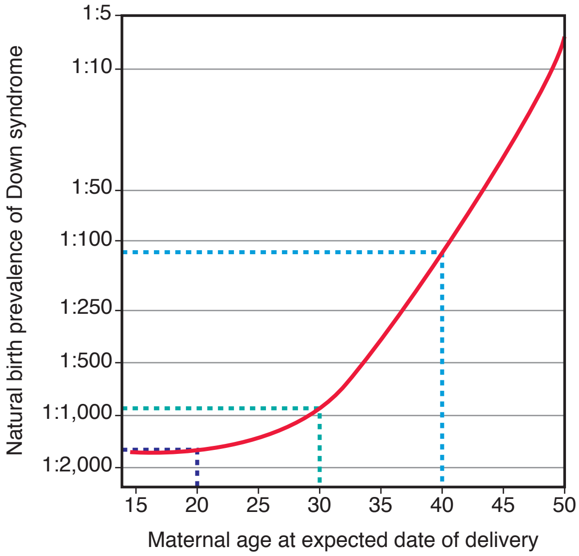

Figure 95-1 Natural birth prevalence of Down syndrome according to maternal age. *(From Wald NJ, Leck I:* Antenatal and neonatal screening, *ed 2, Oxford, 2000, Oxford University Press.)*

Polyhydramnios and **oligohydramnios** indicate high-risk pregnancies. Although the turnover rate of amniotic fluid is rapid, during normal pregnancy the amniotic fluid volume gradually increases at a rate of <10 mL/day until about the 34th wk of pregnancy, after which it slowly diminishes. Volumes vary widely in normal pregnancy; term volume may be 500-2,000 mL. A volume estimated at greater than 2,000 mL in the 3rd trimester constitutes polyhydramnios, and a volume estimated at <500 mL indicates oligohydramnios. Polyhydramnios complicates 1-3%, and oligohydramnios 1-5%, of pregnancies. The ultrasonographic criteria for these diagnoses are based on the amniotic fluid index, which is determined by measuring the vertical diameter of amniotic fluid pockets in four quadrants; an index >24 cm suggests polyhydramnios, whereas an index <5 cm suggests oligohydramnios.

Acute polyhydramnios is rare and is usually associated with preterm labor and delivery. **Chronic polyhydramnios** is diagnosed in the 3rd trimester from the discrepancy between uterine size and gestational age; it is occasionally not diagnosed until the patient has dysfunctional labor or an abnormally large amount of amniotic fluid is noted during delivery. Polyhydramnios is associated with preterm labor, abruptio placentae, multiple congenital anomalies, and fetal neuromuscular dysfunction or obstruction of the gastrointestinal tract that interferes with reabsorption of the amniotic fluid that is normally swallowed by the fetus (Table 95-4). Increased fetal urination or edema formation is also associated with excessive amniotic fluid volume. Ultrasound demonstrates the increased amniotic fluid surrounding the fetus and detects associated fetal anomalies, hydrops, pleural effusions, and ascites. In 60% of patients, no cause is identified. Symptomatic polyhydramnios may be managed by serial amniocenteses or by short-course maternal indomethacin if the problem is caused by excessive fetal urination. Treatment is indicated for acute maternal respiratory distress and threatened preterm labor or to provide time for the administration of corticosteroids to enhance fetal lung maturity.

Oligohydramnios is associated with congenital anomalies; intrauterine growth restriction; severe renal, bladder, or urethral anomalies; and drugs that interfere with fetal urination (see Table 95-4). Oligohydramnios becomes most evident after 20 wk of gestation, when fetal urination is the major source of amniotic fluid. Rupture of the membranes is the most common cause of oligohydramnios and must be ruled out if oligohydramnios is suspected, especially if a normal-sized

Table 95-2 Maternal Conditions Affecting the Fetus or Neonate

DISORDER	EFFECT(S)	MECHANISM(S)
Autoantibody against folate receptors	Neural tube defects	Blockage of cellular uptake of folate
Cervical neoplasia	Preterm premature rupture of membranes	Associated with loop electrosurgical excision procedure or cone therapy
Cholestasis	Preterm delivery, intrauterine fetal demise	Unknown, possibly hepatitis E
Cyanotic heart disease	Intrauterine growth restriction	Low fetal oxygen delivery
Diabetes mellitus:		
Mild	Large for gestational age, hypoglycemia	Fetal hyperglycemia—produces hyperinsulinemia; insulin promotes growth
Severe	Growth restriction	Vascular disease, placental insufficiency
Drug addiction	Intrauterine growth restriction, neonatal withdrawal	Direct drug effect plus poor diet
Endemic goiter	Hypothyroidism	Iodine deficiency
Graves disease	Transient neonatal thyrotoxicosis	Placental immunoglobulin passage of thyroid-stimulating antibody
Herpes gestationis (noninfectious)	Bullous rash, intrauterine fetal demise	Autoantibody similar to that in bullous pemphigoid
Hyperparathyroidism	Neonatal hypocalcemia	Maternal calcium crosses to fetus and suppresses fetal parathyroid gland
Hypertension	Intrauterine growth restriction, intrauterine fetal demise	Placental insufficiency, fetal hypoxia
Idiopathic thrombocytopenic purpura	Thrombocytopenia	Nonspecific maternal platelet antibodies cross placenta
Isoimmune neutropenia or thrombocytopenia	Neutropenia or thrombocytopenia	Specific antifetus neutrophil or platelet antibody crosses placenta after sensitization of mother
Malignant melanoma	Placental or fetal tumor	Metastasis
Myasthenia gravis	Transient neonatal myasthenia	Immunoglobulin to acetylcholine receptor crosses placenta
Myotonic dystrophy	Neonatal myotonic dystrophy, congenital contractures, respiratory insufficiency	Genetic anticipation
Obesity	Macrosomia, hypoglycemia	Unknown
Phenylketonuria	Microcephaly, retardation	Elevated fetal phenylalanine values
Poor nutrition	Intrauterine growth restriction, adult insulin resistance	Reduced fetal nutrients, nutritional programming
Preeclampsia, eclampsia	Intrauterine growth restriction, thrombocytopenia, neutropenia, fetal demise	Uteroplacental insufficiency, fetal hypoxia, vasoconstriction
Renal transplantation	Intrauterine growth restriction	Uteroplacental insufficiency
Rhesus or other blood group sensitization	Fetal anemia, hypoalbuminemia, hydrops, neonatal jaundice	Antibody crosses placenta and is directed to fetal cells with antigen
Sickle cell anemia	Preterm birth, intrauterine growth restriction, stillbirth	Maternal sickling producing fetal hypoxia
Systemic lupus erythematosus	Congenital heart block, rash, anemia, thrombocytopenia, neutropenia	Antibody directed to fetal heart, red and white blood cells, and platelets

bladder is seen on fetal ultrasound. Oligohydramnios causes fetal compression abnormalities such as fetal distress, clubfoot, spadelike hands, and a flattened nasal bridge. The most serious complication of chronic oligohydramnios is **pulmonary hypoplasia.** The risk of umbilical cord compression during labor and delivery is increased in pregnancies complicated by oligohydramnios and may be alleviated by saline amnioinfusion. Prophylactic intrapartum amnioinfusion reduces the need for cesarean section and improves Apgar scores.

Antenatal screening can be used to detect a number of disorders, including Down syndrome and other chromosomal abnormalities, neural tube defects and other structural anomalies, Tay-Sachs disease and other metabolic genetic diseases, hemoglobinopathies and other blood disorders, and cystic fibrosis. Screening methods include maternal blood tests, fetal ultrasound, and diagnostic tests on cells or fluid obtained by amniocentesis or chorionic villus sampling and by fetal blood or tissue sampling. Cell-free fetal DNA in maternal blood has higher sensitivity (>99%) and lower false-positive rates for trisomy 21 (Down syndrome) and other chromosomal abnormalities than a combination of maternal serum analytes and ultrasound.

Second-trimester screening (15-18 wk) of maternal serum α-fetoprotein (MSAFP) values is used to screen for open neural tube defects. Approximately 90% of affected pregnancies can be detected by an elevated MSAFP value. Gastroschisis, omphalocele, congenital nephrosis, twins, and other abnormal conditions can also be identified.

Table 95-3 Maternal Infections Affecting the Fetus or Newborn

INFECTION	MODE(S) OF TRANSMISSION	OUTCOME
BACTERIA		
Group B streptococcus	Ascending cervical	Sepsis, pneumonia
Escherichia coli	Ascending cervical	Sepsis, pneumonia
Listeria monocytogenes	Transplacental	Sepsis, pneumonia
Ureaplasma urealyticum	Ascending cervical	Pneumonia, meningitis
Mycoplasma hominis	Ascending cervical	Pneumonia
Chlamydia trachomatis	Vaginal passage	Conjunctivitis, pneumonia
Syphilis	Transplacental, vaginal passage	Congenital syphilis
Borrelia burgdorferi	Transplacental	Prematurity, fetal demise
Neisseria gonorrhoeae	Vaginal passage	Ophthalmia (conjunctivitis), sepsis, meningitis
Mycobacterium tuberculosis	Transplacental	Prematurity, fetal demise, congenital tuberculosis
Granulocytic ehrlichiosis	Transplacental	Sepsis
VIRUS		
Rubella	Transplacental	Congenital rubella
Cytomegalovirus	Transplacental, breast milk (rare)	Congenital cytomegalovirus or asymptomatic
HIV	Transplacental, vaginal passage, breast milk	Congenital acquired immunodeficiency syndrome
Hepatitis B	Vaginal passage, transplacental, breast milk	Neonatal hepatitis, chronic hepatitis B surface antigen carrier state
Hepatitis C	Transplacental	Uncommon, but neonatal hepatitis, chronic carrier state possible
Lymphocytic choriomeningitis	Transplacental	Fetal, neonatal death; hydrocephalus, chorioretinitis
Herpes simplex type 2 or 1	Transplacental	Congenital herpes simplex virus
	Vaginal passage, ascending	Neonatal encephalitis, disseminated viremia
Varicella-zoster	Transplacental:	
	Early	Congenital anomalies
	Late	Neonatal varicella
Parvovirus	Transplacental	Fetal anemia, hydrops
Coxsackie B	Fecal-oral	Myocarditis, meningitis, hepatitis
Poliomyelitis	Transplacental	Congenital poliomyelitis
Epstein-Barr	Transplacental	Anomalies(?)
Rubeola	Transplacental	Abortion, fetal measles
West Nile	Transplacental	Chorioretinitis, focal cerebral necrosis
Dengue virus	Transplacental	Thrombocytopenia, lymphocytosis
PARASITES		
Toxoplasmosis	Transplacental	Congenital toxoplasmosis or asymptomatic
Malaria	Transplacental	Abortion, prematurity, intrauterine growth restriction
Trypanosomiasis	Transplacental	Congenital Chagas disease
Hookworm	None	Maternal anemia, low birthweight
FUNGI		
Candida	Ascending, cervical	Sepsis, pneumonia, rash
PRION		
Creutzfeldt-Jakob disease	Transplacental, colostrum	Hypothetical route, no long-term data

Low MSAFP is associated with incorrect gestational age estimates, trisomy 18 or 21, and intrauterine growth restriction.

A pregnancy should be considered high risk when the uterus is inappropriately large or small. A uterus large for the estimated stage of gestation suggests the presence of multiple fetuses, hydramnios, or an excessively large infant; an inappropriately small infant suggests oligohydramnios or poor intrauterine growth. PROM more than 24 hr before delivery carries a risk of fetal infection; it also increases the risk of premature birth. PROM at term usually results in the onset of labor within 48 hr but poses a risk of chorioamnionitis and umbilical cord compression. With **PROM** before 37 wk, there is a longer latency until labor starts, and its occurrence has the added risks of cord prolapse, oligohydramnios, abruptio placentae, fetal malposition; also, if membrane rupture is present for >7 days in a fetus during the 2nd trimester, pulmonary hypoplasia, uterine-induced deformations, and extremity contractures can develop. Prolonged and difficult labor increases the risk for mechanical and hypoxic damage. A tumultuous short labor with a precipitous delivery increases the risk of birth asphyxia and intracranial hemorrhage. **Placental separation** at any time before delivery and abnormal implantation or compression of the cord increase the possibility of brain damage from fetal hypoxia; brown or muddy amniotic fluid suggests that meconium has been passed, possibly during an episode of fetal hypoxia.

Although the safety of any type of delivery depends on the skill of the obstetrician, additional hazards accompany particular methods and result from the circumstances that dictated them. The risk of **intracranial hemorrhage** is greater in infants delivered by vacuum extraction or forceps than in those born unassisted in spontaneous vaginal deliveries. Neonatal deaths after mid-forceps delivery, breech extraction, and version are likely to be related to traumatic intracranial injury.

Infants born by **cesarean section** present problems possibly related to the unfavorable obstetric circumstance that necessitated the operation. In normal term pregnancies without any indication of fetal distress, cesarean section delivery carries a greater risk than delivery through the birth canal. Controversy exists regarding the safest type of delivery for a nondistressed, viable immature fetus, especially in a breech presentation; cesarean section may involve less risk than the "stress" of labor and the potentially hypoxic effects of uterine contractions during vaginal delivery. Term infants in breech position (≈3-4% of term births) that do not assume vertex position after external cephalic version attempts may also benefit from cesarean section.

Table 95-4	Conditions Associated with Disorders of Amniotic Fluid Volume

OLIGOHYDRAMNIOS
Amniotic fluid leak/rupture of membranes
Intrauterine growth restriction
Fetal anomalies
Twin–twin transfusion (donor)
Renal agenesis (Potter syndrome)
Urethral atresia
Prune-belly syndrome
Pulmonary hypoplasia
Amnion nodosum
Indomethacin
Angiotensin-converting enzyme inhibitors or receptor antagonists
Intestinal pseudoobstruction

POLYHYDRAMNIOS
Congenital anomalies:
Anencephaly
Hydrocephaly
Tracheoesophageal fistula
Duodenal atresia
Spina bifida
Cleft lip or palate
Cystic adenomatoid lung malformation
Diaphragmatic hernia

Syndromes:
Achondroplasia
Klippel-Feil
Trisomy 18
Trisomy 21
TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex)
Hydrops fetalis
Multiple congenital anomalies

Other:
Diabetes mellitus
Twin–twin transfusion (recipient)
Fetal anemia
Fetal heart failure
Polyuric renal disease
Neuromuscular diseases
Nonimmune hydrops
Chylothorax
Teratoma
Idiopathic

Although transient tachypnea is the most frequently associated problem with cesarean section, respiratory distress syndrome and persistent pulmonary hypertension may develop, particularly in infants born by cesarean section to women who are not in labor, in those with uncertain dates, and in those born to diabetic mothers or after asphyxia. A trial of labor after a previous low segment cesarean section may have benefits and harms but there are limited data to make firm recommendations. In women with more than one previous cesarean section, there is an increased risk of uterine rupture. An elective cesarean section should be delayed until ≥39 wk of gestation. Earlier delivery increases the risk to the newborns.

Anesthesia and analgesia affect the fetus as well as the mother; severe maternal hypoxemia secondary to hypoventilation or hypotension resulting from epidural anesthesia may lead to severe fetal hypoxia and shock. Skilled use of medication avoids severe fetal narcosis while securing the benefits of gentle and unhurried delivery. Even skilled administration may result in a mildly depressed infant whose crying and breathing may be delayed 1-2 min and who may be somewhat inactive for several hours.

Chapter 96

The Fetus

Waldemar A. Carlo and
Namasivayam Ambalavanan

The major emphasis in fetal medicine involves (1) assessment of fetal growth and maturity, (2) evaluation of fetal well-being or distress, (3) assessment of the effects of maternal disease on the fetus, (4) evaluation of the effects of drugs administered to the mother on the fetus, and (5) identification and treatment of fetal disease or anomalies. Some aspects of human fetal growth and development are summarized in Chapter 8.

96.1 Fetal Growth and Maturity

Waldemar A. Carlo and Namasivayam Ambalavanan

Ultrasonography of the fetus, a common obstetric procedure, is both safe and reasonably accurate. Indications for antenatal ultrasonography include estimation of gestational age (unknown dates, discrepancy between uterine size and dates or suspected growth restriction), assessment of amniotic fluid volume, estimation of fetal weight, determination of the location of the placenta and the number and position of fetuses, and identification of congenital anomalies.

Fetal growth can be assessed by ultrasonography as early as 6-8 wk. The most accurate assessment of gestational age is by 1st-trimester ultrasound measurement of crown–rump length. The biparietal diameter is used to assess gestational age beginning in the 2nd trimester. Through 30 wk the biparietal diameter accurately estimates gestation to within ± 10 days. Later in gestation, accuracy falls to ± 3 wk. Methods used to assess gestational age closer to term include measurement of abdominal circumference and femoral length. If a single ultrasound examination is performed, the most information can be obtained with a scan at 18-20 wk, when both gestational age and fetal anatomy can be evaluated. Serial scans may be useful in assessing fetal growth. Two patterns of fetal growth restriction have been identified: continuous fetal growth 2 SD below the mean for gestational age or a normal fetal growth curve that abruptly slows or flattens later in gestation (Fig. 96-1).

Fetal maturity and dating are usually assessed by history (last menstrual period), physical examination, auscultation of fetal heart sounds at 16-18 wk, maternal perception of fetal movements at 18-20 wk, fundal height, and ultrasound (growth). Lung maturation may be estimated by determining the surfactant content of amniotic fluid (see Chapter 101.3).

Bibliography is available at Expert Consult.

96.2 Fetal Distress

Waldemar A. Carlo and Namasivayam Ambalavanan

Fetal compromise may occur during the antepartum or intrapartum period; it may be asymptomatic in the antenatal period. Antepartum fetal surveillance is warranted for women at increased risk for fetal death, including those with a history of stillbirth, intrauterine growth restriction (IUGR), oligohydramnios or polyhydramnios, multiple gestation, rhesus sensitization, hypertensive disorders, diabetes mellitus or other chronic maternal disease, decreased fetal movement, and postterm pregnancy. The predominant cause of antepartum fetal distress is uteroplacental insufficiency, which may manifest clinically as IUGR, fetal hypoxia, increased vascular resistance in fetal blood vessels (Figs. 96-2 and 96-3), and, when severe, mixed respiratory and

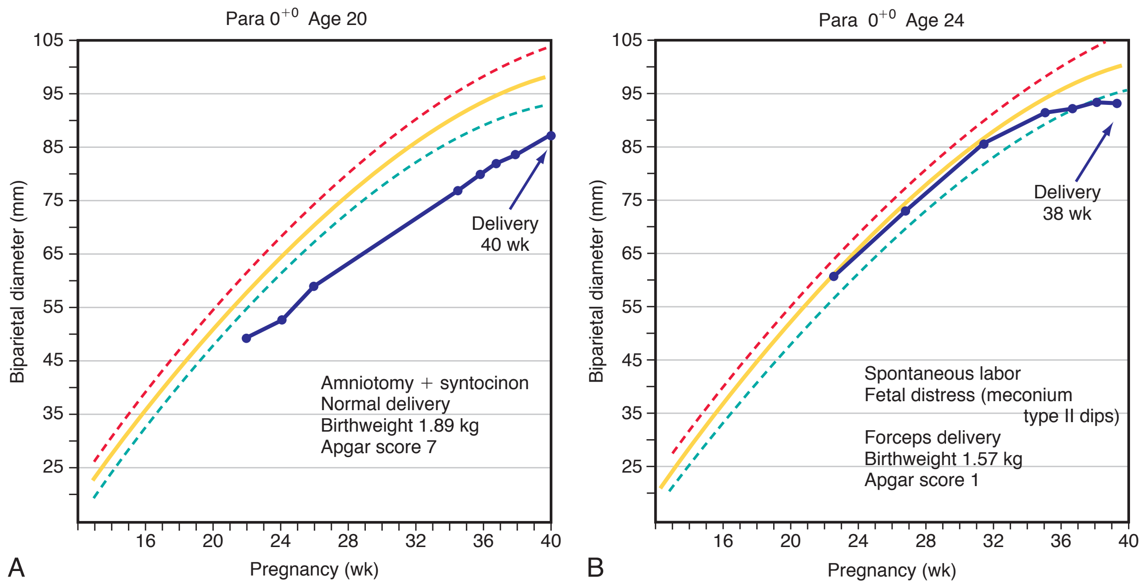

Figure 96-1 **A,** Example of a "low-profile" growth retardation pattern in an uneventful pregnancy and labor. The baby cried at 1 min and hypoglycemia did not develop. Birthweight was below the 5th percentile for gestational age. **B,** Example of a "late-flattening" growth retardation pattern. The mother had a typical history of preeclampsia, and the infant had intrapartum fetal distress, a low Apgar score, and postnatal hypoglycemia. Birthweight was below the 5th percentile for gestational age. *(From Campbell S: Fetal growth,* Clin Obstet Gynecol *1:41–65, 1974.)*

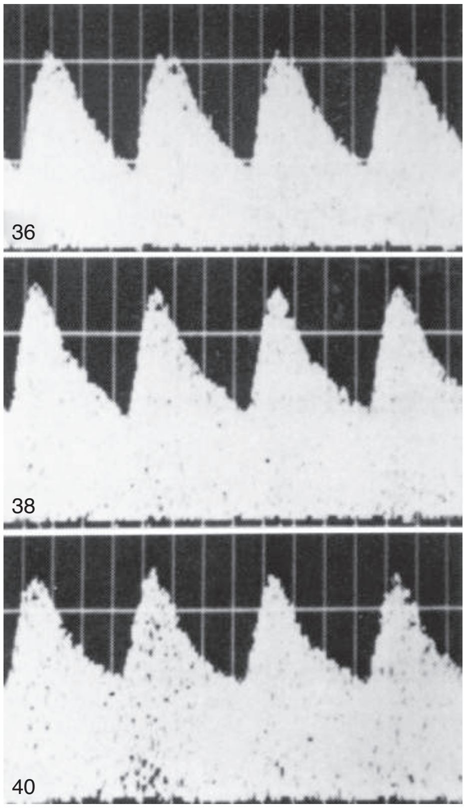

Figure 96-2 **Normal Doppler velocity in sequential studies of fetal umbilical artery flow velocity waveforms from one normal pregnancy.** Note the systolic peak flow with lower but constant heart flow during diastole. The systolic : diastolic ratio can be determined and, in normal pregnancies, is less than 3 after the 30th wk of gestation. The *numbers* indicate the weeks of gestation. *(From Trudinger B: Doppler ultrasound assessment of blood flow. In Creasy RK, Resnik R, editors:* Maternal-fetal medicine: principles and practice, *ed 5, Philadelphia, 2004, WB Saunders.)*

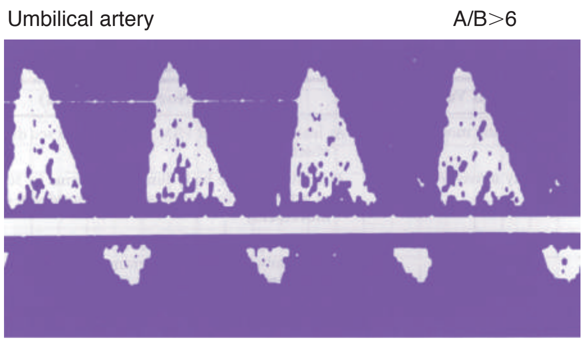

Figure 96-3 **Abnormal umbilical artery Doppler in which the diastolic component shows flow in a reverse direction.** This finding occurs in severe intrauterine hypoxia and intrauterine growth restriction. *(From Trudinger C: Doppler ultrasound assessment of blood flow. In Creasy RK, Resnik R, editors:* Maternal-fetal medicine: principles and practice, *ed 5, Philadelphia, 2004, WB Saunders.)*

metabolic (lactic) acidosis. The goals of antepartum fetal surveillance are to prevent intrauterine fetal demise, to prevent hypoxic brain injury, and to either prolong gestation in women at risk for preterm delivery when such prolongation is safe or deliver a fetus when it is in jeopardy. Table 96-1 lists methods for assessing fetal well-being.

The most commonly used noninvasive tests are the nonstress test (NST), the full and modified biophysical profile (BPP), and, less commonly, the contraction stress test (CST). The **NST** monitors the presence of fetal heart rate accelerations that follow fetal movement. A reactive (normal) NST result demonstrates 2 fetal heart rate accelerations of at least 15 beats/min lasting 15 sec. A nonreactive NST result suggests fetal compromise and requires further assessment with a CST or the BPP. A **CST** observes the fetal heart rate response to spontaneous, nipple-stimulated, or oxytocin-stimulated uterine contractions. Fetal compromise is suggested when the majority of contractions in 10 min are followed by late decelerations. A CST is relatively contraindicated in women with preterm premature rupture of membranes, a previous uterine scar from a classic cesarean section, multiple

Table 96-1 Fetal Diagnosis and Assessment

METHOD	COMMENT(S) AND INDICATION(S)
IMAGING	
Ultrasound (real-time)	Biometry (growth), anomaly (morphology) detection Biophysical profile Amniotic fluid volume, hydrops
Ultrasound (Doppler)	Velocimetry (blood flow velocity) Detection of increased vascular resistance secondary to fetal hypoxia
Embryoscopy	Early diagnosis of limb anomaly
Fetoscopy	Detection of facial, limb, cutaneous anomalies
MRI	Defining of lesions before fetal surgery
FLUID ANALYSIS	
Amniocentesis	Fetal maturity (L : S ratio), karyotype (cytogenetics), biochemical enzyme analysis, molecular genetic DNA diagnosis, bilirubin, or α-fetoprotein determination Bacterial culture, pathogen antigen, or genome detection
Cordocentesis (percutaneous umbilical blood sampling)	Detection of blood type, anemia, hemoglobinopathies, thrombocytopenia, acidosis, hypoxia, polycythemia, immunoglobulin M antibody response to infection Rapid karyotyping and molecular DNA genetic diagnosis Fetal therapy (see Table 96-5)
FETAL TISSUE ANALYSIS	
Chorionic villus biopsy	Karyotype, molecular DNA genetic analysis, enzyme assays
Skin biopsy	Hereditary skin disease*
Liver biopsy	Enzyme assay*
Circulating fetal DNA or cells in maternal blood or plasma	Molecular DNA genetic analysis including microarray analysis, chromosome number, specific gene testing, or genetic sequencing
MATERNAL SERUM α-FETOPROTEIN CONCENTRATION	
Elevated	Twins, neural tube defects (anencephaly, spina bifida), intestinal atresia, hepatitis, nephrosis, fetal demise, incorrect gestational age
Reduced	Trisomies, aneuploidy
MATERNAL CERVIX	
Fetal fibronectin	Indicates risk of preterm birth
Bacterial culture	Identifies risk of fetal infection (group B streptococcus, *Neisseria gonorrhoeae*)
Fluid	Determination of premature rupture of membranes
ANTEPARTUM BIOPHYSICAL MONITORING	
Nonstress test	Fetal distress; hypoxia
Contraction stress test	Fetal distress; hypoxia
Biophysical profile and modified biophysical profile	Fetal distress; hypoxia
Intrapartum fetal heart rate monitoring	See Fig. 96-4

*DNA genetic analysis on chorionic villus samples, amniocytes from amniocentesis, or fetal cells recovered from the maternal circulation may obviate the need for direct fetal tissue biopsy if the gene or genetic marker is available (e.g., the gene for Duchenne muscular dystrophy).
L : S, lecithin : sphingomyelin ratio.

gestations, incompetent cervix, and placenta previa. The goals of fetal monitoring are to prevent intrauterine fetal demise and hypoxic brain injury. Although the CST and NST have low false-negative rates, both have high false-positive rates. The full **BPP** assesses fetal breathing, body movement, tone, heart rate, and amniotic fluid volume, and it is used to improve the accurate and safe identification of fetal compromise (Table 96-2). A score of 2 is given for each observation present. A total score of 8-10 is reassuring; a score of 6 is equivocal, and retesting should be done in 12-24 hr; and a score of 4 or less warrants immediate evaluation and possible delivery. The BPP has good negative predictive value. The modified BPP consists of the combination of an ultrasound estimate of amniotic fluid volume (the amniotic fluid index) and the NST. When results of both are normal, fetal compromise is very unlikely. Signs of progressive compromise seen on Doppler ultrasonography include reduced, absent, or reversed diastolic waveform velocity in the fetal aorta or umbilical artery (see Fig. 96-3 and Table 96-1). High-risk fetuses often have combinations of abnormalities, such as oligohydramnios, reversed diastolic Doppler umbilical artery blood flow velocity, and a low BPP.

Fetal compromise *during labor* may be detected by monitoring the fetal heart rate, uterine pressure, and fetal scalp blood pH (Fig. 96-4). **Continuous fetal heart rate monitoring** detects abnormal cardiac patterns by instruments that compute the beat-to-beat fetal heart rate from a fetal electrocardiographic signal. Signals are derived from an electrode attached to the fetal presenting part, from an ultrasonic transducer placed on the maternal abdominal wall to detect continuous ultrasonic waves reflected from the contractions of the fetal heart, or from a phonotransducer placed on the mother's abdomen. Uterine contractions are simultaneously recorded from an amniotic fluid catheter and pressure transducer or from a tocotransducer applied to the maternal abdominal wall overlying the uterus. Fetal heart rate patterns show various characteristics, some of which suggest fetal compromise. The baseline fetal heart rate is the average rate between uterine contractions, which gradually decreases from approximately 155 beats/min in early pregnancy to approximately 135 beats/min at term; the normal range at term is 110-160 beats/min. **Tachycardia** (>160 beats/min) is associated with early fetal hypoxia, maternal fever, maternal hyperthyroidism, maternal β-sympathomimetic drug or atropine therapy, fetal anemia, infection, and some fetal arrhythmias. The last do not generally occur with congenital heart disease and may resolve spontaneously at birth. **Fetal bradycardia** (<110 beats/min) may be normal (e.g., 105-110 beats/min) but may occur with fetal hypoxia, placental transfer of local anesthetic agents and β-adrenergic blocking agents, and, occasionally, heart block with or without congenital heart disease.

Normally, the baseline fetal heart rate is variable. **Variability** is classified as follows: **absence of variability**, if an amplitude change is undetectable; **minimal variability** if amplitude range is ≤5 beats/min

Table 96-2 Biophysical Profile Scoring: Technique and Interpretation		
BIOPHYSICAL VARIABLE	**NORMAL SCORE (2)**	**ABNORMAL SCORE (0)**
Fetal breathing movements (FBMs)	At least 1 episode of FBM of at least 30 sec duration in 30 min observation	Absence of FBM or no episode ≥30 sec in 30 min
Gross body movement	At least 3 discrete body/limb movements in 30 min (episodes of active continuous movement considered a single movement)	2 or fewer episodes of body/limb movements in 30 min
Fetal tone	At least 1 episode of active extension with return to flexion of fetal limb(s) or trunk Opening and closing of hand considered evidence of normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absence of fetal movement with the hand held in complete or partial deflection
Reactive fetal heart rate (FHR)	At least 2 episodes of FHR acceleration of ≥15 beats/min and at least 15 sec in duration associated with fetal movement in 30 min	Less than 2 episodes of acceleration of FHR or acceleration of <15 beats/min in 30 min
Qualitative amniotic fluid (AF) volume*	At least 1 pocket of AF that measures at least 2 cm in 2 perpendicular planes	Either no AF pockets or a pocket <2 cm in 2 perpendicular planes

*Modification of the criteria for reduced amniotic fluid from less than 1 cm to less than 2 cm would seem reasonable. Ultrasound is used for biophysical assessment of the fetus.

From Creasy RK, Resnik R, Iams JD, editors: Maternal-fetal medicine: principles and practice, *ed 5, Philadelphia, 2004, Saunders.*

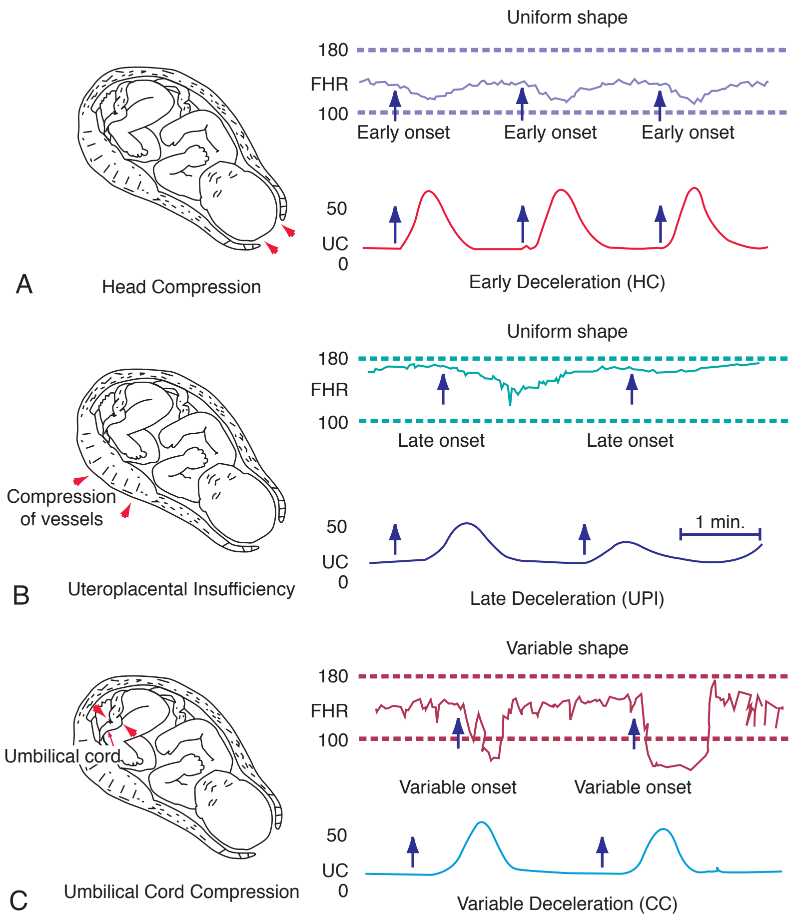

Figure 96-4 **Patterns of periodic fetal heart rate deceleration.** The tracing in **A** shows early deceleration occurring during the peak of uterine contractions as a result of pressure on the fetal head. **B,** Late deceleration caused by uteroplacental insufficiency. **C,** Variable deceleration as a result of umbilical cold compression. *Arrows* denote the time relationship between the onset of fetal heart rate changes and uterine contractions. *(From Hon EH:* An atlas of fetal heart rate patterns, *New Haven, CT, 1968, Harty Press.)*

(beats/min); **moderate variability** if amplitude range is 6-25 beats/min; **marked variability** if amplitude range is >25 beats/min. Variability may be decreased or lost with fetal hypoxemia or the placental transfer of drugs such as atropine, diazepam, promethazine, magnesium sulfate, and most sedative and narcotic agents. Prematurity, the sleep state, and fetal tachycardia may also diminish beat-to-beat variability.

Periodic accelerations or decelerations of the fetal heart rate in response to uterine contractions may also be monitored (see Fig. 96-4). An **acceleration** is an abrupt increase in fetal heart rate of ≥15 beats/

Table 96-3 Characteristics of Decelerations of the Fetal Heart Rate

LATE DECELERATION
- Visually apparent, usually symmetric *gradual* decrease and return of the fetal heart rate (FHR) associated with a uterine contraction.
- A *gradual* FHR decrease is defined as duration of ≥30 sec from the onset to the nadir of the FHR.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction.
- In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively.

EARLY DECELERATION
- Visually apparent, usually symmetric *gradual* decrease and return of the FHR associated with a uterine contraction.
- A *gradual* FHR decrease is defined as duration of ≥30 sec from the onset to the FHR nadir.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The nadir of the deceleration occurs at the same time as the peak of the contraction.
- In most cases, the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively.

VARIABLE DECELERATION
- Visually apparent, *abrupt* decrease in FHR.
- An *abrupt* FHR decrease is defined as duration <30 sec from the onset of the deceleration to the beginning of the FHR nadir of the deceleration.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The decrease in FHR is ≥15 beats/min, lasting ≥15 sec, and <2 min in duration.
- When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive uterine contractions.

From Macones GA, Hankins GDV, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, Obstet Gynecol *112:661–666, 2008.*

min in ≥15 sec. The presence of accelerations or moderate variability reliably predicts the absence of fetal metabolic acidemia. However, their absence does not reliably predict fetal acidemia or hypoxemia. **Early deceleration** associated with head compression is a repetitive pattern of gradual decrease and return of the fetal heart rate that is coincidental with the uterine contraction (Table 96-3). **Variable deceleration** (associated with cord compression) is characterized by variable shape, abrupt onset and occurrence with consecutive contractions, and return to baseline at or after the conclusion of the contraction. **Late deceleration,** associated with fetal hypoxemia, occurs repetitively after a uterine contraction is well established and persists into the interval following contractions. The late deceleration pattern is usually associated with maternal hypotension or excessive uterine activity, but it may be a response to any maternal, placental, umbilical cord, or fetal factor that limits effective oxygenation of the fetus. Reflex late decelerations with normal beat-to-beat variability are associated with chronic compensated fetal hypoxia, and they occur during uterine contractions that temporarily impede oxygen transport to the heart. Nonreflex late decelerations are more ominous and indicate severe hypoxic depression of myocardial function. Approximately 10-15% of term fetuses have terminal (just before delivery) fetal heart rate decelerations that are usually benign if they lasted <10 min prior to delivery. Neonates with longer terminal decelerations without recovery (persistent bradycardia) are associated with fetal acidosis and need neonatal ICU observation or treatment.

If late decelerations are unresponsive to oxygen supplementation, hydration, discontinuation of labor stimulation, and position changes, prompt delivery is indicated. A 3-tier system has been developed by a panel of experts for interpretation of fetal heart rate tracings (Table 96-4). **Category I tracings** are normal and are strongly predictive of normal fetal acid–base status at the time of the observation. **Category II tracings** are not predictive of abnormal fetal status, but there is insufficient evidence to categorize them as category I or III; further evaluation, surveillance, and reevaluation are indicated. **Category III tracings** are abnormal and predictive of abnormal fetal acid–base status at the time of observation. Category III tracings require prompt evaluation and efforts to expeditiously resolve the abnormal fetal heart rate as previously discussed for late decelerations.

Fetal scalp blood sampling during labor through a slightly dilated cervix may aid in confirming fetal distress suspected on the basis of variations in fetal heart rate or the presence of meconium in amniotic

Table 96-4 Three-Tier Fetal Heart Rate Interpretation System

CATEGORY I
Category I fetal heart rate (FHR) tracings include all of the following:
- Baseline rate: 110-160 beats per minute (beats/min)
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

CATEGORY II
Category II FHR tracings include all FHR tracings not categorized as category I or category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of category II FHR tracings include any of the following:

Baseline rate
- Bradycardia not accompanied by absence of baseline variability
- Tachycardia

Baseline FHR variability
- Minimal baseline variability
- Absence of baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

Accelerations
- Absence of induced accelerations after fetal stimulation

Periodic or episodic decelerations
- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration, ≥2 min but <10 min
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," and "shoulders"

CATEGORY III
Category III FHR tracings include either:
- Absence of baseline FHR variability and any of the following:
- Recurrent late decelerations
- Recurrent variable decelerations
- Bradycardia
- Sinusoidal pattern

From Macones GA, Hankins GDV, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, Obstet Gynecol *112:661–666, 2008.*

fluid. The proper use of this technique may result in earlier delivery of depressed infants, who thus have a better chance of successful resuscitation, increased survival, and less morbidity. Alternatively, when continuous fetal heart rate monitoring or general clinical evaluation suggests that a fetus is at risk, a normal fetal scalp blood sample may help avert obstetric intervention.

Fetal scalp blood pH in normal labor decreases from approximately 7.33 early in labor to approximately 7.25 at the time of vaginal delivery; the base deficit is approximately 4-6 mEq/L. Changes in the buffer base may be particularly helpful in assessing fetal status, because they correspond to the accumulation of fetal lactic acid. A pH <7.25 suggests fetal distress, and a pH <7.20 is an indication for further assessment and intervention. Determination of the lactate concentration in fetal scalp blood is another tool for monitoring the condition of the fetus.

Umbilical cord blood samples obtained at the time of delivery are useful to document fetal acid–base status. Although the exact cord blood pH value that defines significant fetal acidemia is unknown, an umbilical artery pH <7.0 has been associated with greater need for resuscitation and a higher incidence of respiratory, gastrointestinal, cardiovascular, and neurologic complications. Nonetheless, in many cases, even when a low pH is detected, newborn infants are neurologically normal.

Intrapartum fetal pulse oximetry is another measure of fetal status. Even though initial data suggested that intrapartum fetal pulse oximetry could help identify fetuses with a nonreassuring status, a large randomized controlled trial showed that intrapartum fetal pulse oximetry does not lead to a reduction in cesarean section rates or improvement in the condition of newborns at birth.

96.3 Maternal Disease and the Fetus

Waldemar A. Carlo and Namasivayam Ambalavanan

INFECTIOUS DISEASES

See Table 95-3.

Almost any maternal infection with severe systemic manifestations may result in miscarriage, stillbirth, or premature labor. Whether these results are a consequence of infection of the fetus or are secondary to maternal illness is not always clear. Maternal hyperthermia may be associated with an increased incidence of congenital anomalies, including neural tube defects (NTDs). Regardless of the severity of the maternal infection, certain agents frequently infect the fetus and have serious sequelae. Fetuses of mothers infected with these agents are often small for gestational age and sometimes microcephalic. Some infections, such as rubella, may also produce congenital malformations if they occur during the period of organogenesis. Intrauterine infection/chorioamnionitis may be an important risk factor for cerebral white matter injury and subsequent cerebral palsy. Infections that affect maternal nutrition (e.g., hookworm) may also result in IUGR.

NONINFECTIOUS DISEASES

See Table 95-2.

Maternal diabetes increases the risk for neonatal hypoglycemia, hypocalcemia, respiratory distress syndrome and other respiratory problems, polycythemia, macrosomia, myocardial dysfunction, jaundice, and congenital malformations (see Chapter 107.1). There is increased risk for incidence of uteroplacental insufficiency, polyhydramnios, and intrauterine death in poorly controlled diabetic mothers. **Eclampsia–preeclampsia** of pregnancy, **chronic hypertension**, and **chronic renal disease** can result in IUGR, prematurity, and intrauterine death, all probably caused by diminished uteroplacental perfusion. Uncontrolled maternal **hypothyroidism** or **hyperthyroidism** is responsible for relative infertility, spontaneous abortion, premature labor, and fetal death. Hypothyroidism in pregnant women (even if mild or asymptomatic) can adversely affect neurodevelopment of the child. Maternal **immunologic diseases** such as idiopathic thrombocytopenic purpura, systemic lupus erythematosus, myasthenia gravis, and Graves disease, all of which are mediated by immunoglobulin G autoantibodies that can cross the placenta, frequently cause transient illness in the newborn. Maternal autoantibodies to the folate receptor are associated with NTDs, whereas maternal immunologic sensitization to paternal antigens may be associated with neonatal hemochromatosis. Untreated maternal **phenylketonuria** results in miscarriage, congenital cardiac malformations, and injury to the brain of a nonphenylketonuric heterozygotic fetus.

Bibliography is available at Expert Consult.

96.4 Maternal Medication and Toxin Exposure and the Fetus

Waldemar A. Carlo and Namasivayam Ambalavanan

The use of medications or herbal remedies during pregnancy is potentially harmful to the fetus. Consumption of medications occurs during the majority of pregnancies. The average mother has taken 4 drugs other than vitamins or iron during pregnancy. Almost 40% of pregnant women receive a drug for which human safety during pregnancy has not been established (category C pregnancy risk; see later). Moreover, many women are exposed to potential reproductive toxins, such as occupational, environmental, or household chemicals, including solvents, pesticides, and hair products. The effects of drugs taken by the mother vary considerably, especially in relation to the time in pregnancy when they are taken and the fetal genotype for drug-metabolizing enzymes. Miscarriage or congenital malformations result from the maternal ingestion of teratogenic drugs during the period of organogenesis. Maternal medications taken later, particularly during the last few weeks of gestation or during labor, tend to affect the function of specific organs or enzyme systems, and they adversely affect the neonate rather than the fetus (Tables 96-5 and 96-6).

The effects of drugs may be evident immediately in the delivery room or later in the neonatal period, or they may be delayed even longer. The administration of diethylstilbestrol during pregnancy, for instance, increased the risk for vaginal adenocarcinoma in female offspring in the 2nd or 3rd decade of life.

Evidence has confirmed an interaction between genetic factors and susceptibility to certain drugs or environmental toxins. Phenytoin teratogenesis may be mediated by genetic differences in the enzymatic production of epoxide metabolites; specific genes may influence the adverse effects of benzene exposure during pregnancy. Polymorphisms of genes encoding enzymes that metabolize the polycyclic aromatic hydrocarbons in cigarette smoke influence the growth-restricting effects of smoking on the fetus.

Often the risk of controlling maternal disease must be balanced with the risk of possible complications in the fetus. The majority of women with epilepsy have normal fetuses. Nonetheless, several commonly used antiepileptic drugs are associated with congenital malformations. Infants exposed to valproic acid may have multiple anomalies, including NTDs, hypospadias, facial anomalies, cardiac anomalies, and limb defects. In addition, they have lower developmental index scores than unexposed infants and infants exposed to other commonly used antiepileptic drugs.

Methotrexate is used for medical termination of pregnancy; surviving exposed infants may be at higher risk for congenital anomalies, IUGR, hypotonia, and developmental delay.

Moderate or high alcohol intake (≥7 drinks per week or ≥3 drinks on multiple occasions) is a risk for fetal alcohol syndrome. The exposed fetuses are at risk for growth failure, central nervous system abnormalities, cognitive defects, and behavioral problems. Smoking during pregnancy is associated with IUGR and facial clefts.

In view of the limits of current knowledge about the fetal effects of maternal medication, drugs and herbal agents should not be prescribed

96.5 Teratogens

Waldemar A. Carlo and Namasivayam Ambalavanan

When an infant or child has a congenital malformation or is developmentally delayed, the parents often wrongly blame themselves and attribute the child's problems to events that occurred during pregnancy. Because benign infections occur and several nonteratogenic drugs are often taken during many pregnancies, the pediatrician must evaluate the presumed viral infections and the drugs ingested to help parents understand their child's birth defect. The causes of approximately 40% of congenital malformations are unknown. Although only a relatively few agents are recognized to be teratogenic in humans (see Tables 96-5 and 96-6), new agents continue to be identified. Overall, only 10% of anomalies are due to recognizable teratogens (see Chapter 108). The time of exposure is usually during organogenesis at less than 60 days of gestation. Specific agents produce predictable lesions. Some agents have a dose or threshold effect; below the threshold, no alterations in growth, function, or structure occur. Genetic variables such as the presence of specific enzymes may metabolize a benign agent into a more toxic-teratogenic form (e.g., phenytoin conversion to its

Table 96-5 Agents Acting on Pregnant Women That May Adversely Affect the Structure or Function of the Fetus and Newborn

DRUG	EFFECT ON FETUS
Accutane (isotretinoin)	Facial-ear anomalies, heart disease, CNS anomalies
Alcohol	Congenital cardiac, CNS, limb anomalies; IUGR; developmental delay; attention deficits; autism
Aminopterin	Abortion, malformations
Amphetamines	Congenital heart disease, IUGR, withdrawal
Angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists	Oligohydramnios, IUGR, renal failure, Potter-like syndrome
Azathioprine	Abortion
Busulfan (Myleran)	Stunted growth; corneal opacities; cleft palate; hypoplasia of ovaries, thyroid, and parathyroids
Carbamazepine	Spina bifida, possible neurodevelopmental delay
Carbimazole	Scalp defects, choanal atresia, esophageal atresia, developmental delay
Carbon monoxide	Cerebral atrophy, microcephaly, seizures
Chloroquine	Deafness
Chorionic villus sampling	Probably no effect, possibly limb reduction
Cigarette smoking	LBW for gestational age
Cocaine/crack	Microcephaly, LBW, IUGR, behavioral disturbances
Cyclophosphamide	Multiple malformations
Danazol	Virilization
17α-Ethinyl testosterone (Progestoral)	Masculinization of female fetus
Hyperthermia	Spina bifida
Infliximab	Possible increased risk of live vaccine associated disease in infant; neutropenia
Lithium	Ebstein anomaly, macrosomia
Lopinavir-ritonavir	Transient adrenal dysfunction
6-Mercaptopurine	Abortion
Methyl mercury	Minamata disease, microcephaly, deafness, blindness, mental retardation
Methyltestosterone	Masculinization of female fetus
Misoprostol	Arthrogryposis, cranial neuropathies (Möbius syndrome), equinovarus
Mycophenolate mofetil	Craniofacial, limb, cardiovascular, CNS anomalies
Norethindrone	Masculinization of female fetus
Penicillamine	Cutis laxa syndrome
Phenytoin	Congenital anomalies, IUGR, neuroblastoma, bleeding (vitamin K deficiency)
Polychlorinated biphenyls	Skin discoloration—thickening, desquamation, LBW, acne, developmental delay
Prednisone	Oral clefts

Table 96-5 Agents Acting on Pregnant Women That May Adversely Affect the Structure or Function of the Fetus and Newborn—cont'd

DRUG	EFFECT ON FETUS
Progesterone	Masculinization of female fetus
Quinine	Abortion, thrombocytopenia, deafness
Selective serotonin reuptake inhibitors	Small increased risk of congenital anomalies, persistent pulmonary hypertension of newborn
Statins	IUGR, limb deficiencies, VACTERAL
Stilbestrol (diethylstilbestrol [DES])	Vaginal adenocarcinoma in adolescence
Streptomycin	Deafness
Tetracycline	Retarded skeletal growth, pigmentation of teeth, hypoplasia of enamel, cataract, limb malformations
Thalidomide	Phocomelia, deafness, other malformations
Toluene (solvent abuse)	Craniofacial abnormalities, prematurity, withdrawal symptoms, hypertonia
Topiramate	Cleft lip
Trimethadione and paramethadione	Abortion, multiple malformations, mental retardation
Valproate	CNS (spina bifida), facial and cardiac anomalies, limb defects, impaired neurologic function, autism spectrum disorder
Vitamin D	Supravalvular aortic stenosis, hypercalcemia
Warfarin (Coumadin)	Fetal bleeding and death, hypoplastic nasal structures

CNS, central nervous system; IUGR, intrauterine growth restriction; LBW, low birthweight. VACTERAL, vertebral, anal, cardiac, tracheoesophageal fistula, renal, arterial, limb.

Table 96-6 Agents Acting on Pregnant Women That May Adversely Affect the Newborn Infant*

Acebutolol—IUGR, hypotension, bradycardia
Acetazolamide—metabolic acidosis
Amiodarone—bradycardia, hypothyroidism
Anesthetic agents (volatile)—CNS depression
Adrenal corticosteroids—adrenocortical failure (rare)
Ammonium chloride—acidosis (clinically inapparent)
Aspirin—neonatal bleeding, prolonged gestation
Atenolol—IUGR, hypoglycemia
Baclofen—withdrawal
Blue cohosh herbal tea—neonatal heart failure
Bromides—rash, CNS depression, IUGR
Captopril, enalapril—transient anuric renal failure, oligohydramnios
Caudal-paracervical anesthesia with mepivacaine (accidental introduction of anesthetic into scalp of baby)—bradypnea, apnea, bradycardia, convulsions
Cholinergic agents (edrophonium, pyridostigmine)—transient muscle weakness
CNS depressants (narcotics, barbiturates, benzodiazepines) during labor—CNS depression, hypotonia
Cephalothin—positive direct Coombs test reaction
Dexamethasone—periventricular leukomalacia
Fluoxetine and other SSRIs—transient neonatal withdrawal, hypertonicity, minor anomalies, preterm birth, prolonged QT interval
Haloperidol—withdrawal
Hexamethonium bromide—paralytic ileus
Ibuprofen—oligohydramnios, pulmonary hypertension
Imipramine—withdrawal
Indomethacin—oliguria, oligohydramnios, intestinal perforation, pulmonary hypertension
Intravenous fluids during labor (e.g., salt-free solutions)—electrolyte disturbances, hyponatremia, hypoglycemia
Iodide (radioactive)—goiter
Iodides—goiter
Lead—reduced intellectual function
Magnesium sulfate—respiratory depression, meconium plug, hypotonia
Methimazole—goiter, hypothyroidism
Morphine and its derivatives (addiction)—withdrawal symptoms (poor feeding, vomiting, diarrhea, restlessness, yawning and stretching, dyspnea and cyanosis, fever and sweating, pallor, tremors, convulsions)
Naphthalene—hemolytic anemia (in G6PD-deficient infants)
Nitrofurantoin—hemolytic anemia (in G6PD-deficient infants)
Oxytocin—hyperbilirubinemia, hyponatremia
Phenobarbital—bleeding diathesis (vitamin K deficiency), possible long-term reduction in IQ, sedation
Primaquine—hemolytic anemia (in G6PD-deficient infants)
Propranolol—hypoglycemia, bradycardia, apnea

Continued

Table 96-6 Agents Acting on Pregnant Women That May Adversely Affect the Newborn Infant—cont'd

Propylthiouracil—goiter, hypothyroidism
Pyridoxine—seizures
Reserpine—drowsiness, nasal congestion, poor temperature stability
Sulfonamides—interfere with protein binding of bilirubin; kernicterus at low levels of serum bilirubin, hemolysis with G6PD deficiency
Sulfonylurea agents—refractory hypoglycemia
Sympathomimetic (tocolytic β-agonist) agents—tachycardia
Thiazides—neonatal thrombocytopenia (rare)
Tumor necrosis factor blocking agents—neutropenia
Valproate—developmental delay
Zolpidem (Ambien)—low birthweight

*See also Table 96-5.
CNS, central nervous system; G6PD, glucose-6-phosphate dehydrogenase; IUGR, intrauterine growth restriction; SSRI, selective serotonin reuptake inhibitor.

epoxide). In many circumstances, the same agent and dose may not consistently produce the lesion.

Reduced enzyme activity of the folate methylation pathway, particularly the formation of 5-methyltetrahydrofolate, may be responsible for neural tube or other birth defects. The common thermolabile mutation of 5,10-methylene tetrahydrofolate reductase may be one of the enzymes responsible. Folate supplementation for all pregnant women (by direct fortification of cereal grains, mandatory in the United States), and oral folic acid tablets taken during organogenesis may overcome this genetic enzyme defect, thus reducing the incidence of neural tube and perhaps other birth defects.

The U.S. Food and Drug Administration (FDA) classifies drugs into 5 pregnancy risk categories. **Category A** drugs pose no risk on the basis of evidence from controlled human studies. For **category B** drugs, either no risk has been shown in animal studies but no adequate studies in humans *or* some risk has been shown in animal studies but these results are not confirmed by human studies. For **category C** drugs, either definite risk has been shown in animal studies but no adequate human studies have been performed *or* no data is available from either animal or human studies. **Category D** includes drugs with some risk but with a benefit that may exceed that risk for the treated life-threatening condition, such as streptomycin for tuberculosis. **Category X** is for drugs that are contraindicated in pregnancy on the basis of animal and human evidence and for which the risk exceeds the benefits.

The specific mechanism of action is known or postulated for very few teratogens. Warfarin, an anticoagulant because it is a vitamin K antagonist, prevents the carboxylation of γ- carboxyglutamic acid, which is a component of osteocalcin and other vitamin K–dependent bone proteins. The teratogenic effect of warfarin on developing cartilage, especially nasal cartilage, appears to be avoided if the pregnant woman's anticoagulation treatment is switched from warfarin to heparin for the period between weeks 6 and 12 of gestation. Hypothyroidism in the fetus may be caused by the maternal ingestion of an excessive amount of iodides or propylthiouracil; each interferes with the conversion of inorganic to organic iodides. Phenytoin may be teratogenic because of the accumulation of a metabolite as a result of deficiency of epoxide hydrolase.

Recognition of teratogens offers the opportunity to prevent related birth defects. If a pregnant woman is informed of the potentially harmful effects of alcohol on her unborn infant, she may be motivated to avoid alcohol consumption during pregnancy. A woman with insulin-dependent diabetes mellitus may significantly decrease her risk for having a child with birth defects by achieving good control of her disease before conception.

96.6 Radiation

Waldemar A. Carlo and Namasivayam Ambalavanan

See also Chapter 718.

Accidental exposure of a pregnant woman to radiation is a common cause for anxiety about whether her fetus will have genetic abnormalities or birth defects. It is unlikely that exposure to diagnostic radiation will cause gene mutations; no increase in genetic abnormalities has been identified in the offspring exposed as unborn fetuses to the atomic bomb explosions in Japan in 1945.

A more realistic concern is whether the exposed human fetus will show birth defects or a higher incidence of malignancy. The estimated radiation dose for most radiographs is less than 0.1 rad, and for most CT scans it is less than 5 rad. Imaging studies with high radiation exposure (such as CT scans) can be modified to ensure that radiation doses are kept as low as possible. Thus, single diagnostic studies do not result in radiation doses high enough to affect the embryo or fetus. Therapeutic abortion should not be recommended, given the low likelihood for high radiation exposure. Most of the evidence suggests that usual fetal radiation exposure does not increase the risk of childhood leukemia and other cancers. The limited data on human fetuses show that large doses of radiation (20-50 rad) may cause fetal death (the most sensitive period is the 3rd and 4th postconception wk) as well as microcephaly, severe mental retardation, and growth retardation (the most sensitive period is 4th to 15th wk). The available data suggest no harmful fetal effect of diagnostic MRI or ultrasonography.

Bibliography is available at Expert Consult.

96.7 Intrauterine Diagnosis of Fetal Disease

Waldemar A. Carlo and Namasivayam Ambalavanan

See Table 96-1 and Chapter 96.2.

Diagnostic procedures are used to identify fetal diseases when abortion is being considered, when direct fetal treatment is possible, or when a decision is made to deliver a viable but premature infant to avoid intrauterine fetal demise. Fetal assessment is also indicated in a broader context when the family, medical, or reproductive history of the mother suggests the presence of a high-risk pregnancy or a high-risk fetus (see Chapters 95 and 96.3).

Various methods are used for identifying fetal disease (see Table 96-1). Fetal ultrasonographic imaging may detect fetal growth abnormalities (by biometric measurements of biparietal diameter, femoral length, or head or abdominal circumference) or fetal malformations (Fig. 96-5). Although 89% of fetuses whose biparietal diameter is 9.5 cm or more are at least in the 37th wk of gestation, the lungs of these fetuses may not be mature. Serial determinations of growth velocity and the head-to-abdomen circumference ratio enhance the ability to detect IUGR. Real-time ultrasonography may identify placental abnormalities (abruptio placentae, placenta previa) and fetal anomalies such as hydrocephalus, NTDs, duodenal atresia, diaphragmatic hernia, renal agenesis, bladder outlet obstruction, congenital heart disease, limb abnormalities, sacrococcygeal teratoma, cystic hygroma, omphalocele, gastroschisis, and hydrops (Table 96-7).

Real-time ultrasonography also facilitates performance of cordocentesis and the BPP by imaging fetal breathing, body movements, tone, and amniotic fluid volume (see Table 96-2). Doppler velocimetry

assesses fetal arterial blood flow (vascular resistance) (see Figs. 96-2 and 96-3). Radiographic examination of the fetus has been replaced by real-time ultrasonography, MRI, and fetoscopy.

Amniocentesis, the transabdominal withdrawal of amniotic fluid during pregnancy for diagnostic purposes (see Table 96-1), is frequently performed to determine the timing of delivery of fetuses with erythroblastosis fetalis or the need for fetal transfusion. It is also done for genetic indications, usually between the 15th and 16th wk of gestation, with results available within 1-2 wk. The most common indication for genetic amniocentesis is advanced maternal age (the risk for chromosome abnormality at age 21 yr is 1:526, vs. 1:8 at age 49 yr). The amniotic fluid may be directly analyzed for amino acids, enzymes, hormones, and abnormal metabolic products, and amniotic fluid cells may be cultivated to permit detailed cytologic analysis for prenatal detection of chromosomal abnormalities and DNA-gene or enzymatic analysis for the detection of inborn metabolic errors. Analysis of amniotic fluid may also help in identifying NTDs (elevation of α-fetoprotein), adrenogenital syndrome (elevation of 17-ketosteroids and pregnanetriol), and thyroid dysfunction. Chorionic villus biopsy (transvaginal or transabdominal) performed in the 1st trimester also provides fetal cells but may pose a slightly increased risk for fetal loss and limb reduction defects. Fetal DNA in maternal plasma and fetal cells circulating in maternal blood are potential noninvasive sources of material for prenatal diagnosis. This technology may eliminate the need for amniocentesis or chorionic villus sampling.

Table 96-7 Significance of Fetal Ultrasonographic Anatomic Findings

PRENATAL OBSERVATION	DEFINITION	DIFFERENTIAL DIAGNOSIS	SIGNIFICANCE	POSTNATAL EVALUATION
Dilated cerebral ventricles	Ventriculomegaly ≥10 mm	Hydrocephalus Hydranencephalous Dandy-Walker cyst Agenesis of corpus callosum	Transient isolated ventriculomegaly is common and usually benign Persistent or progressive ventriculomegaly more worrisome Identify associated cranial and extracranial anomalies Bilateral ventriculomegaly increases risk of developmental delay Unilateral ventriculomegaly may be normal variant	Serial head US or CT Evaluate for extracranial anomalies
Choroid plexus cysts	Size ~10 mm: unilateral or bilateral 1-3% incidence	Abnormal karyotype (trisomy 18, 21) Aneuploidy risk 1 : 100 if isolated. ↑ Risk (1 : 3) with other anomalies. Risk ↑ if large, complex, or bilateral cysts or advanced maternal age	Often isolated, benign; resolves by 24-28 wk Fetus should be examined for other organ anomalies; then amniocentesis should be performed for karyotype	Head US or CT Examine for extracranial anomalies; karyotype if indicated
Nuchal pad thickening	≥6 mm at 15-20 wk	Cystic hygroma trisomy 21, 18 Turner syndrome (XO) Nonchromosomal syndromes Normal (~25%)	≈50% of affected fetuses have chromosome abnormalities Amniocentesis for karyotype needed	Evaluate for multiple organ malformations; karyotype if indicated
Dilated renal pelvis	Pyelectasis ≥5 to 10 mm 0.6-1% incidence	Uteropelvic junction obstruction Vesicoureteral reflux Posterior ureteral valves Entopic ureterocele Large-volume nonobstruction	Often "physiologic" and transient Reflux is common If dilation is >10 mm or associated with caliectasis, pathologic cause should be considered If large bladder present, posterior urethral valves and megacystics-megaduodenum syndrome should be considered	Repeat ultrasonography on day 5 and at 1 mo; voiding cystourethrogram, prophylactic antibiotics
Echogenic bowel	0.6% incidence	CF, meconium peritonitis, trisomy 21 or 18, other chromosomal abnormalities cytomegalovirus, toxoplasmosis, GI obstruction	Often normal (65%) 10% of affected fetuses have CF; 1.5% have aneuploidy	Sweat chloride and DNA testing Karyotype Surgery for obstruction Evaluation for TORCH (toxoplasmosis, other agents, rubella, CMV, herpes simplex) syndrome
Stomach appearance	Small or absent or with double bubble	Upper GI obstruction (esophageal atresia) Double bubble signifies duodenal atresia Abnormal karyotype Polyhydramnios Stomach in chest signifies diaphragmatic hernia	Must also consider neurologic disorders that reduce swallowing Over 30% with double bubble have trisomy 21	Chromosomes, kidney, ureter, and bladder radiograph if indicated, upper GI series, neurologic evaluation

CF, cystic fibrosis; CMV, cytomegalovirus; GI, gastrointestinal; US, ultrasound.

The best available chemical indices of fetal maturity are provided by determination of amniotic fluid creatinine and lecithin levels, which reflect the maturity of the fetal kidneys and lungs, respectively. Lecithin is produced in the lungs by type II alveolar cells and eventually reaches the amniotic fluid via the effluent from the trachea. Until the middle of the 3rd trimester, its concentration nearly equals that of sphingomyelin; thereafter, the sphingomyelin concentration remains constant in amniotic fluid while the lecithin concentration increases. By 35 wk, the lecithin : sphingomyelin (L : S) ratio averages about 2 : 1, indicative of lung maturity.

Earlier lung maturation may occur in the presence of severe premature separation of the placenta, premature rupture of the fetal membranes, narcotic addiction, or maternal hypertensive and renal vascular disease. A delay in pulmonary maturation may be associated with hydrops fetalis or maternal diabetes without vascular disease. The likelihood of hyaline membrane disease is greatly reduced with L : S ratios of 2 : 1 or more, although hypoxia, acidosis, and hypothermia may increase the risk despite this "mature" L : S ratio. Maternal and fetal blood have an L : S ratio of about 1 : 4; thus, contamination will not alter the significance of a ratio of 2 : 1 or more. Meconium contamination,

sample storage, and sample centrifugation may reduce the reliability of the L:S ratio.

Saturated phosphatidylcholine or phosphatidylglycerol concentrations in amniotic fluid may be more specific and sensitive predictors of pulmonary maturity, especially in high-risk pregnancies such as those occurring in women with diabetes (see Chapters 95 and 107.1).

Amniocentesis can be carried out with little discomfort to the mother, but even in experienced hands, the procedure entails some small risk, such as direct damage to the fetus, placental puncture and bleeding with secondary damage to the fetus, stimulation of uterine contraction and premature labor, amnionitis, and maternal sensitization to fetal blood. The earlier in gestation that amniotic puncture is done, the greater the risk to the fetus. Using ultrasound for placental and fetal localization can reduce the risk of complications. The procedure should be limited to cases in which the potential benefits of the findings will outweigh the risk.

Cordocentesis, or percutaneous umbilical blood sampling, is used to diagnose fetal hematologic abnormalities, genetic disorders, infections, and fetal acidosis (see Table 96-1). Under direct ultrasonographic visualization, a long needle is passed into the umbilical vein at its entrance to the placenta or fetal abdominal wall. Umbilical blood may be withdrawn to determine fetal hemoglobin, platelet concentration, lymphocyte DNA, the presence of infection, or $Pa{O_2}$, pH, $P{CO_2}$, and lactate levels.

Transfusion or administration of drugs can be performed through the umbilical vein (Table 96-8). Serum screening is offered to pregnant women at midgestation to evaluate the risk for Down syndrome (trisomy 21) and congenital malformations known to cause elevations of various markers, including abdominal wall and NTDs. A combination of these biochemical markers (including α-fetoprotein, inhibin A, estriol, pregnancy-associated plasma protein A, and β-HCG [human chorionic gonadotropin]) and ultrasound increases the positive

Table 96-8 Fetal Therapy

DISORDER	POSSIBLE TREATMENT
HEMATOLOGIC	
Anemia with hydrops (erythroblastosis fetalis)	Umbilical vein packed red blood cell transfusion
Thalassemia	Fetal stem cell transplantation
Isoimmune thrombocytopenia	Umbilical vein platelet transfusion, maternal IVIG
Autoimmune thrombocytopenia (ITP)	Maternal steroids and IVIG
Chronic granulomatous disease	Fetal stem cell transplantation
METABOLIC-ENDOCRINE	
Maternal phenylketonuria (PKU)	Phenylalanine restriction
Fetal galactosemia	Galactose-free diet (?)
Multiple carboxylase deficiency	Biotin if responsive
Methylmalonic acidemia	Vitamin B_{12} if responsive
21-Hydroxylase deficiency	Dexamethasone
Maternal diabetes mellitus	Tight insulin control during pregnancy, labor, and delivery
Fetal goiter	Maternal hyperthyroidism—maternal propylthiouracil Fetal hypothyroidism—intra-amniotic thyroxine
Bartter syndrome	Maternal indomethacin may prevent nephrocalcinosis and postnatal sodium losses
Neonatal iron storage disease (alloimmune)	Maternal IVIG
FETAL DISTRESS	
Hypoxia	Maternal oxygen, position
Intrauterine growth restriction	Maternal oxygen, position, improve macronutrients and micronutrients if deficient
Oligohydramnios, premature rupture of membranes with variable deceleration	Amnioinfusion (antepartum and intrapartum)
Polyhydramnios	Amnioreduction (serial), indomethacin (if from increased urine output) if indicated
Supraventricular tachycardia	Maternal digoxin,* flecainide, procainamide, amiodarone, quinidine
Lupus anticoagulant	Maternal aspirin, prednisone
Meconium-stained fluid	Amnioinfusion
Congenital heart block	Dexamethasone, pacemaker (with hydrops)
Premature labor	Magnesium sulfate, antibiotics sympathomimetics, indomethacin
RESPIRATORY	
Pulmonary immaturity	Betamethasone
Bilateral chylothorax—pleural effusions	Thoracentesis, pleuroamniotic shunt
CONGENITAL ABNORMALITIES[†]	
Neural tube defects	Folate, vitamins (prevention); fetal surgery[‡]
Posterior urethral valves, urethral atresia (lower urinary tract obstruction)	Percutaneous vesicoamniotic shunt
Cystic adenomatoid malformation (with hydrops)	Pleuroamniotic shunt or resection[‡]
Fetal neck masses	Secure an airway with EXIT procedure[‡]
INFECTIOUS DISEASE	
Group B streptococcus colonization	Ampicillin, penicillin
Chorioamnionitis	Antibiotics
Toxoplasmosis	Spiramycin, pyrimethamine, sulfadiazine, and folic acid
Syphilis	Penicillin
Tuberculosis	Antituberculosis drugs
Lyme disease	Penicillin, ceftriaxone
Parvovirus	Intrauterine red blood cell transfusion for hydrops, severe anemia
Chlamydia trachomatis	Erythromycin
HIV-AIDS	Maternal and neonatal antiretroviral therapy (see Chapter 276)
Cytomegalovirus	Ganciclovir by umbilical vein

Continued

Table 96-8 Fetal Therapy	
DISORDER	**POSSIBLE TREATMENT**
OTHER	
Nonimmune hydrops (anemia)	Umbilical vein packed red blood cell transfusion
Narcotic abstinence (withdrawal)	Maternal low-dose methadone
Severe combined immunodeficiency disease	Fetal stem cell transplantation
Sacrococcygeal teratoma (with hydrops)	In utero resection or catheter directed vessel obliteration
Twin-twin transfusion syndrome	Repeated amniocentesis, yttrium-aluminum-garnet (YAG) laser photocoagulation of shared vessels
Twin reversed arterial perfusion (TRAP) syndrome	Digoxin, indomethacin, cord occlusion
Multifetal gestation	Selective reduction
Neonatal hemochromatosis	Maternal IVIG

*Drug of choice (may require percutaneous umbilical cord sampling and umbilical vein administration if hydrops is present). Most drug therapy is given to the mother, with subsequent placental passage to the fetus.
†Detailed fetal ultrasonography is needed to detect other anomalies; karyotype is also indicated.
‡EXIT permits surgery and other procedures.
EXIT, ex utero intrapartum treatment; IVIG, intravenous immunoglobulin; (?), possible but not proved efficacy.

predictive value of these screening tests. Nonetheless fetal karyotyping by analysis of fetal DNA in maternal plasma is another accurate method to diagnose trisomy 21. Additionally, families with a known genetic syndrome may be offered prenatal genetic testing from amniotic fluid or amniocytes obtained via amniocentesis or chorionic villus sampling.

96.8 Treatment and Prevention of Fetal Disease

Waldemar A. Carlo and Namasivayam Ambalavanan

Management of a fetal disease depends on coordinated advances in diagnostic accuracy and knowledge of the disease's natural history; an understanding of fetal nutrition, pharmacology, immunology, and pathophysiology; the availability of specific active drugs that cross the placenta; and therapeutic procedures. Progress in providing specific treatments for accurately diagnosed diseases has improved with the advent of real-time ultrasonography and cordocentesis (see Tables 96-1 and 96-8).

The incidence of sensitization of Rh-negative women by Rh-positive fetuses has been reduced by prophylactic administration of Rh(D) immunoglobulin to mothers early in pregnancy and after each delivery or abortion, thus reducing the frequency of hemolytic disease in their subsequent offspring. Fetal erythroblastosis (see Chapter 103.2) may be accurately diagnosed by amniotic fluid analysis and treated with intrauterine intraperitoneal or, more often, intraumbilical vein transfusions of packed Rh-negative blood cells to maintain the fetus until it is mature enough to have a reasonable chance of survival.

Fetal hypoxia or distress may be diagnosed with moderate success. Treatment, however, remains limited to supplying the mother with high concentrations of oxygen, positioning the uterus to avoid vascular compression, and initiating operative delivery before severe fetal injury occurs.

Pharmacologic approaches to fetal immaturity (e.g., administration of steroids to the mother to accelerate fetal lung maturation and decrease the incidence of respiratory distress syndrome [Chapter 101.3] in prematurely delivered infants) are successful. Inhibiting labor with tocolytic agents is unfortunately not successful in most patients with premature labor. Management of definitively diagnosed fetal genetic disease or congenital anomalies consists of parental counseling or abortion; rarely, high-dose vitamin therapy for a responsive inborn error of metabolism (biotin-dependent disorders) or fetal transfusion (with red blood cells or platelets) may be indicated. Fetal surgery (see Table 96-8) remains an a largely experimental approach to therapy and is available only in a few highly specialized perinatal centers. The nature of the defect and its consequences, as well as ethical implications for the fetus and the parents, must be considered. In a randomized controlled trial, fetal surgery for myelomeningocele improved neurological function (mental and motor development) and decreased the need for shunts by 50% but increased the prematurity rate.

Folic acid supplementation decreases the incidence and recurrence of (NTDs). Because the neural tube closes within the 1st 28 days of conception, periconceptional supplementation is needed for prevention. It is recommended that women without a prior history of a NTD ingest 400 μg/day of folic acid throughout their reproductive years. Women with a history of a prior pregnancy complicated by an NTD or a 1st-degree relative with an NTD should have preconceptional counseling and should ingest 4 mg/day of supplemental folic acid beginning at least 1 mo before conception. Fortification of cereal grain flour with folic acid is established policy in the United States and some other countries. The optimal concentration of folic acid in enriched grains is somewhat controversial. The incidence of NTD in the United States and other countries has decreased significantly since these public health initiatives were implemented. Use of some antiepileptic drugs (valproate, carbamazepine) during pregnancy is associated with an increased risk of NTD. Women taking these medications should ingest 1-5 mg of folic acid/day in the preconception period.

Chapter 97

The High-Risk Infant

Waldemar A. Carlo

Neonates at risk should be identified as early as possible prenatally or after birth to decrease neonatal morbidity and mortality (see Chapter 93). The term *high-risk infant* designates an infant who should be under close observation by experienced physicians and nurses. Table 97-1 lists the factors that define infants as being high risk. Approximately 10-20% of all births require special or neonatal intensive care. Usually needed for only a few days, such care may last from a few hours to several months. In some institutions, initial care for high-risk infants is provided in a special or transitional care nursery, often within the labor and delivery suite. This facility should be equipped and staffed like a neonatal intensive care area.

Examination of the fresh **placenta**, **cord**, and **membranes** may alert the physician to a newborn infant at high risk and may help confirm a diagnosis in a sick infant. **Fetal blood loss** may be indicated by

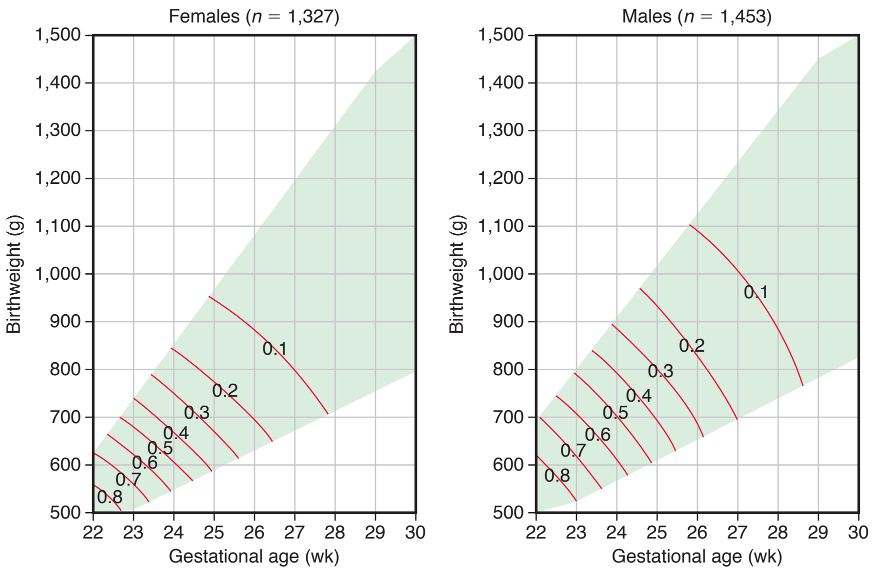

Figure 97-1 Estimated mortality risk by birthweight and gestational age based on singleton infants in National Institute of Child Health and Human Development (NICHD) Neonatal Research Network centers between January 1, 1995, and December 31, 1996. *(From Lemons JA, Bauer CR, Oh W, et al: Very low birthweight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996,* Pediatrics *107:E1, 2001; available at www.pediatrics.org.cgi/content/full/107/1/el.)*

Table 97-1 Factors That Define an Infant as Being High Risk

Factors That Define an Infant as Being High Risk
DEMOGRAPHIC SOCIAL FACTORS
Maternal age <16 or >40 yr
Illicit drug, alcohol, cigarette use
Poverty
Unmarried
Emotional or physical stress
PAST MEDICAL HISTORY
Genetic disorders
Diabetes mellitus
Hypertension
Asymptomatic bacteriuria
Rheumatologic illness (systemic lupus erythematosus)
Immune-mediated diseases (immunoglobulin G crossing placenta)
Long-term medication (see Tables 96-5 and 96-6 in Chapter 96)
PREVIOUS PREGNANCY
Intrauterine fetal demise
Neonatal death
Prematurity
Intrauterine growth restriction
Congenital malformation
Incompetent cervix
Blood group sensitization, neonatal jaundice
Neonatal thrombocytopenia
Hydrops
Inborn errors of metabolism
PRESENT PREGNANCY
Vaginal bleeding (abruptio placentae, placenta previa)
Sexually transmitted infections (colonization: herpes simplex, group B streptococcus, chlamydia, syphilis, hepatitis B, HIV)
Multiple gestation
Preeclampsia
Premature rupture of membranes
Short interpregnancy time
Poly-/oligohydramnios
Acute medical or surgical illness
Inadequate prenatal care
Familial or acquired hypercoagulable states
Abnormal fetal ultrasonographic findings
Treatment of infertility
LABOR AND DELIVERY
Premature labor (<37 wk)
Postdates pregnancy (≥42 wk)
Fetal distress
Immature lethicin : sphingomyelin ratio; absence of phosphatidylglycerol
Breech presentation
Meconium-stained fluid
Nuchal cord
Cesarean section
Forceps delivery
Apgar score <4 at 1 min
NEONATE
Birthweight <2,500 or >4,000 g
Birth <37 or ≥42 wk of gestation
Small or large for gestational age
Respiratory distress, cyanosis
Congenital malformation
Pallor, plethora, petechiae

placental pallor, retroplacental hematoma, and tears in the velamentous cords or chorionic blood vessels supplying the succenturiate lobes. Placental edema and secondary possible immunoglobulin G deficiency in a newborn may be associated with fetofetal transfusion syndrome, hydrops fetalis, congenital nephrosis, or hepatic disease. **Amnion nodosum** (granules on the amnion) and **oligohydramnios** are associated with pulmonary hypoplasia and renal agenesis, whereas small whitish nodules on the cord suggest a candidal infection. Short cords and noncoiled cords occur with chromosome abnormalities and omphalocele. True umbilical cord knots are seen in approximately 1% of births and are associated with a long cord, small fetal size, polyhydramnios, monoamniotic twinning, fetal demise, and low Apgar scores.

Chorioangiomas are associated with prematurity, abruptio placentae, polyhydramnios, and intrauterine growth restriction (IUGR). **Meconium staining** suggests in utero stress, and opacity of the fetal surface of the placenta suggests infection. Single umbilical arteries are associated with an increased incidence of congenital renal abnormalities and syndromes.

For many infants who are born prematurely, are small for gestational age (SGA), have significant perinatal asphyxia, are breech, or are born with life-threatening congenital anomalies, there are no previously identified risk factors. For any given duration of gestation, the lower the birthweight, the higher the neonatal mortality; for any given birthweight, the shorter the gestational duration, the higher the neonatal mortality (Fig. 97-1). The highest risk of neonatal and infant mortality occurs in infants who weigh <1,000 g at birth and whose gestation was <28 wk. The lowest risk of neonatal mortality occurs in infants with a birthweight of 3,000-4,000 g and a gestational age of 39-41 wk. As

birthweight increases from 400 to 3,000 g and gestational age increases from 23 to 39 wk, a logarithmic decrease in neonatal mortality occurs. In the United States, approximately 50% of all infant deaths occur in infants born after less than 27 wk of gestation or infants weighing less than 1,000 g. Neonatal mortality rates rise sharply for infants weighing more than 4,000 g at birth and for those whose gestational period is 42 wk or longer. Because neonatal mortality largely depends on birthweight and gestational age, Figure 97-1 can be used to help identify high-risk infants quickly. This analysis is based on total live births and therefore describes the mortality risk only at birth. Because most neonatal mortality occurs within the 1st hours and days after birth, the outlook improves dramatically with increasing postnatal survival. Prediction of death as well as neurodevelopmental impairment improves after birth and continues to improve over the first days and weeks after birth. The importance of gestational age, birth weight, and other perinatal factors for prediction of outcomes decline whereas the importance of respiratory illnesses and other morbidities increase.

97.1 Multiple-Gestation Pregnancies

Waldemar A. Carlo

INCIDENCE

The incidence of spontaneous twinning is highest among blacks and East Indians, followed by northern European whites, and is lowest in the Asian races. Specific rates are 1/56 in Belgium, 1/70 among American blacks, 1/86 in Italy, 1/88 among American whites, 1/130 in Greece, 1/150 in Japan, and 1/300 in China. Differences in the incidence of twins mainly involve fraternal (polyovular) dizygotic twins. Triplets are estimated to occur in 1 in 86^2 pregnancies and quadruplets in 1 in 86^3 pregnancies in the United States. The incidence of monozygotic twins (3-5/1,000) is unaffected by racial or familial factors. The incidence of twins detected by ultrasonography at 12 wk of gestation (3-5%) is much higher than that occurring later in pregnancy; the **vanishing twin syndrome** results in a singleton fetus. Although the incidence of spontaneous multifetal gestation has been stable over the years, the overall incidence of multifetal gestation is increasing as a result of treatment of infertility with ovarian stimulants (clomiphene, gonadotropins) and in vitro fertilization. Twins account for about 2.5% of births but approximately 15% of extremely low birthweight (ELBW, ≤1,000 g) infants.

ETIOLOGY

The occurrence of monovular twins appears to be independent of genetic influence. Polyovular pregnancies are more frequent beyond the second pregnancy, in older women, and in families with a history of polyovular twins. They may result from simultaneous maturation of multiple ovarian follicles, but follicles containing 2 ova have been described as a genetic trait leading to twin pregnancies. Twin-prone women have higher levels of gonadotropin. Polyovular pregnancies occur in many women treated for infertility.

Conjoined twins (Siamese twins—incidence 1/50,000) result from relatively late monovular separation. The prognosis for conjoined twins depends on the possibility of surgical separation, which, in turn, depends on the extent to which vital organs are shared. The site of connections varies: thoracoomphalopagus (28% of conjoined twins), thoracopagus (18%), omphalopagus (10%), craniopagus (6%), and incomplete duplication (10%). Difficult-to-separate conjoined twins have occasionally survived to adulthood. Most conjoined twins are female.

Superfecundation, or fertilization of an ovum by an insemination that takes place after 1 ovum has already been fertilized, and **superfetation,** or fertilization and subsequent development of an embryo when a fetus is already present in the uterus, have been proposed as uncommon explanations for differences in size and appearance of certain twins at birth.

A prenatal diagnosis of pregnancy with twins is suggested by a uterine size that is greater than that expected for gestational age, auscultation of 2 fetal hearts, and elevated maternal serum α-fetoprotein or human chorionic gonadotropin levels, and it is confirmed by ultrasonography.

MONOZYGOTIC VERSUS DIZYGOTIC TWINS

Identifying twins as monozygotic or dizygotic (monovular or polyovular) is useful in determining the relative influence of heredity and environment on human development and disease. Twins not of the same sex are dizygotic. In twins of the same sex, zygosity should be determined and recorded at birth through careful examination of the placenta. Detailed blood typing, gene analysis, or tissue (human leukocyte antigen) typing can also be used to determine zygosity. Monozygotic twins may have physical and cognitive differences because their in utero environment may have been different; differences may exist in the mitochondrial genome, in posttranslational gene product modification, and in the epigenetic modification of nuclear genes in response to environmental factors.

Examination of the Placenta

If the placentas are separate, they are always dichorionic (present in 75%), but the twins are not necessarily dizygotic, because initiation of monovular twinning at the first cell division or during the morula stage may result in 2 amnions, 2 chorions, and even 2 placentas. One-third of monozygotic twins are dichorionic and diamnionic.

An apparently single placenta may be present with either monovular or polyovular twins; yet inspection of a polyovular placenta usually reveals that each twin has a separate chorion that crosses the placenta between the attachments of the cords and two amnions. Separate or fused dichorionic placentas may be disproportionate in size. The fetus attached to the smaller placenta or the smaller portion of the placenta is usually smaller than its twin or is malformed. **Monochorionic twins** are usually diamnionic, and almost invariably, the placenta is a single mass.

Problems of twin gestation include polyhydramnios, hyperemesis gravidarum, preeclampsia, premature rupture of membranes, vasa previa, velamentous insertion of the umbilical cord, abnormal presentations (breech), and premature labor. **Monoamniotic twins** have a high fatality rate owing to obstruction of the circulation secondary to intertwining of the umbilical cords. Twins of widely discrepant size are usually monochorionic.

When compared with the first-born twin, the second twin is at increased risk for respiratory distress syndrome and asphyxia. Twins are at risk for IUGR, twin–twin transfusion, and congenital anomalies, which occur predominantly in monozygotic twins. Anomalies are a result of compression deformation of the uterus from crowding (hip dislocation), vascular communication with embolization (ileal atresia, porencephaly, cutis aplasia) or without embolization (acardiac twin), and unknown factors that cause twinning (conjoined twins, anencephaly, meningomyelocele).

Placental vascular anastomoses occur with high frequency only in monochorionic twins. In monochorionic placentas, the fetal vasculature is usually joined, sometimes in a very complex manner. The vascular anastomoses in monochorionic placentas may be artery to artery, vein to vein, or artery to vein. They are usually balanced so that neither twin suffers. Artery-to-artery communications cross over placental veins, and when anastomoses are present, blood can readily be stroked from one fetal vascular bed to the other. Vein-to-vein communications are similarly recognized but are less common. A combination of artery-to-artery and vein-to-vein anastomoses is associated with the condition of **acardiac fetus.** This rare lethal anomaly (1/35,000) is secondary to the **TRAP** (twin reversed arterial perfusion) **syndrome**. In utero neodynium : yttrium-aluminum-garnet (Nd : YAG) laser ablation of the anastomosis or cord occlusion can be used to treat heart failure in the surviving twin. In rare cases, 1 umbilical cord may arise from the other after leaving the placenta. In such cases, the twin attached to the secondary cord usually is malformed or dies in utero.

In the **fetal transfusion syndrome,** an artery from 1 twin acutely or chronically delivers blood that is drained into the vein of the other. The

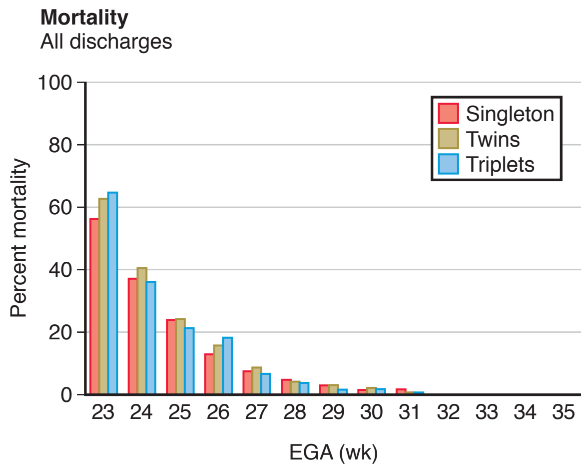

Figure 97-2 **Mortality, all discharges.** The neonatal mortality rate for all babies who died during the original hospitalization at each week of gestational age is given. The *bars on the left* represent singletons; the *middle bars* represent twins, and the *bars on the right* represent triplets. There are no differences among singleton births, twin births, and triplet births. EGA, estimated gestational age. *(From Garite TJ, Clark RH, Elliott JP, et al: Twins and triplets: the effect of plurality and growth on neonatal outcome compared with singleton infants,* Am J Obstet Gynecol *191:700–707, 2004.)*

latter becomes plethoric and large, and the former is anemic and small. Generally, with chronicity, 5 g/dL hemoglobin and 20% body weight differences can be noted in this syndrome. Maternal hydramnios in a twin pregnancy suggests fetal transfusion syndrome. Anticipating this possibility by preparing to transfuse the donor twin or bleed the recipient twin may be lifesaving. Death of the donor twin in utero may result in generalized fibrin thrombi in the smaller arterioles of the recipient twin, possibly as the result of transfusion of thromboplastin-rich blood from the macerating donor fetus. Disseminated intravascular coagulation may develop in the surviving twin. Table 97-2 lists the more frequent changes associated with a large uncompensated arteriovenous shunt from the placenta of 1 twin to that of the other. Treatment of this highly lethal problem includes maternal digoxin, aggressive amnioreduction for polyhydramnios, selective twin termination, and Nd : YAG laser or fetoscopic ablation of the anastomosis.

Postnatal Identification

The following physical criteria can be used to determine whether twins are monovular: (1) both must be of the same sex; (2) their features, including ears and teeth, must be obviously alike (but they need not resemble each other more than the lateral halves of one individual); (3) their hair must be identical in color, texture, natural curl, and distribution; (4) their eyes must be of the same color and shade; (5) their skin must be of the same texture and color (nevi may be differently apportioned and distributed); (6) their hands and feet must be of the same conformation and of similar size; and (7) their anthropometric values must show close agreement.

PROGNOSIS

Most twins are born prematurely, and maternal complications of pregnancy are more common than with single pregnancies. The risk for twins is most often associated with twin–twin transfusion, assisted reproductive technology, and early-onset discordant growth. Although monochorionic twins have a significantly higher perinatal mortality, there is no significant difference between the neonatal mortality rates of twin births and single births in comparable weight and gestational age groups (Fig. 97-2). Because most twins are premature, their overall mortality is higher than that of single-birth infants. The perinatal mortality of twins is about 4 times that of singletons. Monoamnionic twins have an increased likelihood of entangling the cords, which may lead to asphyxia. Theoretically, the second twin is more subject to anoxia than the first because the placenta may separate after birth of the first twin and before birth of the second. In addition, delivery of the second twin may be difficult because it may be in an abnormal presentation (breech, entangled), uterine tone may be decreased, or the cervix may begin to close after the first twin's birth. Triplet or higher-order births are associated with an increased risk of death or neurodevelopmental impairment when compared with ELBW singleton and twin infants.

The mortality for multiple gestations with 4 or more fetuses is excessively high for each fetus. Because of this poor prognosis, selective fetal reduction (with transabdominal intrathoracic fetal injection of KCl) to 2 or3 fetuses has been offered as a treatment option. Monozygotic twins have an increased risk of 1 twin dying in utero. The surviving twin has a greater risk for cerebral palsy and other neurodevelopmental sequelae.

The risk of multiple gestation pregnancies using assisted reproductive technologies may be reduced by elective single embryo transfers. In addition, elective delivery of twins at 37 wk reduces the complication rate for the fetuses and the mother. Furthermore, in twin pregnancies between 32 and 39 wk of gestation, planned vaginal delivery is preferred if the first twin is in the cephalic presentation.

TREATMENT

Prenatal diagnosis enables the obstetrician and pediatrician to anticipate the birth of infants who are at high risk because of twinning. Close observation is indicated during labor and in the immediate neonatal period so that prompt treatment of asphyxia or fetal transfusion syndrome can be initiated. The decision to perform an immediate blood transfusion in a severely anemic "donor twin" or to perform a partial exchange transfusion of a "recipient twin" must be based on clinical judgment.

deliver within 10 days of the estimated delivery date. Human gestation length from ovulation to birth may be 268 days, with a range of 37 days.

Liveborn infants delivered before 37 wk from the 1st day of the last menstrual period are termed premature by the World Health Organization. Low birthweight (LBW; birthweight of 2,500 g or less) is a consequence of prematurity, poor intrauterine growth (IUGR, also referred to as SGA), or both.

The American College of Obstetrics and Gynecology redefines term into subgroups: early term (37 0/7 wk of gestation to 38 6/7 wk), full term (39 0/7–40 6/7 wk), and late term (41 0/7–41 6/7 wk). Early term was previously referred to as late preterm.

Prematurity and IUGR are associated with increased neonatal morbidity and mortality. Ideally, definitions of LBW for individual populations should be based on data that are as genetically and environmentally homogeneous as possible. As previously mentioned, Figure 97-1 presents variations in mortality based on birthweight, gestational age, and gender.

INCIDENCE

There is an increasing percentage of deaths in children <5 yr of age that occur in the neonatal period. More than 5% of deaths in children <5 yr of age occur within the 1st mo of life, with about half of the deaths attributable to prematurity. Approximately 8% of liveborn neonates in the United States weigh <2,500 g; the rate for blacks is almost twice that for whites. Over the past 2 decades, the LBW rate has increased primarily because of an increased number of preterm births registered as live births. Women whose first births are delivered before term are at increased risk for recurrent preterm delivery. Approximately 30% of LBW infants in the United States have IUGR and are born after 37 wk of gestation. At LBW rates >10%, the contribution of IUGR increases and that of prematurity decreases. In developing countries, approximately 70% of LBW infants have IUGR. Infants with IUGR have greater morbidity and mortality than do appropriately grown, gestational age–matched infants (see Fig. 97-1). Although U.S. infant mortality rates have fallen since 1971, the ethnic disparity between black infants and white or Hispanic infants remains unchanged. Black infants have higher neonatal mortality rates and comprise a larger percentage of low birthweight births in the United States.

The incidence of preterm births in the United States continues to rise (Figs. 97-3 and 97-4) and is partly a result of multiple gestation pregnancies and increased reporting as live births of the most immature babies.

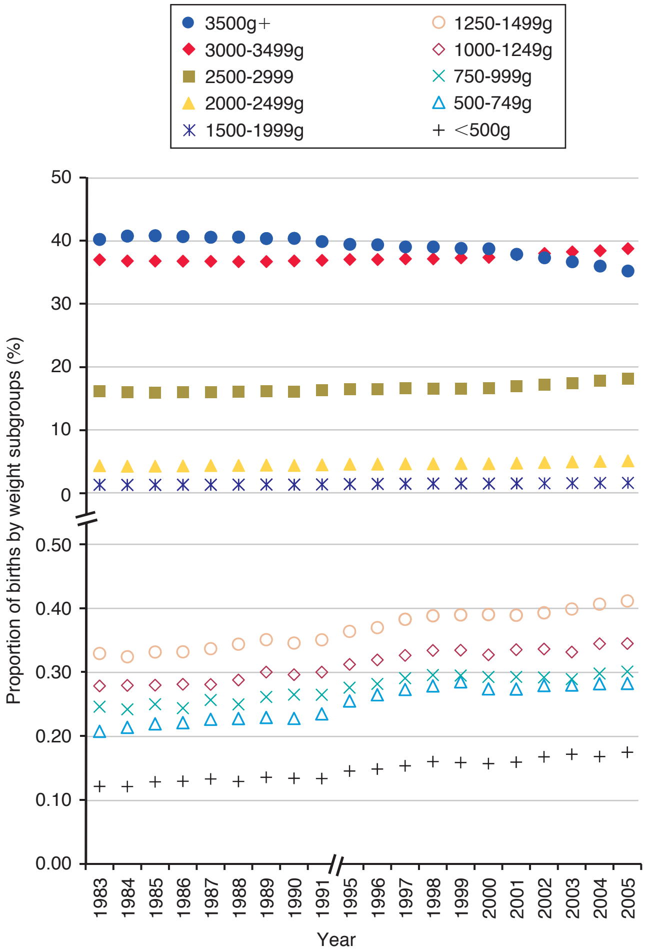

Figure 97-3 **Percentage contributions of infants in each very-low birthweight subgroup to total births for 1983-2005.** The contribution of infants in each very-low birthweight subgroup increased during the study period. *(From Lau C, Ambalavanan N, Chakraborty H, et al: Extremely low birth weight and infant mortality rates in the United States,* Pediatrics *131:855–860, 2013.)*

VERY LOW BIRTHWEIGHT INFANTS

Very-low birthweight (VLBW) infants weigh <1,500 g and are predominantly premature. In the United States in 2011, the VLBW rates were approximately 1.44% overall, 2.99% among blacks, and 1.14% among whites. The VLBW rate is an accurate predictor of the infant mortality rate. VLBW infants account for more than 50% of neonatal deaths and 50% of handicapped infants; their survival is directly related to birthweight, with approximately 20% of those between 500 and 600 g and >90% of those between 1,250 and 1,500 g surviving. The VLBW rate has remained unchanged for black Americans but has increased among whites, perhaps because of a rise in multiple births among whites. Perinatal care has improved the rate of survival of VLBW infants. When compared with term infants, VLBW neonates have a higher incidence of rehospitalization during the 1st yr of life for sequelae of prematurity, infections, neurologic complications, and psychosocial disorders.

FACTORS RELATED TO PREMATURE BIRTH AND LOW BIRTHWEIGHT

It is difficult to separate completely the factors associated with prematurity from those associated with IUGR (see Chapters 94 and 95). A strong positive correlation exists between both preterm birth and IUGR and low socioeconomic status. Families of low socioeconomic status have higher rates of maternal undernutrition, anemia, and illness; inadequate prenatal care; drug misuse; obstetric complications; and maternal history of reproductive inefficiency (abortions, stillbirths, premature or LBW infants). Other associated factors, such as single-parent families, teenage pregnancies, short interpregnancy interval, and mothers who have borne more than 4 previous children, are also encountered more frequently in such families. Systematic differences in fetal growth have also been described in association with maternal size, birth order, sibling weight, social class, maternal smoking, and other factors. The degree to which the variance in birthweight among various populations is caused by environmental (extrafetal) rather than genetic differences in growth potential is difficult to determine.

The etiology of preterm birth is multifactorial and involves a complex interaction between fetal, placental, uterine, and maternal factors (Table 97-3).

Premature birth of infants whose LBW is appropriate for their preterm gestational age is associated with medical conditions characterized by an inability of the uterus to retain the fetus, interference with the course of the pregnancy, premature rupture of the amniotic membranes or premature separation of the placenta, multifetal gestation, or an undetermined stimulus to effective uterine contractions before term.

Overt or asymptomatic bacterial infection (group B streptococci, *Listeria monocytogenes, Ureaplasma urealyticum, Mycoplasma hominis, Chlamydia, Trichomonas vaginalis, Gardnerella vaginalis, Bacteroides* spp.) of the amniotic fluid and membranes (chorioamnionitis) may initiate preterm labor. Bacterial products may stimulate the production

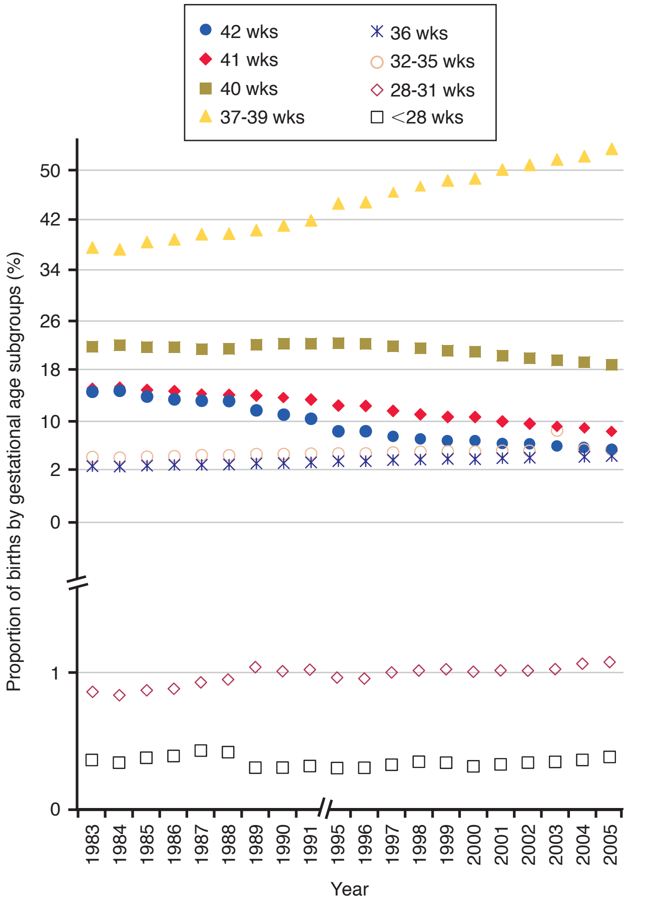

Figure 97-4 Percentage contributions of infants in gestational age subgroups to total births for 1983-2005. *(From Lau C, Ambalavanan N, Chakraborty H, et al: Extremely low birth weight and infant mortality rates in the United States,* Pediatrics *131:855–860, 2013.)*

of local inflammatory mediators (interleukin-6, prostaglandins), which may induce premature uterine contractions or a local inflammatory response with focal amniotic membrane rupture. Appropriate antibiotic therapy reduces the risk of fetal infection and may prolong gestation.

Most preterm births are "spontaneous" without an identifiable cause; genetic predisposition may increase the risk of prematurity. In one study, 6 genes were associated with prematurity. In addition, attempts at prevention of prematurity with hydroxyprogesterone caproate intramuscular injections or vaginal progesterone therapy, suggest a role for an endocrine–genetic relationship.

IUGR is associated with medical conditions that interfere with the circulation and efficiency of the placenta, with the development or growth of the fetus, or with the general health and nutrition of the mother (Table 97-4). Many factors are common to both prematurely born and LBW infants with IUGR. IUGR is associated with decreased insulin production or insulin (or insulin-like growth factor) action at the receptor level. Infants with insulin-like growth factor-1 receptor defects, pancreatic hypoplasia, or transient neonatal diabetes have IUGR. Genetic mutations affecting the glucose-sensing mechanisms of the pancreatic islet cells that result in decreased insulin release (loss of function of the glucose-sensing glucokinase gene) give rise to IUGR.

IUGR may be a normal fetal response to nutritional or oxygen deprivation. Therefore, the issue is not the IUGR but rather the ongoing risk of fetal malnutrition or hypoxia. Similarly, some preterm births signify a need for early delivery from a potentially disadvantageous intrauterine environment. IUGR is often classified as reduced growth that is symmetric (head circumference, length, and weight equally affected) or asymmetric (with relative sparing of head growth) (see Fig. 96-1 in Chapter 96). **Symmetric IUGR** often has an earlier onset and is associated with diseases that seriously affect fetal cell number, such as conditions with chromosomal, genetic, malformation, teratogenic, infectious, or severe maternal hypertensive etiologies. It is important to assess gestational age carefully in infants suspected to have symmetric IUGR because incorrect overestimation of gestational age may lead to the diagnosis of symmetric IUGR. **Asymmetric IUGR** is often of late onset, demonstrates preservation of Doppler waveform velocity to the carotid vessels, and is associated with poor maternal nutrition or with late onset or exacerbation of maternal vascular

disease (preeclampsia, chronic hypertension). Table 97-5 lists the problems of infants with IUGR.

ASSESSMENT OF GESTATIONAL AGE AT BIRTH

When compared with a premature infant of appropriate weight, an infant with IUGR has a reduced birthweight and may appear to have a disproportionately larger head relative to body size; infants in both groups lack subcutaneous fat. Neurologic maturity (nerve conduction velocity) in the absence of asphyxia correlates with gestational age despite reduced fetal weight. Physical signs may be useful in estimating gestational age at birth. Commonly used, the Ballard scoring system is accurate to ±2 wk (Figs. 97-5 to 97-7). An infant should be presumed to be at high risk for mortality or morbidity if a discrepancy exists between the estimation of gestational age by physical examination, the mother's estimated date of her last menstrual period, and fetal ultrasonographic evaluation.

Table 97-5 Problems of Infants Small for Gestational Age or with Intrauterine Growth Retardation*

PROBLEM	PATHOGENESIS
Intrauterine fetal demise	Hypoxia, acidosis, infection, lethal anomaly
Perinatal asphyxia	↓ Uteroplacental perfusion during labor ± chronic fetal hypoxia–acidosis; meconium aspiration syndrome
Hypoglycemia	↓ Tissue glycogen stores, ↓ gluconeogenesis, hyperinsulinism, ↑ glucose needs of hypoxia, hypothermia, large brain
Polycythemia–hyperviscosity	Fetal hypoxia with ↑ erythropoietin production
Reduced oxygen consumption/hypothermia	Hypoxia, hypoglycemia, starvation effect, poor subcutaneous fat stores
Dysmorphology	Syndrome anomalads, chromosomal-genetic disorders, oligohydramnios-induced deformation, TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infection

*Other problems include pulmonary hemorrhage and those common to the gestational age-related risks of prematurity if born at less than 37 wk.
↓, Decreased; ↑, increased.

SPECTRUM OF DISEASE IN LOW-BIRTHWEIGHT INFANTS

Immaturity increases the severity but reduces the distinctiveness of the clinical manifestations of most neonatal diseases. Immature organ function, complications of therapy, and the specific disorders that caused the premature onset of labor contribute to the neonatal

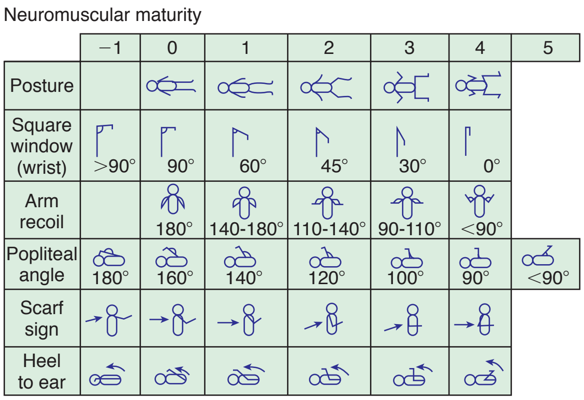

Figure 97-6 **Neuromuscular criteria for maturity.** The expanded New Ballard score includes extremely premature infants and has been refined to improve accuracy in more mature infants. *(From Ballard JL, Khoury JC, Wedig K, et al: New Ballard score, expanded to include extremely premature infants, J Pediatr 119:417–423, 1991.)*

Figure 97-7 **Maturity rating.** The physical and neurologic scores are added to calculate gestational age. *(From Ballard JL, Khoury JC, Wedig K, et al: New Ballard score, expanded to include extremely premature infants,* J Pediatr *119:417–423, 1991.)*

morbidity and mortality associated with premature, LBW infants (Table 97-6). Among VLBW infants, morbidity is inversely related to birthweight. Respiratory distress syndrome is noted in approximately 80% of infants weighing 501-750 g; in 65% of those weighing 751-1,000 g; in 45% of those weighing 1,001-1,250 g; and in 25% of those weighing 1,251-1,500 g. Severe intraventricular hemorrhage (IVH) is noted in approximately 25% of infants weighing 501-750 g; in 12% of those weighing 751-1,000 g; in 8% of those weighing 1,001-1,250 g; and in 3% of those weighing 1,251-1,500 g. Overall, the risk of late sepsis (24%), bronchopulmonary dysplasia (23%), severe IVH (11%), necrotizing enterocolitis (7%), and prolonged hospitalization (45-125 days) is high in VLBW infants. Problems associated with IUGR LBW infants are noted in Table 97-5; these added problems are often superimposed on those noted in Table 97-6 if an infant with IUGR is also premature. Poor postnatal growth is an important problem for both preterm and IUGR infants.

NURSERY CARE

At birth, the measures needed to clear the airway, initiate breathing, care for the umbilical cord and eyes, and administer vitamin K are the same for immature infants as for those of normal weight and maturity (see Chapter 94). Special care is required to maintain a patent airway. Additional considerations are the need for (1) thermal control and monitoring of the heart rate and respiration, (2) oxygen therapy, and (3) special attention to the details of fluid requirements and nutrition. Safeguards against infection can never be relaxed. Routine procedures that disturb these infants may result in hypoxia. The need for regular and active participation by the parents in the infant's care in the nursery, the need to instruct the mother in at-home care of her infant, and the question of prognosis for later growth and development require special consideration.

Thermal Control

The survival rate of LBW and sick infants is higher when they are cared for at or near their **neutral thermal environment.** This environment is a set of thermal conditions, including air and radiating surface temperatures, relative humidity, and airflow, at which heat production (measured experimentally as oxygen consumption) is minimal and the infant's core temperature is within the normal range. The neutral thermal environment is a function of the size and postnatal age of an infant; larger, older infants require lower environmental temperatures than smaller, younger infants do. Incubators or radiant warmers can be used to maintain body temperature. Body heat is conserved through provision of a warm environment and humidity. The optimal environmental temperature for minimal heat loss and oxygen consumption for an unclothed infant is one that maintains the infant's core temperature at 36.5-37.0°C (97.7-98.6°F). It depends on an infant's size and maturity; the smaller and more immature the infant, the higher the environmental temperature required. An additional acrylic resin (Plexiglas) heat shield or head cap and body clothing may be required to keep an extremely LBW (ELBW) preterm infant warm. Infant warmth can be maintained by heating the air to a desired temperature or by servocontrolling the infant's body temperature at a desired set point. Continuous monitoring of the infant's temperature is required so that the environmental temperature can be adjusted to maintain optimal body temperature. **Kangaroo mother care** with direct skin-to-skin contact and a hat and blanket covering the infant is a safe alternative, with careful monitoring to avoid the risk of serious hypothermia when

incubators are unavailable or when the infant is stable and the parent desire close contact with their infant.

Maintaining a relative humidity of 40-60% aids in stabilizing body temperature by reducing heat loss at lower environmental temperatures; by preventing drying and irritation of the lining of respiratory passages, especially during the administration of oxygen and after or during endotracheal intubation (usually 100% humidity); and by thinning viscid secretions and reducing insensible water loss from the lungs. An infant should be weaned and then removed from the incubator or radiant warmer only when the gradual change to the atmosphere of the nursery does not result in a significant change in the infant's temperature, color, activity, or vital signs.

Administering oxygen to reduce the risk of injury from hypoxia and circulatory insufficiency must be balanced against the risk of hyperoxia to the eyes (retinopathy of prematurity) and oxygen injury to the lungs. Oxygen should be administered via a head hood, nasal cannula, continuous positive airway pressure apparatus, or endotracheal tube to maintain stable and safe inspired oxygen concentrations. Although cyanosis must be treated immediately, oxygen is a drug, and its use must be carefully regulated to maximize benefit and minimize potential harm. The concentration of inspired oxygen must be adjusted in accordance with the oxygen tension of arterial blood (Pa_{O_2}) or a noninvasive method such as continuous pulse oximetry or transcutaneous oxygen measurements. Capillary blood gas determinations are inadequate for estimating arterial oxygen levels.

Fluid Requirements

Fluid needs vary according to gestational age, environmental conditions, and disease states. Assuming minimal water loss in the stool of infants not receiving oral fluids, their water needs are equal to their insensible water loss, excretion of renal solutes, growth, and any unusual ongoing losses. Insensible water loss is indirectly related to gestational age; very immature preterm infants (<1,000 g) may lose as much as 2-3 mL/kg/hr, partly because of immature skin, lack of subcutaneous tissue, and a large exposed surface area. Insensible water loss is increased under radiant warmers, during phototherapy, and in febrile infants. High humidity can be used to reduce insensible water losses. The loss is diminished when an infant is clothed, is covered by an acrylic resin inner heat shield, breathes humidified air, or is of advanced postnatal age. A larger premature infant (2,000-2,500 g) nursed in an incubator may have an insensible water loss of approximately 0.6-0.7 mL/kg/hr.

Adequate fluid intake is essential for excretion of the urinary solute load (urea, electrolytes, phosphate). The amount varies with dietary intake and the anabolic or catabolic state of nutrition. Formulas with a high solute load, high protein intake, and catabolism increase the end products that require urinary excretion and thus increase the requirement for water. **Renal solute loads** may vary between 7.5 and 30 mOsm/kg. Newborn infants, especially VLBW ones, are also less able to concentrate urine, so they need higher fluid intake to excrete solutes.

Fluid intake in term infants is usually begun at 60-70 mL/kg on day 1 and increased to 100-120 mL/kg by days 2-3. Smaller, more premature infants may need to start with 70-80 mL/kg on day 1 and advance gradually to 150 mL/kg/day. Fluid volumes should be titrated individually, although it is unusual to exceed 150 mL/kg/24 hr. Infants weighing <750 g in the 1st wk of life have immature skin and a large surface area, characteristics that lead to a high rate of transepidermal fluid loss, at times requiring higher rates of intravenous fluids. Daily weights, urine output, and serum urea nitrogen and sodium levels should be monitored carefully to determine water balance and fluid needs. Clinical observation and physical examination are poor indicators of the state of hydration of premature infants. Conditions that increase fluid loss, such as glycosuria, the polyuric phase of acute tubular necrosis, and diarrhea, may place additional strain on kidneys that have not yet acquired their maximal capacity to conserve water and electrolytes, the result of which may be severe dehydration. Alternatively, fluid overload may lead to edema, heart failure, patent ductus arteriosus, and bronchopulmonary dysplasia.

Parenteral Nutrition

Before complete enteral feeding has been established or when enteral feeding is impossible for prolonged periods, total intravenous alimentation may provide sufficient fluid, calories, amino acids, electrolytes, and vitamins to sustain the growth of ill infants. This technique has been lifesaving for VLBW and preterm infants and infants who have had intractable diarrheal syndromes or extensive bowel resection. Infusions may be administered through a percutaneously or, less often, surgically placed indwelling central venous catheter or through a peripheral vein. The umbilical vein may also be used for up to 2 wk.

The goal of parenteral alimentation is to deliver sufficient calories from glucose, protein, and lipids to promote optimal growth. The infusate should contain 2.5-3.5 g/dL of synthetic amino acids and usually 10-15 g/dL of glucose, in addition to appropriate quantities of electrolytes, trace minerals, and vitamins. If a peripheral vein is used, it is advisable to keep the glucose concentration below 12.5 g/dL. If a central vein is used, glucose concentrations as high as 25 g/dL may be used (rarely). Intravenous fat emulsions such as Intralipid 20% (2.2 kcal/mL) may be administered to provide calories without an appreciable osmotic load, thereby decreasing the need for infusion of the higher concentrations of glucose by central or peripheral vein while preventing the development of essential fatty acid deficiency. A 20% fat emulsion may be initiated at 0.5 g/kg/24 hr and advanced to 3 g/kg/24 hr, if triglyceride levels remain normal; 0.5 g/kg/24 hr is sufficient to prevent essential fatty acid deficiency. Electrolytes, trace minerals, and vitamin additives are included in amounts approximating established intravenous maintenance requirements. The content of each day's infusate should be determined after careful assessment of the infant's clinical and biochemical status. Slow and continuous infusion is advisable. A well-trained pharmacist should mix all solutions under a laminar flow hood.

After a caloric intake of >100 kcal/kg/24 hr is established by total parenteral intravenous nutrition, the infants can be expected to gain about 15 g/kg/24 hr, with a positive nitrogen balance of 150-200 mg/kg/24 hr, in the absence of episodes of sepsis, surgical procedures, and other severe stress. This goal can usually be achieved (and the catabolic tendency during the 1st wk of life reversed, with subsequent weight gain) by peripheral vein infusion of 2.5-3.5 g/kg/24 hr of an amino acid mixture, 10 g/dL of glucose, and 2-3 g/kg/24 hr of a 20% fat emulsion.

Complications of intravenous alimentation are related to both the catheter and the metabolism of the infusate. Sepsis, the most important problem of central vein infusions, can be minimized only by meticulous catheter care and aseptic preparation of the infusate; a vancomycin–heparin solution also reduces the risk of line sepsis. Coagulase-negative *Staphylococcus* is the most common infecting organism. Treatment includes appropriate antibiotics. If an infection persists (repeatedly positive blood culture results while the infant is receiving appropriate antibiotics), the line must be removed. Thrombosis, extravasation of fluid, and accidental dislodgment of catheters have also occurred. Although sepsis is less often attributable to peripheral vein infusion, phlebitis, cutaneous sloughing, and superficial infection may occur. Metabolic complications of parenteral nutrition include hyperglycemia from the high glucose concentration of the infusate, which may lead to osmotic diuresis and dehydration; azotemia; a possible increased risk of nephrocalcinosis; hypoglycemia from sudden accidental cessation of the infusate; hyperlipidemia and possibly hypoxemia from intravenous lipid infusions; and hyperammonemia, which may result from high levels of certain amino acids. Metabolic bone disease and/or cholestatic jaundice and liver disease may develop in infants who require long-term parenteral nutrition and receive no enteral nutrition. Biochemical and physiologic monitoring of infants receiving intravenous alimentation is indicated because of the frequency and seriousness of complications.

Feeding

The method of feeding each LBW or preterm infant should be individualized. It is important to avoid fatigue and aspiration of food

through regurgitation or the feeding process. No feeding method averts these problems unless the person feeding the infant has been well trained in the method. Oral feeding (nipple) should not be initiated or should be discontinued in infants with respiratory distress, hypoxia, circulatory insufficiency, excessive secretions, gagging, sepsis, central nervous system depression, severe immaturity, or signs of serious illness. These high-risk infants require parenteral nutrition or gavage feeding to supply calories, fluid, and electrolytes. The process of oral alimentation requires, in addition to a strong sucking effort, coordination of swallowing, epiglottal and uvular closure of the larynx and nasal passages, and normal esophageal motility, a synchronized process that is usually absent before 34 wk of gestation.

Preterm infants at 34 wk of gestation or more can often be fed by bottle or at the breast. Because the effort of sucking is usually the limiting factor, direct breastfeeding is less likely to succeed in very preterm infants until they mature. Bottle-feeding of expressed breast milk may be a temporary alternative. In bottle-feeding, the infant's effort may be reduced by use of special small, soft nipples with large holes. Smaller or less vigorous infants should be fed by gavage: A soft plastic tube with No. 5 French external and approximately 0.05 cm internal diameters and with a rounded atraumatic tip and two holes on alternate sides is preferable. The tube is passed through the nose until approximately 2.5 cm (1 inch) of the lower end is in the stomach. The free end of the tube has an adapter into which the tip of a syringe is fitted, and a measured amount of fluid is given by pump or by gravity. Such a tube may be left in place for 3-7 days before being replaced by a similar tube through the other nostril. Infants occasionally have enough local irritation from an indwelling tube that they may gag or troublesome secretions may gather around it in the nasopharynx. In such cases, a catheter may be passed through the mouth by a skilled person and removed at the end of each feeding.

The infant may be fed with intermittent bolus feedings or continuous feeding. In the occasional infant with feeding intolerance, nasojejunal feeding may be successful. Intestinal perforation is a risk with nasojejunal feeding. A change to breast- or bottle-feeding may be instituted gradually as soon as an infant displays general vigor adequate for oral feeding without fatigue.

Gastrostomy feeding is not usually indicated in premature or LBW infants except as an adjunct to surgical management of specific gastrointestinal conditions or in patients with permanent neurologic injuries who are unable to suck and swallow normally.

Initiation of Feeding

The optimal time to introduce enteral feeding to a sick premature or LBW infant is controversial. **Trophic feeding** is the practice of feeding very small amounts of enteral nourishment to VLBW preterm infants to stimulate development of the immature gastrointestinal tract. The benefits of trophic feeding include enhanced gut motility, improved growth, decreased need for parenteral nutrition, fewer episodes of sepsis, and shortened hospital stay. Once the infant is stable, small-volume feedings are given in addition to intravenous fluids/nutrition. Feeding is gradually advanced, and parenteral nutrition decreased. This approach may reduce the incidence of necrotizing enterocolitis. The main principle in feeding premature infants is to proceed cautiously and gradually. Careful early feeding of breast milk or formula tends to reduce the risk of hypoglycemia, dehydration, and hyperbilirubinemia without the additional risk of aspiration, provided that there is no indication for withholding oral feedings, such as the presence of respiratory distress or other disorders.

If an infant is well, is making sucking movements, and is in no distress, oral feeding may be attempted, although most infants weighing <1,500 g require tube feeding because they are unable to coordinate breathing, sucking, and swallowing. Intestinal tract readiness for feeding may be determined by active bowel sounds, passage of meconium, and the absence of abdominal distention, bilious gastric aspirates, and emesis. For infants <1,000 g, the initial trophic feedings can be given at 10-20 mL/kg/24 hr as a continuous nasogastric tube drip (or given by intermittent gavage every 2-3 hr) for

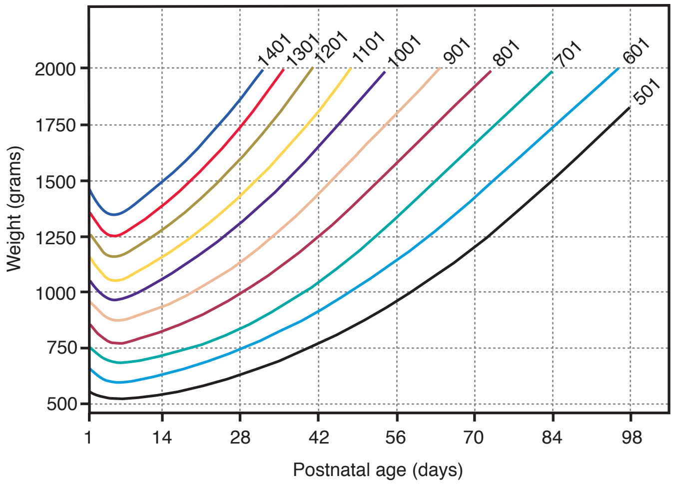

Figure 97-8 Average daily body weight versus postnatal age in days for infants stratified by 100-g birthweight intervals. *(From Ehrenkranz RA, Younes N, Lemons JA, et al: Longitudinal growth of hospitalized very low birth weight infants. Pediatrics 104:280-289, 1999.)*

5-10 days. If the initial feedings are tolerated, the volume is increased by 20-30 mL/kg/24 hr. Once a volume of 150 mL/kg/24 hr has been achieved, the caloric content may be increased to 24 or 27 kcal/oz. With high caloric density, infants are at risk for dehydration, edema, lactose intolerance, diarrhea, flatus, and delayed gastric emptying with emesis. Intravenous fluids are needed until feedings provide approximately 120 mL/kg/24 hr. The feeding protocol for premature infants weighing >1,500 g is initiated at a volume of 20-30 mL/kg/24 hr with increments in total daily formula volume of 20-30 mL/kg/24 hr. Figure 97-8 projects the expected weight increments for premature infants of various birthweights. Infants with IUGR may not demonstrate the marked initial weight loss noted in premature infants.

Regurgitation, vomiting, abdominal distention, or gastric residuals from previous feedings should arouse suspicion of sepsis, necrotizing enterocolitis, or intestinal obstruction; these conditions are indications to stop feedings, at least temporarily, and to increase subsequent feedings slowly only as tolerated or to change to intravenous alimentation and evaluate the infant for more serious problems (see Chapter 102.2). Weight gain may not be achieved for 10-12 days. Alternatively, in infants whose feeding schedule is advanced successfully in calories or volume, weight gain may appear within a few days.

When tube feeding is used, the contents of the stomach should be aspirated before each feeding. If only air or small amounts of mucus are obtained, the feeding is given as planned. If all or a substantial part of the previous feeding is aspirated, it is advisable to withhold feedings or to reduce the amount of the feeding and proceed more gradually with subsequent increases, depending on the physical findings and other evidence of feeding intolerance.

The digestive enzyme systems of infants older than 28 wk of gestation are mature enough to permit adequate digestion and absorption of protein and carbohydrate. Fat is less-well absorbed, primarily because of inadequate amounts of bile salt; unsaturated fats and the fat of human milk are absorbed better than the fat of cow's milk. The weight gain of infants weighing <2,000 g at birth should be adequate when either human milk or "humanized" milk premature formula (40% casein and 60% whey) with a protein intake of 2.25-2.75 g/kg/24 hr is fed. These 2 alternatives should provide all amino acids essential for premature infants, including tyrosine, cystine, and histidine. Higher protein intake may be well tolerated and is generally safe, especially in older, rapidly growing infants. Protein intake >4-5 g/kg/24 hr may be hazardous. Although they may promote linear growth, high-protein formulas may cause abnormal plasma

aminogram results; elevations in blood urea nitrogen, ammonia, and sodium concentrations; metabolic acidosis (cow's milk formulas); and untoward effects on neurologic development. Furthermore, the high protein and mineral contents of balanced cow's milk formulas with a high caloric content constitute a large solute load for the kidneys, a fact important in maintaining water balance, especially in infants with diarrhea or fever.

Breast milk from their mothers is the preferred milk for all infants, including VLBW infants. In addition to nutritional advantages, the benefits of breast milk include protection against a wide range of infections (through both specific and nonspecific anti-infective factors in breast milk and beneficial effects on intestinal flora), a decreased risk of necrotizing enterocolitis in preterm infants, a lower risk of sudden infant death syndrome, and possible long-term effects, including a lower risk of childhood/adolescent obesity and improved neurodevelopmental outcome. Once a premature infant takes 120 mL/kg/24 hr, **breast milk fortifiers** are added to supplement breast milk with protein, calcium, and phosphorus. If breast milk is unavailable, special preterm formulas should be used.

Properly fed premature infants may have from 1 to 8 daily stools of semisolid consistency; a sudden increase in their number, the appearance of occult or gross blood, or change to a watery consistency is more reason for concern than any arbitrarily stated stooling frequency.

Vitamins

Although formula in amounts necessary for adequate growth probably contains adequate quantities of all vitamins, the volume of milk sufficient to satisfy these requirements may not be ingested for several weeks. Therefore, LBW and preterm infants should be given supplemental vitamins. Because requirements for these infants have not been precisely established, the recommended daily allowances for term infants should be given (see Chapter 44). Furthermore, infants may have a special need for certain vitamins. Intermediary metabolism of phenylalanine and tyrosine depends, in part, on vitamin C. Decreased fat absorption with increased fecal fat loss may be associated with decreased absorption of vitamin D, other fat-soluble vitamins, and calcium in premature infants. VLBW infants are particularly prone to the development of osteopenia, but their total intake of vitamin D should not exceed 1,500 IU/24 hr. Folic acid is essential for the formation of DNA and production of new cells; serum and erythrocyte levels decrease in preterm infants during the 1st few wk of life and remain low for 2-3 mo. Therefore, folic acid supplementation is recommended, although it does not result in improved growth or an increased hemoglobin concentration. Deficiency of vitamin E is uncommon, but is associated with increased hemolysis and, if severe, with anemia and edema in premature infants. Vitamin E functions as an antioxidant to prevent the peroxidation of excessive polyunsaturated fatty acids in red blood cell membranes; its need may increase because of the higher membrane content of these fatty acids when formulas with high polyunsaturated fatty acids are used. Vitamin A supplementation reduces bronchopulmonary dysplasia in ELBW infants. Vitamin K deficiency is discussed in Chapter 97.4.

In LBW and premature infants, **physiologic anemia** from postnatal suppression of erythropoiesis is exacerbated by smaller fetal iron stores and greater expansion of blood volume from the more rapid growth than that of term infants; therefore, the anemia develops earlier and reaches a lower ultimate level. Fetal or neonatal blood loss accentuates this problem. Iron stores, even in a VLBW neonate, are usually adequate until an infant's birthweight has doubled; iron supplementation (2 mg/kg/24 hr) should then be started. If erythropoietin is used, iron supplementation is also required.

Prevention of Infection

Premature infants have an increased susceptibility to infection, and thus meticulous attention to infection control is required. Prevention strategies include strict compliance with handwashing and universal precautions, minimizing the risk of catheter contamination and duration, meticulous skin care, encouraging early appropriate advancement of enteral feeding, education and feedback to staff, and surveillance of nosocomial infection rates in the nursery. Although no one with an active infection should be permitted in the nursery, the risks of infection must be balanced against the disadvantages of limiting the infant's contact with the family. Early and frequent participation by parents in the nursery care of their infant does not increase the risk of infection when preventive precautions are maintained.

Preventing transmission of infection from infant to infant is difficult because often neither term nor premature newborn infants have clear clinical evidence of an infection early in its course. When epidemics occur within a nursery, cohort nursing and isolation rooms should be used. Universal precautions require gloves to be worn with all patient contact. Because premature infants have immature immune function, some will develop nosocomial infection even when all precautions are followed.

Routine immunizations should be given on the regular schedule at standard doses (see Chapter 172).

IMMATURITY OF DRUG METABOLISM

Renal clearance of almost all substances excreted in the urine is diminished in newborn infants, but more so in premature ones. The glomerular filtration rate rises with increasing gestational age; therefore drug dosing recommendations vary with age. Intervals between doses may therefore need to be extended with administration of drugs excreted chiefly by the kidneys. Longer intervals are required for many drugs administered to preterm infants. Drugs that are detoxified in the liver or require chemical conjugation before renal excretion should also be given with caution and in doses smaller than usual.

When possible, blood levels should be determined for potentially toxic drugs, especially if renal or hepatic dysfunction is present. Decisions about the choice and dose of antibacterial agents and the route of administration should be made on an individual basis rather than routinely because of the dangers of (a) development of infections with organisms resistant to antibacterial agents, (b) inhibition of intestinal bacteria that manufacture significant amounts of essential vitamins (vitamin K and thiamine), and (c) harmful interference in important metabolic processes.

Many drugs apparently safe for adults on the basis of toxicity studies may be harmful to newborn infants, especially premature ones. Oxygen and a number of drugs have proved toxic to premature infants in amounts not harmful to term infants (Table 97-7). Thus, administering any drug, particularly in high doses, that has not undergone pharmacologic testing in premature infants should be undertaken carefully after risks have been weighed against benefits.

PROGNOSIS

Infants born weighing 1,501-2,500 g have a 95% or greater chance of survival, but those weighing still less have significantly higher mortality (see Fig. 97-1). Intensive care has extended the period during which a VLBW infant is at increased risk of dying of complications of prematurity, such as bronchopulmonary dysplasia, necrotizing enterocolitis, and nosocomial infection (Table 97-8). The postdischarge mortality rate of LBW infants is higher than that of term infants during the 1st 2 yr of life. Because many of the deaths are attributable to infection (e.g., respiratory syncytial virus), they are at least theoretically preventable. In addition, premature infants have an increased incidence of failure to thrive, sudden infant death syndrome, child abuse, and inadequate maternal-infant bonding. The biologic risk associated with poor cardiorespiratory regulation as a result of immaturity or complications of underlying perinatal disease and the social risk associated with poverty also contribute to the high mortality and morbidity of these infants. Congenital anomalies are present in approximately 3-7% of LBW infants.

In the absence of congenital abnormalities, central nervous system injury, VLBW, or marked IUGR, the **physical growth** of LBW infants tends to approximate that of term infants by the 2nd yr; the approximation occurs earlier in premature infants with larger birth size. VLBW infants may not catch up, especially if they have severe chronic sequelae, insufficient nutritional intake, or an inadequate caretaking

Table 97-7 Potential Adverse Reactions to Drugs Administered to Premature Infants

DRUG	REACTION(S)
Oxygen	Retinopathy of prematurity, bronchopulmonary dysplasia
Sulfisoxazole	Kernicterus
Chloramphenicol	Gray baby syndrome—shock, bone marrow suppression
Vitamin K analogs	Jaundice
Novobiocin	Jaundice
Hexachlorophene	Encephalopathy
Benzyl alcohol	Acidosis, collapse, intraventricular bleeding
Intravenous vitamin E	Ascites, shock
Phenolic detergents	Jaundice
$NaHCO_3$	Intraventricular hemorrhage
Amphotericin	Anuric renal failure, hypokalemia, hypomagnesemia
Reserpine	Nasal stuffiness
Indomethacin	Oliguria, hyponatremia, intestinal perforation
Cisapride	Prolonged QTc interval
Tetracycline	Enamel hypoplasia
Tolazoline	Hypotension, gastrointestinal bleeding
Calcium salts	Subcutaneous necrosis
Aminoglycosides	Deafness, renal toxicity
Enteric gentamicin	Resistant bacteria
Prostaglandins	Seizures, diarrhea, apnea, hyperostosis, pyloric stenosis
Phenobarbital	Altered state, drowsiness
Morphine	Hypotension, urine retention, withdrawal
Pancuronium	Edema, hypovolemia, hypotension, tachycardia, vecuronium contractions, prolonged hypotonia
Iodine antiseptics	Hypothyroidism, goiter
Fentanyl	Seizures, chest wall rigidity, withdrawal
Dexamethasone	Gastrointestinal bleeding, hypertension, infection, hyperglycemia, cardiomyopathy, reduced growth
Furosemide	Deafness, hyponatremia, hypokalemia, hypochloremia, nephrocalcinosis, biliary stones
Heparin (not low-dose prophylactic use)	Bleeding, intraventricular hemorrhage, thrombocytopenia
Erythromycin	Pyloric stenosis

environment (see Table 97-8). Infrequently, infants with IUGR (SGA) grow poorly and do not demonstrate catch-up growth. These infants may benefit from recombinant human growth hormone therapy beginning at age 4 yr.

Premature birth in itself may adversely affect later development. The greater the immaturity and the lower the birthweight, the greater the likelihood of intellectual and neurologic deficit; as many as 50% of 500-750 g infants have significant neurodevelopmental impairment (mental retardation, cerebral palsy, blindness, deafness). Small head circumference at birth may be related to a poor neurobehavioral prognosis. Many surviving LBW infants have hypotonia before 8 mo corrected age, which improves by the time they are 8 mo to 1 yr old. This transient hypotonia is not a poor prognostic sign. Thirty percent to 50% of VLBW children have poor school performance at 7 yr of age (repeating of grades, special classes, learning disorders, poor speech and language), despite a normal IQ. Factors posing a risk for poor academic performance include birthweight below 750 g, severe IVH, periventricular leukomalacia, bronchopulmonary dysplasia, cerebral atrophy, posthemorrhagic hydrocephalus, IUGR, low socioeconomic status, and, possibly, low thyroxine levels. Antenatal exposure to magnesium sulfate may have neuroprotective effects and may reduce the incidence of cerebral palsy in high-risk neonates. Adolescents who were VLBW report satisfactory health; 94% are integrated in regular classes despite neurosensory disabilities (hearing, vision, cerebral palsy, cognition) in 24%.

Table 97-8 Sequelae of Low Birthweight

IMMEDIATE	LATE
Hypoxia, ischemia	Mental retardation, spastic diplegia, microcephaly, seizures, poor school performance
Intraventricular hemorrhage	Mental retardation, spasticity, seizures, hydrocephalus
Sensorineural injury	Hearing, visual impairment, retinopathy of prematurity, strabismus, myopia
Respiratory failure	Bronchopulmonary dysplasia, cor pulmonale, bronchospasm, malnutrition, subglottic stenosis
Necrotizing enterocolitis	Short-bowel syndrome, malabsorption, malnutrition, infectious diarrhea
Cholestatic liver disease	Cirrhosis, hepatic failure, malnutrition
Nutrient deficiency	Osteopenia, fractures, anemia, growth failure
Social stress	Child abuse or neglect, failure to thrive, divorce
Other	Sudden infant death syndrome, infections, inguinal hernia, cutaneous scars (chest tube, patent ductus arteriosus ligation, intravenous infiltration), gastroesophageal reflux, hypertension, craniosynostosis, cholelithiasis, nephrocalcinosis, cutaneous hemangiomas

Both premature and IUGR infants are at risk for significant metabolic conditions (obesity, type II diabetes) and cardiovascular disorders (ischemic heart disease, hypertension) as adults. This **fetal origins** hypothesis of adult morbidities may involve insulin resistance, which may be evident in early childhood.

PREDICTING NEONATAL MORTALITY

Birthweight and gestational age have traditionally been used as strong indicators for the risk of neonatal death. Indeed, survival at 22 wk of gestation is poor, particularly in those infants requiring aggressive resuscitation in the delivery room. With increasing gestational age, survival rates rise to approximately 15% at 23 wk, 56% at 24 wk, and 79% at 25 wk. The survival of infants of <24 wk gestation, weighing <750 g, and with a 1-min Apgar score <3 is 30%. Antenatal steroids to increase lung maturation, female sex, and singleton pregnancy increase the chance for survival. However, extremely premature infants are also at risk for poor neurodevelopmental outcome.

Birthweight-specific neonatal diseases such as IVH, group B streptococcal sepsis/pneumonia, and pulmonary hypoplasia also contribute to a poor outcome. **Scoring systems** that have been developed take into consideration physiologic abnormalities (hypotension–hypertension, acidosis, hypoxia, hypercapnia, anemia, neutropenia), as in the **Score for Neonatal Acute Physiology,** or clinical parameters (gestational age, birthweight, anomalies, acidosis, FIO_2), as in the **Clinical Risk Index for Babies.** The Clinical Risk Index for Babies includes 6 parameters collected in the 1st 12 hr after birth, and the Score for Neonatal Acute Physiology has 26 variables collected in the 1st 24 hr. Prediction models can be used before birth, but additional data from throughout the hospitalization improve the identification of infants at high risk for death or neurodevelopmental impairment. Combining a physician's judgment and an objective score may produce a more accurate assessment of the risk of death.

DISCHARGE FROM THE HOSPITAL

Before discharge, a premature infant should be taking all nutrition by nipple, either bottle or breast (Table 97-9). Some medically fragile infants may be discharged home while receiving gavage feedings after the parents have received appropriate training and education. Growth should be occurring at steady increments of approximately 30 g/day. Temperature should be stabile in an open crib. Infants should have had no recent episodes of apnea or bradycardia, and parenteral drug administration should have been discontinued or converted to oral dosing. Stable infants recovering from bronchopulmonary dysplasia may be discharged on a regimen of oxygen given by nasal cannula as long as careful follow-up is arranged with frequent pulse oximetry monitoring and outpatient visits. All infants with birthweight <1,500 g and those with birthweights between 1,500 and 2,000 g with an unstable clinical course requiring oxygen should undergo an eye examination to screen for retinopathy of prematurity. All infants should have a hearing test prior to discharge. In those who had indwelling umbilical arterial catheters, blood pressure should be measured to check for renal vascular hypertension. The hemoglobin level or hematocrit should be determined to evaluate for possible anemia. If all major medical problems have resolved and the home setting is adequate, premature infants may then be discharged when their weight approaches 1,800-2,100 g; close follow-up plus easy access to healthcare providers is essential for early discharge protocols. Alternatively, if the medical or social environment is not ideal, high-risk neonates who have been transported to neonatal intensive care units and whose major illnesses have resolved may be returned to their hospital of birth for an additional period of hospitalization. Standard vaccinations with full doses should commence after discharge or, if infants are still in the hospital, with vaccines that do not contain live viruses. For respiratory syncytial virus prophylaxis, see Chapter 260.

Table 97-9	Readiness for Discharge of High-Risk Infants Criteria

Resolution of acute life-threatening illnesses
Ongoing follow-up for chronic but stable problems:
Bronchopulmonary dysplasia
Intraventricular hemorrhage
Necrotizing enterocolitis after surgery or recovery
Ventricular septal defect, other cardiac lesions
Anemia
Retinopathy of prematurity
Hearing problems
Apnea
Cholestasis
Stable temperature regulation
Gain of weight with oral feedings:
Breastfeeding
Bottle-feeding
Gastric tube
Free of significant apnea; home monitoring for apnea if needed
Appropriate immunizations and planning for respiratory syncytial virus prophylaxis if indicated
Hearing screenings
Ophthalmologic examination if <27 wk of gestation or <1,250 g at birth
Mother's knowledge, skill, confidence documented in:
  Administration of medications (diuretics, methylxanthines, aerosols, etc.)
  Use of oxygen, apnea monitors, oximeters
Nutritional support:
  Timing
  Volume
  Mixing concentrated formulas
Recognition of illness and deterioration
Basic cardiopulmonary resuscitation
Infant safety (see Table 97-1)
Scheduling of referrals:
Primary care provider
Neonatal follow-up clinic
Occupational therapy/physical therapy
Imaging (head ultrasound)
Assessment of and solution to social risks (see Table 97-1)

HOME CARE

While the infant is in the hospital, the mother should receive instruction on how to care for the baby after discharge and should be allowed to provide infant care in the hospital. Ideally, a home care program should include at least 1 home visit by someone capable of evaluating domestic arrangements and advising about any needed improvements. Early developmental intervention programs focused on parent-infant relationship and/or infant development after discharge improve cognitive development in the short to medium term (up to preschool) but do not improve motor outcomes. However these benefits are not sustained at school age.

Bibliography is available at Expert Consult.

97.3 Postterm Infants

Waldemar A. Carlo

Postterm infants are those born after 42 completed weeks of gestation, as calculated from the mother's last menstrual period, regardless of weight at birth. Historically, approximately 12% of pregnancies ended after the 294th day. Obstetric interventions often occur earlier, and the rate of postterm births is decreasing. The cause of postterm birth or postmaturity is unknown.

CLINICAL MANIFESTATIONS

Postterm infants have normal length and head circumference but may have decreased weight if there is placental insufficiency. Infants born postterm in association with presumed placental insufficiency may have various physical signs. Desquamation, long nails, abundant hair, pale skin, alert faces, and loose skin, especially around the thighs and buttocks, give them the appearance of having recently lost weight; meconium-stained nails, skin, vernix, umbilical cord, and placental membranes may also be noted (see Fig. 88-1 in Chapter 88). Common complications of postmaturity include perinatal depression, meconium aspiration, persistent pulmonary hypertension, hypoglycemia, hypocalcemia, and polycythemia.

PROGNOSIS

When delivery is delayed 3 wk or more beyond term, mortality is significantly increased and, in some series, has been approximately 3 times that of a control group of infants born at term. Mortality has been lowered markedly through improved obstetric management.

MANAGEMENT

Careful obstetric monitoring, including nonstress testing, biophysical profile, or Doppler velocimetry, usually provides a rational basis for choosing one of three courses: nonintervention, induction of labor, or cesarean section. Induction of labor or cesarean section may be indicated in older primigravidas more than 2-4 wk beyond term, particularly if evidence of fetal distress is present. Medical problems in the newborn are treated if they arise.

97.4 Large-for-Gestational-Age Infants

Waldemar A. Carlo

See also Chapter 101.1.

Infants with birthweight > the 90th percentile for gestational age are called **large for gestational age** (LGA). Neonatal mortality rates decrease with increasing birthweight until approximately 4,000 g, after which they increase. These oversized infants are usually born at term, but preterm infants with weights high for gestational age also have a significantly higher mortality than infants of the same size born at term; maternal diabetes and obesity are predisposing factors. Some infants are constitutionally large because of large parental size. LGA infants, regardless of their gestational age, have a higher incidence of birth injuries, such as cervical and brachial plexus injuries, phrenic nerve damage with paralysis of the diaphragm, fractured clavicles, cephalohematomas, subdural hematomas, and ecchymoses of the head and face. LGA infants are also at increased risk for hypoglycemia and polycythemia.

The incidence of congenital anomalies, particularly congenital heart disease, is also higher in LGA infants than in term infants of normal weight. Intellectual and developmental retardation is statistically more common in high birthweight term and preterm infants than in babies of appropriate weight for gestational age.

97.5 Infant Transport

Waldemar A. Carlo

With the advent of regionalized care of high-risk neonates, increasing numbers of high-risk mothers and sick infants are transported to hospitals with neonatal intensive care units. Neonatal transport should include consultation about the infant's problem and care before transport, ease of access to the transport team, and transport and stabilization by the team before moving the infant. Securing an airway, providing oxygen, assisting with infant ventilation, providing antimicrobial therapy, maintaining the circulation, providing a warmed environment, and placing intravenous or arterial lines or chest tubes should be initiated, if indicated, before transport. Infant and maternal records and laboratory reports should also be provided. Before departure of an infant, the mother should be briefly reassured and allowed to see her stabilized infant; the father should enter his car and follow the transport vehicle to the unit. The transport officer or nurse should also call ahead to inform the receiving unit about the nature of the patient's illness.

The transport vehicle should be equipped with appropriate medicines, fluids, oxygen tanks, catheters, chest tubes, endotracheal tubes, laryngoscopes, and an infant warming device. It should be well illuminated and have ample room for emergency procedures and monitoring equipment. With efficient transport and appropriately educated nursing and medical staff at the referring hospitals, the mortality of "outborn" neonates should be no higher than that of those born within the tertiary care center.

Chapter 98

Clinical Manifestations of Diseases in the Newborn Period

Waldemar A. Carlo

The wide varieties of disorders that affect the newborn originate in utero, during birth, or in the immediate postnatal period. These disorders may be caused by prematurity, genetic mutations, chromosomal aberrations, or acquired diseases and injuries. Recognizing disease in newborn infants depends on knowledge of the disorder and evaluation of a limited number of relatively nonspecific clinical signs and symptoms.

Central cyanosis has respiratory, cardiac, central nervous system (CNS), hematologic, and metabolic causes (Table 98-1). Respiratory insufficiency may be a result of pulmonary conditions or may be secondary to CNS depression from drugs, intracranial hemorrhage, or anoxia. If respiratory insufficiency is caused by pulmonary conditions, respirations tend to be rapid and may be accompanied by retraction of the thoracic cage. If it is caused by the CNS depression, respirations tend to be irregular and weak and are often slow. Cyanosis unaccompanied by obvious signs of respiratory difficulty suggests cyanotic congenital heart disease or methemoglobinemia. Cyanosis resulting from congenital heart disease may, however, be difficult to distinguish clinically from cyanosis caused by respiratory disease. Episodes of cyanosis may also be the initial sign of hypoglycemia, bacteremia, meningitis, shock, or pulmonary hypertension. Peripheral acrocyanosis is common in neonates and does not usually warrant concern unless poor perfusion is suspected.

Pallor, in addition to anemia or acute hemorrhage, should suggest hypoxia, asphyxia, hypoglycemia, sepsis, shock, or adrenal failure.

Hypotension in term infants suggests shock from hypovolemia (hemorrhage, dehydration), the systemic inflammatory response syndrome (bacterial sepsis, intrauterine infection, necrotizing enterocolitis), cardiac dysfunction (left heart obstructive lesions—hypoplastic left-heart syndrome, myocarditis, asphyxia-induced myocardial stunning, anomalous coronary artery), pneumothorax, pneumopericardium, pericardial effusion, or metabolic disorders (hypoglycemia, adrenal insufficiency–salt-losing adrenogenital syndrome). Hypotension is a common problem in sick preterm infants and may also be caused by any of the problems noted in a term infant. Hypotension may develop in preterm infants with severe respiratory distress syndrome. Strategies used to support blood pressure include volume expansion (normal saline is equally as effective as 5% albumin), pressors (dopamine, dobutamine, epinephrine, norepinephrine, vasopressin), and corticosteroids. Hypotension in some infants weighing <1,000 g does not respond to fluids or inotropic agents but may respond to therapy with intravenous hydrocortisone. Sudden onset of hypotension in a very-low birthweight infant suggests pneumothorax, intraventricular hemorrhage, or subcapsular hepatic hematoma.

Seizures (see Chapter 593.7) usually point to a disorder of the CNS and suggest hypoxic–ischemic encephalopathy, intracranial hemorrhage, cerebral anomaly, subdural effusion, meningitis, hypocalcemia, hypoglycemia, cerebral infarction, benign familial seizures, or, rarely, pyridoxine dependence, hyponatremia, hypernatremia, inborn errors of metabolism, or drug withdrawal. Seizures beginning in the delivery room or shortly thereafter may be the result of the unintentional injection of maternal local anesthetic into the fetus. Seizures may also result from hyponatremia and water intoxication in the infant after the administration of large amounts of hypotonic fluid to the mother shortly before and during delivery.

Table 98-1 Differential Diagnosis of Cyanosis in the Newborn
CENTRAL OR PERIPHERAL NERVOUS SYSTEM HYPOVENTILATION
Birth asphyxia
Intracranial hypertension, hemorrhage
Oversedation (direct or through maternal route)
Diaphragm palsy
Neuromuscular diseases
Seizures
RESPIRATORY DISEASE
Airway
Choanal atresia/stenosis
Pierre Robin syndrome
Intrinsic airway obstruction (laryngeal/bronchial/tracheal stenosis)
Extrinsic airway obstruction (bronchogenic cyst, duplication cyst, vascular compression)
Lung
Respiratory distress syndrome
Transient tachypnea
Meconium aspiration
Pneumonia (sepsis)
Pneumothorax
Congenital diaphragmatic hernia
Pulmonary hypoplasia
CARDIAC RIGHT-TO-LEFT SHUNT
Abnormal connections (pulmonary blood flow normal or increased)
Transposition of great vessels
Total anomalous pulmonary venous return
Truncus arteriosus
Hypoplastic left heart syndrome
Single ventricle or tricuspid atresia with large ventricular septal defect but without pulmonic stenosis
Obstructed pulmonary blood flow (pulmonary blood flow decreased)
Pulmonic atresia with intact ventricular septum
Tetralogy of Fallot
Critical pulmonic stenosis with patent foramen ovale or atrial septal defect
Tricuspid atresia
Single ventricle with pulmonic stenosis
Ebstein malformation of the tricuspid valve
Persistent fetal circulation (persistent pulmonary hypertension of newborn)
METHEMOGLOBINEMIA
Congenital (hemoglobin M, methemoglobin reductase deficiency)
Acquired (nitrates, nitrites)
Inadequate ambient O_2 or less O_2 delivered than expected (rare)
Disconnection of O_2 supply to nasal cannula, head hood
Connection of air, rather than O_2, to a mechanical ventilator
SPURIOUS/ARTIFACTUAL
Oximeter artifact (poor contact between probe and skin, poor pulse searching)
Arterial blood gas artifact (contamination with venous blood)
OTHER
Hypoglycemia
Adrenogenital syndrome
Polycythemia
BLOOD LOSS

From Smith F: Cyanosis. In Kliegman RM: Practical strategies in pediatric diagnosis and therapy, *Philadelphia, 1996, WB Saunders.*

Seizures should be distinguished from the jitteriness that may be present in normal newborns, in infants of diabetic mothers, in those who experienced birth asphyxia or drug withdrawal, and in polycythemic neonates. An examiner may stop the jitteriness resembling simple tremors by holding the infant's extremity; this jitteriness often depends on sensory stimuli and occurs when the infant is active, and it is not associated with abnormal eye movements. Tremors are often more rapid with a smaller amplitude than those of tonic-clonic seizures. Seizures in premature infants are often subtle and associated with abnormal eye (fluttering, deviation, stare) or facial (chewing, tongue thrusting) movements; the motor component is often that of tonic extension of the limbs, neck, and trunk. Term infants may have focal or multifocal, clonic or myoclonic movements, but they may also have more subtle seizure activity. Apnea may be the first manifestation of seizure activity, particularly in a premature infant. Seizures may adversely affect the subsequent neurodevelopmental outcome and may even predispose an infant to nonneonatal seizures. Seizures should be treated aggressively.

After severe birth asphyxia, infants may have **motor automatisms** characterized by oral-buccal-lingual movements, rotary limb activities (rowing, pedaling, swimming), tonic posturing, or myoclonus. These motor activities are not usually accompanied by time-synchronized electroencephalographic discharges, may not signify cortical epileptic activity, respond poorly to anticonvulsant therapy, and are associated with a poor prognosis. Such automatisms may represent cortical depression that produces a brainstem release phenomenon or subcortical seizures.

Lethargy may be a manifestation of infection, asphyxia, hypoglycemia, hypercapnia, sedation from maternal analgesia or anesthesia, a cerebral defect, or, indeed, almost any severe disease, including an inborn error of metabolism. Lethargy appearing after the 2nd day should, in particular, suggest infection. Lethargy with emesis suggests increased intracranial pressure or an inborn error of metabolism.

Irritability may be a sign of discomfort accompanying intraabdominal conditions, meningeal irritation, drug withdrawal, infections, congenital glaucoma, or any condition producing pain. As in later infancy, the eardrums should always be examined as a possible source of pain. Hyperactivity, especially in a premature infant, may be a sign of hypoxia, pneumothorax, emphysema, hypoglycemia, hypocalcemia, CNS damage, drug withdrawal, neonatal thyrotoxicosis, bronchospasm, esophageal reflux, or discomfort from a cold environment.

Failure to feed well is seen in most sick newborn infants and should lead a careful search for infection, a central or peripheral nervous system disorder, intestinal obstruction, and other abnormal conditions.

Fever may be the result of too high an environmental temperature because of weather, overheated nurseries or incubators/radiant warmers, or too many clothes. It is also noted in "dehydration fever" of newborn infants. If these causes of fever can be eliminated, serious infection (pneumonia, bacteremia, meningitis, and viral infections, particularly herpes simplex or enteroviruses) must be considered, although such infections often occur without provoking a febrile response in newborn infants (see Chapters 176 and 177). Unexplained **hypothermia** may accompany infection or other serious disturbances of the circulation or CNS. A sudden servocontrolled increase in incubator ambient temperature to maintain body temperature is a sign of temperature instability and may be associated with sepsis or any of the conditions already mentioned.

Periods of **apnea**, particularly in premature infants, may be associated with various disturbances (see Chapter 101.2). When apnea recurs, or when the intervals are longer than 20 sec, or are associated with cyanosis or bradycardia, an immediate diagnostic evaluation is needed.

Jaundice during the 1st 24 hr of life warrants diagnostic evaluation and should be considered to be due to hemolysis until proven otherwise. Septicemia and intrauterine infections, such as syphilis, cytomegalovirus, and toxoplasmosis, should also be considered, especially in infants with an increase in direct bilirubin value.

Jaundice after the 1st 24 hr may be "physiologic" or may be caused by septicemia, hemolytic anemia, galactosemia, hepatitis, congenital atresia of the bile ducts, inspissated bile syndrome after erythroblastosis fetalis, syphilis, herpes simplex, other congenital infections, or other conditions (see Chapter 102.3).

Vomiting during the 1st day of life suggests obstruction in the upper digestive tract or increased intracranial pressure. Roentgenographic studies are indicated when obstruction is suspected. Vomiting may also be a nonspecific symptom of an illness such as septicemia. It is a common manifestation of overfeeding, inexperienced feeding technique, or normal reflux and is rarely caused by pyloric stenosis, milk allergy, duodenal ulcer, stress ulcer, an inborn error of metabolism

Table 98-2 Pain in the Neonate: General Considerations

- Pain in newborns is often unrecognized and/or undertreated.
- If a procedure is painful in adults, it should be considered painful in newborns.
- Healthcare institutions should develop and implement patient care policies to assess, prevent, and manage pain in neonates.
- Pharmacologic agents with known pharmacokinetic and pharmacodynamic properties and demonstrated efficacy in neonates should be used. Agents known to compromise cardiorespiratory function should be administered only by persons experienced in neonatal airway management and in settings with the capacity for continuous monitoring.
- Educational programs to increase the skills of healthcare professionals in the assessment and management of stress and pain in neonates should be provided.
- Further research is needed to develop and validate neonatal pain assessment tools that are useful in the clinical setting; to determine optimal behavioral and pharmacologic interventions; and to study long-term effects of pain and pain management.

Table 98-3 Common Life-Threatening Congenital Anomalies

NAME	MANIFESTATIONS
Choanal atresia	Respiratory distress in delivery room, nasogastric tube cannot be passed through nares Suspect CHARGE (coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies) syndrome
Pierre Robin syndrome Stickler syndrome	Micrognathia, cleft palate, airway obstruction
Diaphragmatic hernia	Scaphoid abdomen, bowel sounds present in chest, respiratory distress
Tracheoesophageal fistula	Polyhydramnios, aspiration pneumonia, excessive salivation, nasogastric tube cannot be placed in stomach Suspect VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) syndrome
Intestinal obstruction: volvulus, duodenal atresia, ileal atresia	Polyhydramnios, bile-stained emesis, abdominal distention Suspect trisomy 21, cystic fibrosis, cocaine
Gastroschisis, omphalocele	Polyhydramnios, intestinal obstruction
Renal agenesis, Potter syndrome	Oligohydramnios, anuria, pulmonary hypoplasia, pneumothorax
Neural tube defects: anencephalus, meningomyelocele	Polyhydramnios, elevated α-fetoprotein, decreased fetal activity
Ductus-dependent congenital heart disease	Cyanosis, hypotension, murmur

(hyperammonemia, metabolic acidosis), or adrenal insufficiency. Vomitus containing dark blood is usually a sign of a serious illness; the benign possibility of swallowed maternal blood should also be considered. Bile-stained vomitus strongly suggests obstruction below the ampulla of Vater and warrants contrast-enhanced radiography in many cases.

Diarrhea may be a symptom of overfeeding (especially high–caloric density formula), acute gastroenteritis, or malabsorption, or it may be a nonspecific symptom of infection. Diarrhea may occur in conditions accompanied by compromised circulation of part of the intestinal or genital tract, such as mesenteric thrombosis, necrotizing enterocolitis, strangulated hernia, intussusception, and torsion of the ovary or testis.

Abdominal distention, usually a sign of intestinal obstruction or an intraabdominal mass, may also be seen in infants with enteritis, necrotizing enterocolitis, isolated intestinal perforation, ileus accompanying sepsis, respiratory distress, ascites, or hypokalemia.

Failure to move an extremity **(pseudoparalysis)** suggests fracture, dislocation, or nerve injury. It is also seen in osteomyelitis and other infections that cause pain on movement of the affected part.

Pain in neonates may be unrecognized and/or undertreated. The intensive care of neonates may involve a number of painful procedures, including blood sampling (heelstick, venous or arterial puncture), endotracheal intubation and suctioning, mechanical ventilation, and insertion of chest tubes and intravascular catheters. Pain in neonates results in obvious distress and acute physiologic stress responses, which may have developmental implications for pain in later life. Moreover, the knowledge that infants may experience pain contributes to the stress of parents of sick newborns.

Pain and discomfort are potentially avoidable problems during the treatment of sick infants. Preemptive relief from painful stimuli should be provided before pain or anxiety develops. The most frequently used drugs are intermittent or continuous doses of opioids (morphine, fentanyl) and benzodiazepines (midazolam, lorazepam). Although the long-term effects of opioids and sedatives are not well established, the first concern should be the treatment and/or prevention of acute pain. Continuous opiate infusions should be used with caution. Some minor but painful procedures performed in well neonates can be managed with oral sucrose solutions (Table 98-2).

CONGENITAL ANOMALIES

Congenital anomalies are a major cause of stillbirths and neonatal deaths. In the United States and other developed countries, congenital anomalies are one of the main causes of neonatal mortality. In addition, congenital anomalies are a major cause of acute illness and long-term morbidity. Anomalies are discussed in general in Chapters 81 and 108, and specifically in the chapters on the various systems of the body. Early recognition of anomalies is important for planning care; with some, such as congenital heart disease, tracheoesophageal fistula, diaphragmatic hernia, choanal atresia, and intestinal obstruction, immediate medical and/or surgical therapy is essential for survival (Table 98-3). Parents are likely to feel anxious and guilty upon learning of the existence of a congenital anomaly and require sensitive counseling.

Chapter 99

Nervous System Disorders

Waldemar A. Carlo and Namasivayam Ambalavanan

Central nervous system (CNS) disorders are important causes of neonatal mortality and both short- and long-term morbidity. The CNS can be damaged as a result of asphyxia, hemorrhage, trauma, hypoglycemia, or direct cytotoxicity. The etiology of CNS damage is often multifactorial and includes perinatal complications, postnatal hemodynamic instability, and developmental abnormalities that may be genetic and/or environmental. Predisposing factors for brain injury include chronic and acute maternal illness resulting in uteroplacental dysfunction, intrauterine infection, macrosomia/dystocia, malpresentation, prematurity, and intrauterine growth restriction. Acute and often unavoidable emergencies during the delivery process sometimes result in mechanical and/or hypoxic–ischemic brain injury.

99.1 The Cranium

Waldemar A. Carlo and Namasivayam Ambalavanan

Erythema, abrasions, ecchymoses, and subcutaneous fat necrosis of facial or scalp soft tissues may be noted after a normal delivery or after forceps or vacuum-assisted deliveries. Their location depends on the area of contact with the pelvic bones or of application of the forceps. Traumatic hemorrhage may involve any layer of the scalp as well as intracranial contents (Fig. 99-1).

Caput succedaneum is a diffuse, sometimes ecchymotic, edematous swelling of the soft tissues of the scalp involving the area presenting during vertex delivery (see Fig. 99-1). It may extend across the midline and across suture lines. The edema disappears within the 1st few days of life. Molding of the head and overriding of the parietal bones are frequently associated with caput succedaneum and become more evident after the caput has receded; they disappear during the 1st few wk of life. Rarely, a hemorrhagic caput may result in shock and require blood transfusion. Analogous swelling, discoloration, and distortion of the face are seen in face presentations. No specific treatment is needed, but if extensive ecchymoses are present, hyperbilirubinemia may develop.

Cephalohematoma (Fig. 99-2) is a subperiosteal hemorrhage, hence always limited to the surface of 1 cranial bone. Cephalohematomas occur in 1-2% of live births. No discoloration of the overlying scalp occurs, and swelling is not usually visible for several hours after birth because subperiosteal bleeding is a slow process. The lesion becomes a firm tense mass with a palpable rim localized over 1 area of the skull. Most cephalohematomas are resorbed within 2 wk-3 mo, depending on their size. They may begin to calcify by the end of the 2nd wk. A few remain for years as bony protuberances and are detectable on radiographs as widening of the diploic space; cystlike defects may persist for months or years. An underlying skull fracture, usually linear and not depressed, may be associated with 10-25% of cases. A sensation of central depression suggesting but not indicative of an underlying fracture or bony defect is usually encountered on palpation of the organized rim of a cephalohematoma. Cephalohematomas require no treatment, although phototherapy may be necessary to treat hyperbilirubinemia. Infection of the hematoma is a very rare complication.

A **subgaleal hemorrhage** is a collection of blood beneath the aponeurosis that covers the scalp and serves as the insertion for the occipitofrontalis muscle. Bleeding can be very extensive into this large potential space and may even dissect into the subcutaneous tissues of the neck. There is often an association with vacuum-assisted delivery. The mechanism of injury is most likely secondary to rupture of emissary veins connecting the dural sinuses within the skull with the superficial veins of the scalp, sometimes associated with skull fractures, suture diastasis, and fragmentation of the superior margin of the parietal bone. Extensive subgaleal bleeding is occasionally secondary to a hereditary coagulopathy (hemophilia). A subgaleal hemorrhage manifests as a fluctuating mass that straddles cranial sutures or fontanels that increases in size after birth. Some patients have a consumptive coagulopathy owing to massive blood loss. Patients should be monitored for hypotension, anemia, and the development of hyperbilirubinemia. These lesions typically resolve over 2-3 wk.

Fractures of the skull may occur as a result of pressure from forceps or from the maternal symphysis pubis, sacral promontory, or ischial spines. Linear fractures, the most common, cause no symptoms and require no treatment. Depressed fractures are usually indentations of the calvaria similar to the dents in a ping-pong ball; they are generally a complication of forceps delivery or fetal compression. Affected infants may be asymptomatic unless they have associated intracranial injury; it is advisable to elevate severe depressions to prevent cortical injury from sustained pressure. Although some may elevate spontaneously, some require treatment. Percutaneous microscrew elevation is one method successfully used to elevate depressed skull fractures. Fracture of the occipital bone with separation of the basal and squamous portions frequently causes fatal hemorrhage because of disruption of the underlying vascular sinuses. Such fractures may result

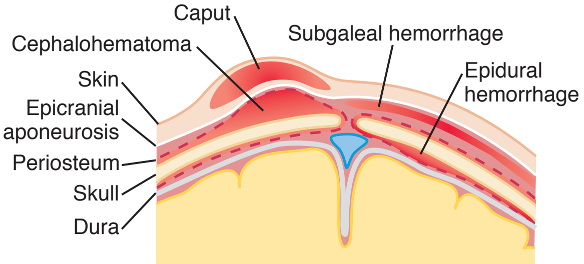

Figure 99-1 Sites of extracranial (and extradural) hemorrhages in the newborn. Schematic diagram of important tissue planes from skin to dura. *(From Volpe JJ:* Neurology of the newborn, *ed 4, Philadelphia, 2001, WB Saunders.)*

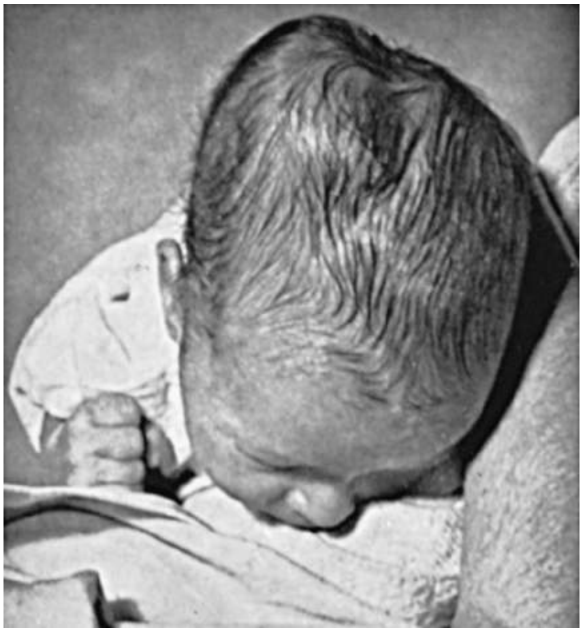

Figure 99-2 Cephalohematoma of the right parietal bone.

during breech deliveries from traction on the hyperextended spine of the infant while the head is fixed in the maternal pelvis.

Subconjunctival and **retinal hemorrhages** are frequent; petechiae of the skin of the head and neck are also common. All are probably secondary to a sudden increase in intrathoracic pressure during passage of the chest through the birth canal. Parents should be assured that these hemorrhages are temporary and the result of normal events of delivery. The lesions resolve rapidly within the 1st 2 wk of life.

99.2 Traumatic, Epidural, Subdural, and Subarachnoid Hemorrhage

Waldemar A. Carlo and Namasivayam Ambalavanan

Traumatic **epidural, subdural, or subarachnoid hemorrhage** is especially likely when the fetal head is large in proportion to the size of the mother's pelvic outlet, with prolonged labor, in breech or precipitous deliveries, or as a result of mechanical assistance with delivery. Asymptomatic subdural hemorrhage may be noted within 48 hr of birth after vaginal or cesarean delivery. Massive **subdural hemorrhage**, often associated with tears in the tentorium cerebelli or, less frequently, in the falx cerebri, is rare but is encountered more often in full-term than in premature infants. Patients with massive hemorrhage caused by tears of the tentorium or falx cerebri rapidly deteriorate and may die soon after birth. The majority of **subdural and epidural hemorrhages** resolve without intervention; consultation with a neurosurgeon is recommended. The diagnosis of subdural hemorrhage may be delayed until the chronic subdural fluid volume expands and produces megalocephaly, frontal bossing, a bulging fontanel, anemia, and, sometimes, seizures. CT scan and MRI are useful imaging techniques to confirm these diagnoses. Symptomatic subdural hemorrhage in large term infants should be treated by removal of the subdural fluid collection with a needle placed through the lateral margin of the anterior fontanel. In addition to birth trauma, **child abuse** must be suspected in all infants with subdural effusion after the immediate neonatal period; asymptomatic subdural hemorrhages following labor should resolve by 4 wk of age.

Subarachnoid hemorrhage is rare and typically is clinically silent. The anastomoses between the penetrating leptomeningeal arteries or the bridging veins are the most likely source of the bleeding. The majority of affected infants have no clinical symptoms, but the subarachnoid hemorrhage may be detected because of an elevated number of red blood cells in a lumbar puncture sample. Some infants experience benign seizures, which tend to occur on the 2nd day of life. Rarely, an infant has a life-threatening catastrophic hemorrhage and dies. There are usually no neurologic abnormalities during the acute episode or on follow-up. Significant neurologic findings should suggest an arteriovenous malformation; this lesion can easily be detected on CT or MRI; ultrasonography is a less-sensitive tool.

99.3 Intracranial–Intraventricular Hemorrhage and Periventricular Leukomalacia

Waldemar A. Carlo and Namasivayam Ambalavanan

ETIOLOGY

Intracranial hemorrhage usually develops spontaneously; less commonly, it may be caused by trauma or asphyxia, and rarely, it occurs from a primary hemorrhagic disturbance or congenital vascular anomaly. Intracranial hemorrhage often involves the ventricles (**intraventricular hemorrhage** [IVH]) of premature infants delivered spontaneously without apparent trauma. Primary hemorrhagic disturbances and vascular malformations are rare and usually give rise to subarachnoid or intracerebral hemorrhage. In utero hemorrhage associated with maternal idiopathic or, more often, fetal alloimmune thrombocytopenia may occur as severe cerebral hemorrhage or a porencephalic cyst after resolution of a fetal cortical hemorrhage. Intracranial bleeding may be associated with disseminated intravascular coagulopathy, isoimmune thrombocytopenia, and neonatal vitamin K deficiency, especially in infants born to mothers receiving phenobarbital or phenytoin.

EPIDEMIOLOGY

The overall incidence of IVH has decreased over the past decades as a result of improved perinatal care and increased use of antenatal corticosteroids, surfactant to treat respiratory distress syndrome (RDS), and, possibly, prophylactic indomethacin; however, it continues to be an important cause of morbidity in preterm infants. Approximately 30% of premature infants <1,500 g have IVH. The risk is inversely related to gestational age and birthweight, with the smallest and most immature infants being at the highest risk; 7% of infants weighing 1,001-1,500 g have a severe IVH (grade III or IV), compared with 14% of infants weighing 751-1,000 g and 24% of infants weighing ≤750 g. In 3% of infants weighing <1,000 g, **periventricular leukomalacia (PVL)** develops.

PATHOGENESIS

The major neuropathologic lesions associated with very-low-birthweight (VLBW) infants are IVH and PVL. IVH in premature infants occurs in the gelatinous subependymal germinal matrix. This periventricular area is the site of origin for embryonal neurons and fetal glial cells, which migrate outwardly to the cortex. Immature blood vessels in this highly vascular region of the developing brain combined with poor tissue vascular support predispose premature infants to hemorrhage. The germinal matrix involutes as the infant approaches full-term gestation and the tissue's vascular integrity improves; therefore IVH is much less common in the term infant. **Periventricular hemorrhagic infarction** often develops after a large IVH owing to venous congestion. Predisposing factors for IVH include prematurity, RDS, hypoxic–ischemic or hypotensive injury, reperfusion injury of damaged vessels, increased or decreased cerebral blood flow, reduced vascular integrity, increased venous pressure, pneumothorax, thrombocytopenia, hypervolemia, and hypertension.

Understanding of the pathogenesis of PVL is evolving, and it appears to involve both intrauterine and postnatal events. A complex interaction exists between the development of the cerebral vasculature and the regulation of cerebral blood flow (both of which are gestational age-dependent), disturbances in the oligodendrocyte precursors required for myelination, and maternal/fetal infection and/or inflammation. Similar factors (hypoxia–ischemia), venous obstruction from an IVH, or undetected fetal stress may result in decreased perfusion to the brain, leading, in turn, to periventricular hemorrhage and necrosis. PVL is characterized by focal necrotic lesions in the periventricular white matter and/or more diffuse white matter damage. The risk for PVL increases in infants with severe IVH and/or ventriculomegaly. The corticospinal tracts descend through the periventricular white matter, hence the association between cerebral white matter injury/PVL and motor abnormalities, including cerebral palsy.

CLINICAL MANIFESTATIONS

The majority of patients with IVH, including some with moderate to severe hemorrhages, have no initial clinical signs. Some premature infants in whom severe IVH develops may have acute deterioration on the 2nd or 3rd day of life. Hypotension, apnea, pallor, or cyanosis; poor suck; abnormal eye signs; a high-pitched, shrill cry; convulsions, or decreased muscle tone; metabolic acidosis; shock; and a decreased hematocrit or failure of the hematocrit to increase after transfusion may be the first clinical indications. IVH may rarely manifest at birth; 50% of cases are diagnosed within the 1st day of life, and up to 75% within the 1st 3 days. A small percentage of infants have late hemorrhage, between days 14 and 30. IVH as a primary event is rare after the 1st mo of life.

PVL is usually clinically asymptomatic until the neurologic sequelae of white matter damage become apparent in later infancy as spastic motor deficits. PVL may be present at birth but usually occurs later as

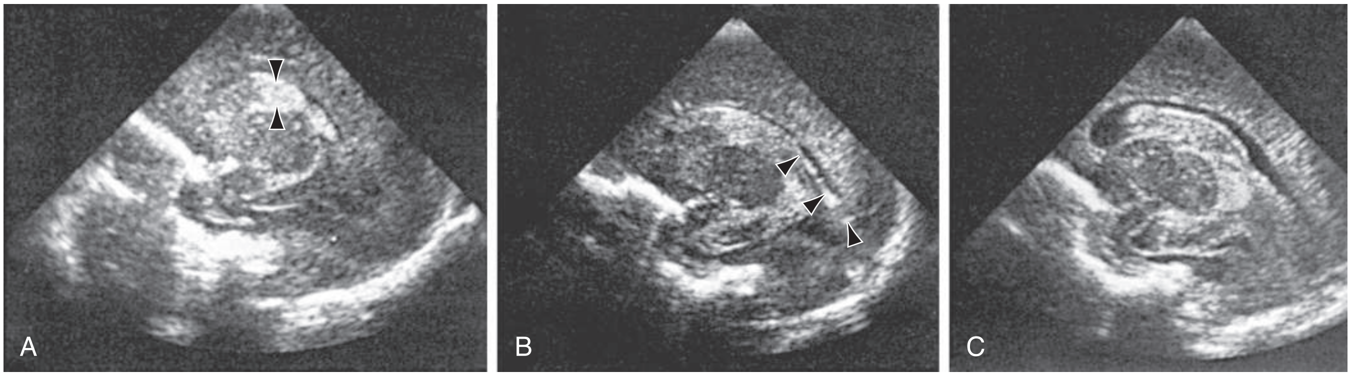

Figure 99-3 Grading the severity of germinal matrix intraventricular hemorrhage with parasagittal ultrasound scans. *A,* Grade I: Note the echogenic blood in the germinal matrix *(arrowheads)* just anterior to the anterior tip of the choroid plexus, which (normally) is also echogenic. *B,* Grade II: Note the echogenic blood *(arrowheads)* filling <50% of the ventricular area. *C,* Grade III: Note the large blood clot nearly completely filling and distending the entire lateral ventricle. *(From Intracranial hemorrhage: germinal matrix-intraventricular hemorrhage of the premature infant. In Volpe JJ:* Neurology of the newborn, *ed 4, Philadelphia, 2001, WB Saunders.)*

an early echodense phase (3-10 days of life), followed by the typical echolucent (cystic) phase (14-20 days of life).

The severity of hemorrhage may be defined on cranial imaging by the location and degree of bleeding and ventricular dilation. In a **grade I** hemorrhage, bleeding is isolated to the subependymal area. In **Grade II** hemorrhage, there is bleeding within the ventricle but without evidence of ventricular dilation. **Grade III** hemorrhage consists of IVH with ventricular dilation. In **Grade IV** hemorrhage, there is intraventricular and parenchymal hemorrhage. Another grading system describes 3 levels of increasing severity of IVH detected on ultrasound: In **grade I,** bleeding is confined to the germinal matrix–subependymal region or to <10% of the ventricle (≈35% of IVH cases); **grade II** is defined as intraventricular bleeding with 10-50% filling of the ventricle (≈40% of IVH cases) and in **grade III**, more than 50% of the ventricle is involved, with dilated ventricles (Fig. 99-3). **Ventriculomegaly** is defined as mild (0.5-1 cm dilation), moderate (1.0-1.5 cm dilation), or severe (>1.5 cm dilation).

DIAGNOSIS

Intracranial hemorrhage is suspected on the basis of the history, clinical manifestations, and knowledge of the birthweight-specific risks for IVH. The associated clinical signs of IVH are typically nonspecific or absent; therefore, it is recommended that premature infants <32 wk of gestation be evaluated with routine real-time cranial ultrasonography through the anterior fontanel to screen for IVH. Infants <1,000 g are at highest risk and should undergo cranial ultrasonography within the 1st 3-7 days of age, when approximately 75% of lesions will be detectable. Ultrasonography is the preferred imaging technique for screening because it is noninvasive, portable, reproducible, and sensitive and specific for detection of IVH. All at-risk infants should undergo follow-up ultrasonography at 36-40 wk of postmenstrual age to evaluate adequately for PVL, because cystic changes related to perinatal injury may not be visible for at least 2-4 wk. In one study, 29% of low-birthweight (LBW) infants who later experienced cerebral palsy did not have radiographic evidence of PVL until after 28 days of age. Ultrasonography also detects the precystic and cystic symmetric lesions of PVL and the asymmetric intraparenchymal echogenic lesions of cortical hemorrhagic infarction. Furthermore, the delayed development of cortical atrophy, porencephaly, and the severity, progression, or regression of posthemorrhagic hydrocephalus can be determined by serial ultrasonographic examinations.

Approximately 3-5% of VLBW infants develop **posthemorrhagic hydrocephalus (PHH)** that sometimes requires ventriculoperitoneal shunt insertion; if the initial ultrasonography findings are abnormal, additional interval ultrasonographic studies are indicated to monitor for the development of hydrocephalus.

IVH represents only 1 facet of brain injury in the term or preterm infant. MRI is a more sensitive tool for evaluation of extensive periventricular injury and may be more predictive of adverse long-term outcome. CT or, more reliably, diffusion-weighted MRI is indicated for term infants in whom brain injury or stroke is suspected, because ultrasonography may not reveal edema or intraparenchymal hemorrhage and infarction.

PROGNOSIS

The degree of IVH and the presence of PVL are strongly linked to neurodevelopmental impairment. For infants with a birthweight of <1,000 g, the incidences of severe neurologic impairment (defined as Bayley Scales of Infant Development II mental developmental index <70, psychomotor development index <70, cerebral palsy, blindness, or deafness) are approximately 50%, 55%, and 70% for infants with grade II, grade III, and grade IV IVH, respectively (Table 99-1). In contrast, the rate of neurodevelopmental impairment is approximately 40% in infants (weighing <1,000 g) without IVH and those with grade I IVH. PVL, cystic PVL, and progressive hydrocephalus requiring shunt insertion are each independently associated with a poorer prognosis.

Most infants with IVH and acute ventricular distention do not have **PHH.** Ten percent to 15% of LBW neonates with IVH demonstrate PHH, which may initially be present without clinical signs, such as an enlarging head circumference, lethargy, a bulging fontanel or widely split sutures, apnea, and bradycardia. In infants in whom symptomatic hydrocephalus develops, clinical signs may be delayed 2-4 wk despite progressive ventricular distention with compression and thinning of the cerebral cortex. Many infants with PHH have spontaneous regression; 3-5% of VLBW infants with PHH require shunt insertion. Infants with PHH requiring shunt insertion have lower cognitive and psychomotor performance at 18-22 mo.

PREVENTION

Improved perinatal care is imperative to minimize traumatic brain injury and decrease the risk of preterm delivery. The incidence of traumatic intracranial hemorrhage may be reduced by judicious management of cephalopelvic disproportion and operative (forceps, vacuum) delivery. Fetal or neonatal hemorrhage caused by maternal idiopathic thrombocytopenic purpura or alloimmune thrombocytopenia may be reduced by maternal treatment with steroids, intravenous immunoglobulin, fetal platelet transfusion, or cesarean section. Meticulous care of the LBW infant's respiratory status and fluid and electrolyte management—including avoidance of acidosis, hypocarbia, hypoxia, hypotension, wide fluctuations in neonatal blood pressure or P_{CO_2}, and pneumothorax—are important factors that may affect the risk for development of IVH and PVL.

A single course of antenatal corticosteroids is recommended in pregnancies 24-34 wk of gestation that are at risk for preterm delivery. Antenatal steroids decrease the risk of death, grades III and IV IVH,

Table 99-1 Percentage of Infants with Each Neurologic Outcome at 18 to 22 Mo Corrected Age by Head Ultrasound Findings*

HEAD ULTRASOUND VARIABLE	NDI (N = 929)	MDI > 70 (N = 174)	PDI < 70 (N = 478	CEREBRAL PALSY (N = 478)	BLINDNESS (N = 66)	DEAFNESS (N = 42)	NONINDEPENDENT WALKING (N = 260)	NONINDEPENDENT FEEDING (N = 318)
Normal (n = 1308)	39.4	31.9	18.8	10.1	1.6	1.5	7.7	12.8
Intracranial hemorrhage:								
Grade 1 (n = 244)	40.6	31.5	18.0	17.2	2.9	1.2	10.7	13.9
Grade 2 (n = 151)	51.0	36.9	22.3	17.2	4.0	3.3	9.3	13.9
Grade 3 (n = 215)	55.4	43.3	36.7	31.3	7.0	2.8	25.1	23.4
Grade 4 (n = 145)	69.7	52.6	55.5	51.4	11.2	4.9	42.4	28.5
Periventricular leukomalacia (n = 134)	72.4	60.3	52.8	50.0	10.5	3.7	44.0	29.1
Cystic periventricular leukomalacia (n = 50)	76.0	60.4	64.6	64.0	18.0	6.3	50.0	32.0

*All infants were counted only once and were assigned the highest grade of intracranial hemorrhage/leukomalacia from either head ultrasound scan. Missing values in either the row or column variable were excluded from the analysis.

MDI, Mental Developmental Index; NDI, neurodevelopment impairment; PDI, Psychomotor Developmental Index.

Data from Broitman E, Ambalavanan N, Higgins RD, et al: Clinical data predict neurodevelopmental outcome better than head ultrasound in extremely low birth weight infants, J Pediatr *151:500–505, 2007.*

and PVL in the neonate. The prophylactic administration of low-dose indomethacin (0.1 mg/kg/day for 3 days) to VLBW preterm infants reduces the incidence of severe IVH.

TREATMENT

Although no treatment is available for IVH, it may be associated with other complications that require therapy. Seizures should be treated with anticonvulsant drugs. Anemia and coagulopathy require transfusion with packed red blood cells or fresh-frozen plasma. Shock and acidosis are treated with the judicious and slow administration of sodium bicarbonate and fluid resuscitation.

Insertion of a ventriculoperitoneal shunt is the preferred method to treat progressive and symptomatic PHH; some infants require temporary cerebrospinal fluid diversion before a permanent shunt can be safety inserted. Diuretics and acetazolamide are not effective. Serial lumbar punctures, ventricular taps or reservoirs, and externalized ventricular drains are potential temporizing interventions; they have an associated risk of infection and of "puncture porencephaly" owing to injury to the surrounding parenchyma. A ventriculosubgaleal shunt inserted from the ventricle into a surgically created subgaleal pocket provides a closed system for constant ventricular decompression without these additional risk factors. Decompression is regulated by the pressure gradient between the ventricle and the subgaleal pocket.

99.4 Brain Injury from Inflammation, Infection, and Medications

Waldemar A. Carlo and Namasivayam Ambalavanan

Severe IVH and PVL are the most commonly associated risk factors for adverse outcome in the VLBW infant. Other factors are also involved in the etiology of perinatal brain injury. Cytokines and

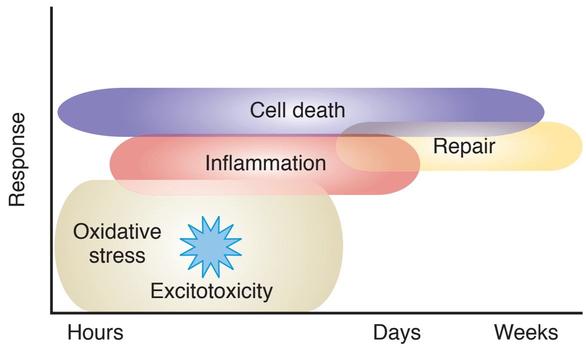

Figure 99-4 **Mechanisms of brain injury in the term neonate.** Oxidative stress and excitotoxicity, through downstream intracellular signaling, produce both inflammation and repair. Cell death begins immediately and continues during a period of days to weeks. The cell-death phenotype changes from an early necrotic morphology to a pathology resembling apoptosis. This evolution is called the necrosis-apoptosis continuum. *(From Ferriero DM: Neonatal brain injury,* N Engl J Med *351:1985–1995, 2004.Copyright © 2004 Massachusetts Medical Society. All rights reserved.)*

prenatal or postnatal infection or inflammation may contribute to brain injury. A systemic inflammatory response syndrome in the mother, fetus, or infant may induce the production of various inflammatory mediators that are directly cytotoxic or cause decreased CNS perfusion (Fig. 99-4). Preterm infants with evidence (often subclinical) of intrauterine or postnatal infection or maternal chorioamnionitis are more likely than uninfected infants to have adverse neurodevelopmental outcome including cerebral palsy.

In utero infections may involve the developing CNS and directly impair cell growth or produce cell neurosis, resulting in microcephaly, developmental delay, mental retardation, or cerebral palsy. These specific congenital or perinatal acquired infections include those caused by cytomegalovirus (see Chapter 255), toxoplasmosis (see Chapter

290), herpes simplex (see Chapter 252), syphilis (see Chapter 218), rubella (see Chapter 247), and human immunodeficiency virus (see Chapter 276). Postnatal acquired bacterial meningitis in the 1st yr, but even more so in the 1st mo of life, is another major risk factor for CNS injury and associated adverse neurodevelopmental outcome (see Chapter 603).

Long-term adverse neurodevelopmental outcomes are also associated with high-dose postnatal corticosteroid use in VLBW infants. Early postnatal exposure to dexamethasone, within the 1st wk of life, is associated with metabolic derangements, poor growth, increased risk for sepsis, and an increased risk of spontaneous bowel perforation. Infants exposed to postnatal steroids after the 1st wk of life have an increased risk of cerebral palsy and developmental delay. The risk may be increased with prolonged steroid use (>6 wk). At 8 yr of age, dexamethasone-treated children are smaller, have smaller head circumferences, poorer motor skills and coordination, more difficulty with visual motor integration, and lower full-scale verbal IQ and performance IQ scores. It is recommended that postnatal corticosteroid use in VLBW infants be limited to exceptional clinical circumstances and that parents of infants in whom corticosteroids are used be informed of the potential adverse side effects, including increased risk for developmental delay, cerebral palsy, and impaired growth.

Necrotizing enterocolitis (NEC) affects approximately 9-14% of LBW infants and is associated with significant morbidity and mortality (see Chapter 102.2). Patients with NEC requiring surgery are more likely to have Mental Developmental Index (MDI) scores <70, Psychomotor Developmental Index (PDI) scores <70, and evidence of overall neurodevelopmental impairment. Infants with severe NEC are reported to have a higher incidence of PVL, postnatal infections, and poor growth.

Bibliography is available at Expert Consult.

99.5 Hypoxic–Ischemic Encephalopathy

Namasivayam Ambalavanan and Waldemar A. Carlo

Anoxia is a term used to indicate the consequences of complete lack of oxygen as a result of a number of primary causes. **Hypoxemia** refers to decreased arterial concentration of oxygen. **Hypoxia** refers to a decreased oxygenation to cells or organs. **Ischemia** refers to blood flow to cells or organs that is insufficient to maintain their normal function. **Hypoxic–ischemic encephalopathy (HIE)** is an important cause of permanent damage to CNS tissues that may result in neonatal death or manifest later as cerebral palsy or developmental delay. Approximately 20-30% of infants with HIE die in the neonatal period, and ≈33-50% of survivors are left with permanent neurodevelopmental abnormalities (cerebral palsy, mental retardation). The greatest risk of adverse outcome is seen in infants with severe fetal acidosis (pH <6.7) (90% death/impairment) and a base deficit >25 mmol/L (72% mortality). Multiorgan failure and insult can occur (Table 99-2).

Table 99-2 Multiorgan Systemic Effects of Asphyxia

SYSTEM	EFFECT(S)
CNS	HIE, infarction, intracranial hemorrhage, seizures, cerebral edema, hypotonia, hypertonia
Cardiovascular	Myocardial ischemia, poor contractility, cardiac stunning, tricuspid insufficiency, hypotension
Pulmonary	Pulmonary hypertension, pulmonary hemorrhage, RDS
Renal	Acute tubular or cortical necrosis
Adrenal	Adrenal hemorrhage
Gastrointestinal	Perforation, ulceration with hemorrhage, necrosis
Metabolic	Inappropriate secretion of antidiuretic hormone, hyponatremia, hypoglycemia, hypocalcemia, myoglobinuria
Integument	Subcutaneous fat necrosis
Hematology	Disseminated intravascular coagulation

ETIOLOGY

Most neonatal encephalopathic or seizure disorders, in the absence of major congenital malformations or syndromes, appear to be caused by perinatal events. Brain MRI or autopsy findings in full-term neonates with encephalopathy demonstrate that 80% have acute injuries, <1% have prenatal injuries, and 3% have non–hypoxic-ischemic diagnoses. Fetal hypoxia may be caused by various disorders in the mother, including (1) inadequate oxygenation of maternal blood from hypoventilation during anesthesia, cyanotic heart disease, respiratory failure, or carbon monoxide poisoning; (2) low maternal blood pressure from acute blood loss, spinal anesthesia, or compression of the vena cava and aorta by the gravid uterus; (3) inadequate relaxation of the uterus to permit placental filling as a result of uterine tetany caused by the administration of excessive oxytocin; (4) premature separation of the placenta; (5) impedance to the circulation of blood through the umbilical cord as a result of compression or knotting of the cord; and (6) placental insufficiency from toxemia or postmaturity.

Placental insufficiency often remains undetected on clinical assessment. Intrauterine growth restriction may develop in chronically hypoxic fetuses without the traditional signs of fetal distress. Doppler umbilical waveform velocimetry (demonstrating increased fetal vascular resistance) and cordocentesis (demonstrating fetal hypoxia and lactic acidosis) identify a chronically hypoxic infant (see Chapter 96). Uterine contractions may further reduce umbilical oxygenation, depressing the fetal cardiovascular system and CNS and resulting in low Apgar scores and respiratory depression at birth.

After birth, hypoxia may be caused by (1) failure of oxygenation as a result of severe forms of cyanotic congenital heart disease or severe pulmonary disease; (2) severe anemia (severe hemorrhage, hemolytic disease); or (3) shock severe enough to interfere with the transport of oxygen to vital organs from overwhelming sepsis, massive blood loss, and intracranial or adrenal hemorrhage.

PATHOPHYSIOLOGY AND PATHOLOGY

The topography of injury typically correlates with areas of decreased cerebral blood flow. After an episode of hypoxia and ischemia, anaerobic metabolism occurs and generates increased amounts of lactate and inorganic phosphates. Excitatory and toxic amino acids, particularly glutamate, accumulate in the damaged tissue. Increased amounts of intracellular sodium and calcium may result in tissue swelling and cerebral edema. There is also increased production of free radicals and nitric oxide in these tissues. The initial circulatory response of the fetus is increased shunting through the ductus venosus, ductus arteriosus, and foramen ovale, with transient maintenance of perfusion of the brain, heart, and adrenals in preference to the lungs, liver, kidneys, and intestine.

The pathology of hypoxia–ischemia depends on the affected organ and the severity of the injury. Early congestion, fluid leak from increased capillary permeability, and endothelial cell swelling may then lead to signs of coagulation necrosis and cell death. Congestion and petechiae are seen in the pericardium, pleura, thymus, heart, adrenals, and meninges. Prolonged intrauterine hypoxia may result in inadequate perfusion of the periventricular white matter, resulting, in turn, in PVL. Pulmonary arteriole smooth muscle hyperplasia may develop, which predisposes the infant to pulmonary hypertension (see Chapter 101.7). If fetal distress produces gasping, the amniotic fluid contents (meconium, squames, lanugo) may be aspirated into the trachea or lungs.

The combination of chronic fetal hypoxia and acute hypoxic-ischemic injury around the time of birth results in gestational age–specific neuropathology (Table 99-3). Term infants demonstrate neuronal necrosis of the cortex (later, cortical atrophy) and parasagittal

Table 99-3 Topography of Brain Injury in Term Infants with HIE and Clinical Correlates

AREA OF INJURY	LOCATION OF INJURY	CLINICAL CORRELATE(S)	LONG-TERM SEQUELA(E)
Selective neuronal necrosis	Entire neuraxis, deep cortical area, brainstem and pontosubicular	Stupor or coma Seizures Hypotonia Oculomotor abnormalities Suck/swallow abnormalities	Cognitive delay Cerebral palsy Dystonia Seizure disorder Ataxia Bulbar and pseudobulbar palsy
Parasagittal injury	Cortex and subcortical white matter Parasagittal regions, especially posterior	Proximal limb weakness Upper extremities affected more than lower extremities	Spastic quadriparesis Cognitive delay Visual and auditory processing difficulty
Focal ischemic necrosis	Cortex and subcortical white matter Vascular injury (usually middle cerebral artery distribution)	Unilateral findings Seizures common and typically focal	Hemiparesis Seizures Cognitive delays
Periventricular injury	Injury to motor tracts, especially lower extremity	Bilateral and symmetric weakness in lower extremities More common in preterm infants	Spastic diplegia

Modified from Volpe JJ: Neurology of the newborn, *ed 4, Philadelphia, 2001, WB Saunders.*

ischemic injury. Preterm infants demonstrate PVL (later, spastic diplegia), status marmoratus of the basal ganglia, and IVH. Term more often than preterm infants have focal or multifocal cortical infarcts that manifest clinically as focal seizures and hemiplegia.

CLINICAL MANIFESTATIONS

Intrauterine growth restriction with increased vascular resistance may be the first indication of fetal hypoxia. During labor, the fetal heart rate slows and beat-to-beat variability declines. Continuous heart rate recording may reveal a variable or late deceleration pattern (see Fig. 96-4). Particularly in infants near term, these signs should lead to the administration of high concentrations of oxygen to the mother and consideration of immediate delivery to avoid fetal death and CNS damage.

At delivery, the presence of meconium-stained amniotic fluid indicates that fetal distress may have occurred. At birth, affected infants may be depressed and may fail to breathe spontaneously. During the ensuing hours, they may remain hypotonic or change from a hypotonic to a hypertonic state, or their tone may appear normal (Tables 99-4 and 99-5). Pallor, cyanosis, apnea, a slow heart rate, and unresponsiveness to stimulation are also signs of HIE. Cerebral edema may develop during the next 24 hr and result in profound brainstem depression. During this time, seizure activity may occur; it may be severe and refractory to the usual doses of anticonvulsants. Though most often a result of the HIE, seizures in asphyxiated newborns may also be a result of hypocalcemia, hypoglycemia, or infection.

In addition to CNS dysfunction, systemic organ dysfunction is noted in up to 80% of affected neonates; heart failure and cardiogenic shock, persistent pulmonary hypertension, RDS, gastrointestinal perforation, and acute kidney injury are associated with perinatal asphyxia secondary to inadequate perfusion (see Table 99-2).

The severity of neonatal encephalopathy depends on the duration and timing of injury. Symptoms develop over a series of days, making it important to perform serial neurologic examinations (see Tables 99-4 and 99-5). During the initial hours after an insult, infants have a depressed level of consciousness. Periodic breathing with apnea or bradycardia is present, but cranial nerve functions are often spared with intact pupillary responses and spontaneous eye movement. Seizures are common with extensive injury. Hypotonia is also common as an early manifestation.

DIAGNOSIS

Diffusion-weighted MRI is the preferred imaging modality in neonates with HIE because of its increased sensitivity and specificity early in the process and its ability to outline the topography of the lesion (Figs. 99-5 to 99-8, Table 99-6). CT scans are helpful in identifying focal hemorrhagic lesions, diffuse cortical injury, and damage to the basal ganglia; CT has limited ability to identify cortical injury during the 1st few days of life. Ultrasonography has limited utility in evaluation of hypoxic injury in the term infant; it is the initial preferred modality in evaluation of the preterm infant.

Table 99-4 Predictor Variables, Odds Ratios, and Scores Assigned to Each Variable for Death/Disability Scoring in Infants with HIE

VARIABLE	LEVEL OF VARIABLE	ODDS RATIO	SCORE*
Posture	Normal Distal flexion Decerebrate	0.037 0.401 1	1 11 27
Spontaneous activity	Normal/decreased None	0.147 1	1 7
Base deficit of first postnatal blood gas analysis	<15 mmol/L 15-22 mmol/L >22 mmol/L	0.073 0.304 1	1 4 14
Apgar score at 5 min	7-10 4-6 0-3	0.082 0.676 1	14 8 12
Chronic hypertension/ preeclampsia/eclampsia	Yes No	0.2 1	1 5

*The total score is obtained by adding the scores for each of the variables. Interpretation of the total score is as follows: <23: no death or moderate/severe disability even without hypothermia; 23-28: probable benefit from hypothermia; 29-52: possible benefit; >52: death/disability likely despite hypothermia. =172.

From Ambalavanan, N, Carlo WA, Shankaran S, et al; National Institute of Child Health and Human Development Neonatal Research Network: Predicting outcomes of neonates diagnosed with hypoxemic-ischemic encephalopathy, Pediatrics *118:2084–2093, 2006.*

Amplitude-integrated electroencephalography (aEEG) may help to determine which infants are at highest risk for long-term brain injury. A single-channel tracing is generated from 2 electrodes placed in the biparietal area. A filter is used to filter and attenuate the signal between 2 Hz and 15 Hz. This technique is simple to perform and correlates with standard electroencephalogram (EEG) It has good reliability, a positive predictive value of 85%, and a negative predictive value of 91-96% for infants who will have adverse neurodevelopmental outcome. The technique provides information quickly within the window during which intervention is most likely to be useful. Also, aEEG is able to detect seizure activity, which is common in patients

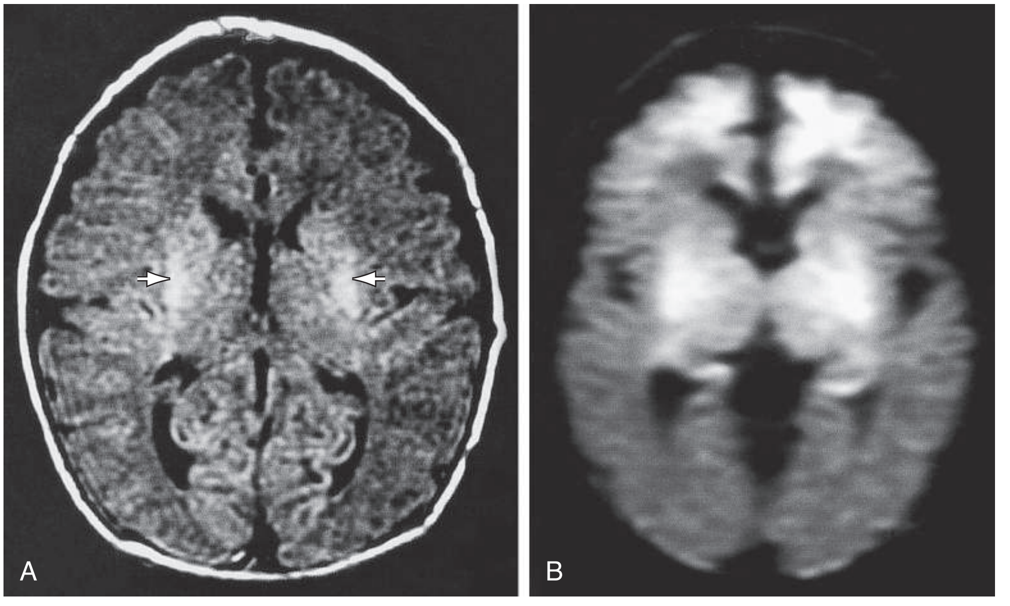

Figure 99-5 **MR images of selective neuronal injury.** The infant experienced intrapartum asphyxia and had seizures on the 1st postnatal day. MRI was performed on the 5th postnatal day. *A,* An axial, fluid-attenuated inversion recovery image shows increased signal in the putamen bilaterally *(arrows)* but no definite abnormality in the cerebral cortex. *B,* By contrast, a diffusion-weighted image shows striking increased signal intensity (i.e., decreased diffusion) in the frontal cortex (in addition to a more pronounced basal ganglia abnormality). *(From Volpe JJ, editor:* Neurology of the newborn, *ed 5, Philadelphia, 2008, Saunders/Elsevier, p. 420.)*

Table 99-5 HIE in Term Infants

SIGNS	STAGE 1	STAGE 2	STAGE 3
Level of consciousness	Hyperalert	Lethargic	Stuporous, coma
Muscle tone	Normal	Hypotonic	Flaccid
Posture	Normal	Flexion	Decerebrate
Tendon reflexes/clonus	Hyperactive	Hyperactive	Absent
Myoclonus	Present	Present	Absent
Moro reflex	Strong	Weak	Absent
Pupils	Mydriasis	Miosis	Unequal, poor light reflex
Seizures	None	Common	Decerebration
Electroencephalographic findings	Normal	Low voltage changing to seizure activity	Burst suppression to isoelectric
Duration	<24 hr if progresses; otherwise, may remain normal	24 hr-14 days	Days to weeks
Outcome	Good	Variable	Death, severe deficits

Modified from Sarnat HB, Sarnat MS: Neonatal encephalopathy following fetal distress: a clinical and electroencephalographic study, Arch Neurol *33:696–705, 1976. Copyright 1976, American Medical Association.*

with HIE. Continuous aEEG monitoring detects subclinical seizure activity during the subacute phase.

TREATMENT

Whole body (systemic) or selective cerebral therapeutic hypothermia reduces mortality or major neurodevelopmental impairment in term and near-term infants with HIE. Hypothermia decreases the rate of apoptosis and suppresses production of mediators known to be neurotoxic, including extracellular glutamate, free radicals, nitric oxide, and lactate.

Isolated cerebral cooling or more often systemic induced servo controlled hypothermia to a core (rectal) temperature of 33.5°C (92.3°F) within the 1st 6 hr after birth (duration 72 hr) reduces mortality and major neurodevelopmental impairment at 18 mo of age. Systemic hypothermia may result in more uniform cooling of the brain and deeper CNS structures. Infants treated with systemic hypothermia have a lower incidence of cortical neuronal injury on MRI. Complications of induced hypothermia include thrombocytopenia (usually without bleeding), reduced heart rate, and subcutaneous fat necrosis (associated with hypercalcemia in some) and the potential for overcooling and the cold injury syndrome. The latter is avoided with a servocontrolled cooling system. Therapeutic hypothermia may theoretically alter drug metabolism, prolong the QT interval, and effect the interpretation of blood gases. In practice, none of these concerns have been observed during therapeutic hypothermia.

Phenobarbital, the drug of choice for seizures, is given with an intravenous loading dose (20 mg/kg); additional doses of 5-10 mg/kg (up to 40-50 mg/kg total) may be needed. Phenytoin (20 mg/kg

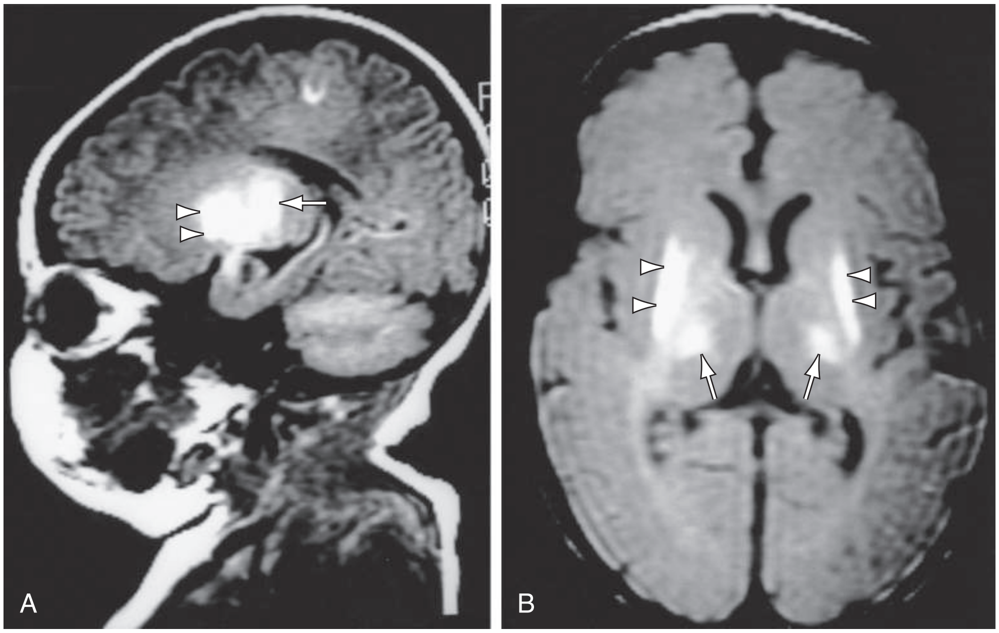

Figure 99-6 **MR images of hypoxic-ischemic injury to basal ganglia and thalamus.** MRI was performed in a 5 day old infant who experienced severe perinatal asphyxia. *A,* Note, in this parasagittal T1-weighted image, the markedly increased signal intensity in the basal ganglia, especially the putamen *(arrowheads)* and the thalamus *(arrow). B,* An axial proton density image also demonstrates the injury well in the same distribution. *(From Volpe JJ, editor:* Neurology of the newborn, *ed 5, Philadelphia, 2008, Saunders/Elsevier, p. 420.)*

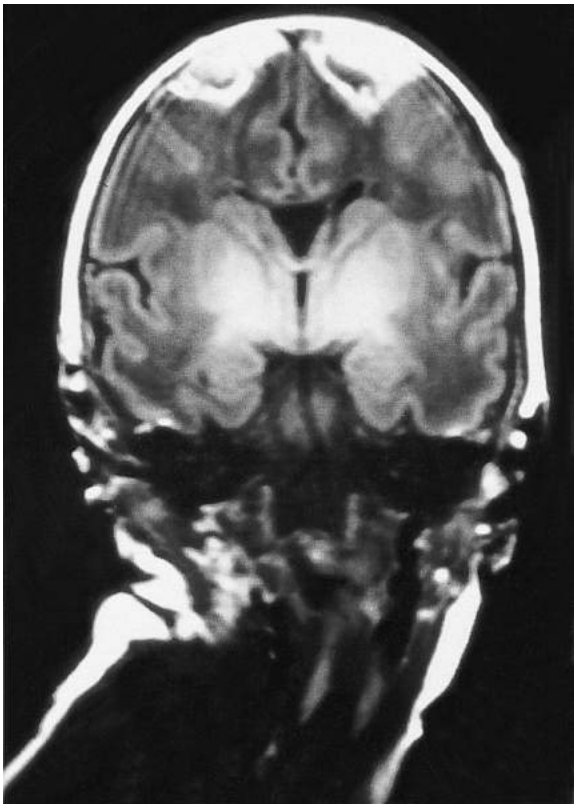

Figure 99-7 **MR image of a parasagittal cerebral injury.** A coronal T1-weighted image, obtained on the 5th postnatal day in an asphyxiated term infant, shows striking triangular lesions in the parasagittal areas bilaterally; increased signal intensity is also apparent in the basal ganglia and thalamus bilaterally. *(From Volpe JJ, editor:* Neurology of the newborn, *ed 5, Philadelphia, 2008, Saunders/Elsevier, p. 421.)*

Table 99-6	Major Aspects of MRI in the Diagnosis of HIE in the Term Infant
Major Conventional MRI Findings in the First Week	
Cerebral cortical gray-white differentiation lost (on T1W or T2W)	
Cerebral cortical high signal (T1W and FLAIR), especially in parasagittal perirolandic cortex	
Basal ganglia–thalamus, high signal (T1W and FLAIR, usually associated with the cerebral cortical changes but possibly alone with increased signal in brainstem tegmentum in cases of acute severe insults	
Parasagittal cerebral cortex, subcortical white matter, high signal (T1W and FLAIR)	
Periventricular white matter, decreased signal (T1W) or increased signal (T2W)	
Posterior limb of internal capsule, decreased signal (T1W or FLAIR)	
Cerebrum in a vascular distribution, decreased signal (T1W), but much better visualized as decreased diffusion (increased signal) on diffusion-weighted MRI	
Diffusion-weighted MRI more sensitive than conventional MRI, especially in 1st days after birth, when former shows decreased diffusion (increased signal) in injured areas	

FLAIR, fluid-attenuated inversion recovery; MRI, magnetic resonance imaging; T1W and T2W, T1- and T2-weighted images.

(From Volpe JJ, editor: Neurology of the newborn, *ed 5, Philadelphia, 2008, Elsevier, Table 9-16, p. 419.)*

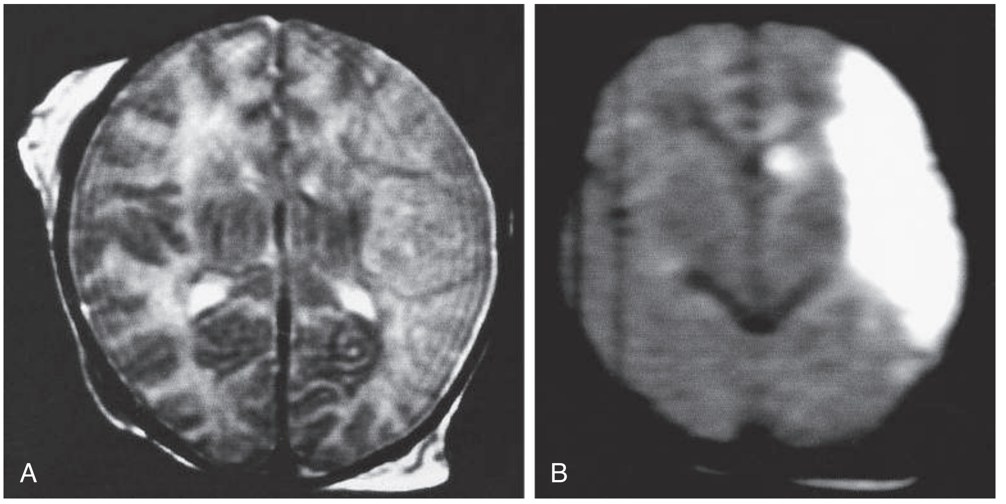

Figure 99-8 MR images of focal ischemic cerebral injury. MRI was performed on the 3rd postnatal day. *A,* An axial T2-weighted image shows a lesion in the distribution of the main branch of the left middle cerebral artery. *B,* A diffusion-weighted image demonstrates the lesion more strikingly. *(From Volpe JJ, editor:* Neurology of the newborn, *ed 5, Philadelphia, 2008, Saunders/Elsevier, p. 422.)*

loading dose) or lorazepam (0.1 mg/kg) may be needed for refractory seizures. Phenobarbital levels should be monitored 24 hr after the loading dose has been given and maintenance therapy (5 mg/kg/24hr) is begun. Therapeutic phenobarbital levels are 20-40 µg/mL. There is some clinical evidence that high-dose prophylactic phenobarbital may decrease neurodevelopmental impairment in infants with HIE. Status epilepticus, multifocal seizures and multiple anticonvulsant medications during therapeutic hypothermia, is associated with a poor prognosis. Subclinical (EEG detected) seizures have a better prognosis.

Additional therapy for infants with HIE includes supportive care directed at management of organ system dysfunction. Hyperthermia has been found to be associated with impaired neurodevelopment, so it is important to prevent hyperthermia before initiation of hypothermia. Careful attention to ventilatory status and adequate oxygenation, blood pressure, hemodynamic status, acid–base balance, and possible infection is important. Secondary hypoxia or hypotension from complications of HIE must be prevented. Aggressive treatment of seizures is critical and may necessitate continuous EEG monitoring. In addition hyperoxia, hypocarbia, and hypoglycemia are associated with poor outcomes so careful attention to resuscitation, ventilation, and blood glucose homeostasis are essential.

PROGNOSIS

The outcome of HIE, which correlates with the timing and severity of the insult, ranges from complete recovery to death. The prognosis varies depending on the severity of the insult and the treatment. Infants with initial cord or initial blood pH <6.7 have a 90% risk for death or severe neurodevelopmental impairment at 18 mo of age. In addition, infants with Apgar scores of 0-3 at 5 min, high base deficit (>20-25 mmol/L), decerebrate posture, severe basal ganglia–thalamic lesions, persistence of severe HIE at 72 hr, and lack of spontaneous activity are also at increased risk for death or impairment. These predictor variables can be combined to determine a score that helps with prognosis (see Table 99-4). Infants with the highest risk are likely to die or have severe disability despite aggressive treatment including hypothermia. Those with intermediate scores are likely to benefit from treatment. In general, severe encephalopathy, characterized by flaccid coma, apnea, absence of oculocephalic reflexes, and refractory seizures, is associated with a poor prognosis (see Table 99-5). A low Apgar score at 20 min, absence of spontaneous respirations at 20 min of age, and persistence of abnormal neurologic signs at 2 wk of age also predict death or severe cognitive and motor deficits. The combined use of early EEG and MRI is of some help in predicting outcome in term infants with HIE. Normal MRI and EEG findings are associated with a good recovery, whereas severe MRI and EEG abnormalities predict a poor outcome. Microcephaly and poor head growth during the 1st year of life also correlate with injury to the basal ganglia and white matter and adverse developmental outcome at 12 mo. All survivors of moderate to severe encephalopathy require comprehensive high-risk medical and developmental follow-up. Early identification of neurodevelopmental problems allows prompt referral for developmental, rehabilitative, neurologic care, and early intervention services so that the best possible outcome can be achieved.

Brain death after neonatal HIE is diagnosed from the clinical findings of coma unresponsive to pain, auditory, or visual stimulation; apnea with P_{CO_2} rising from 40 to >60 mm Hg without ventilatory support; and absence of brainstem reflexes (pupillary, oculocephalic, oculovestibular, corneal, gag, sucking) (see Chapter 68.1). These findings must occur in the absence of hypothermia, hypotension, and elevations of depressant drugs (phenobarbital). An absence of cerebral blood flow on radionuclide scans and of electrical activity on EEG (electrocerebral silence) is inconsistently observed in clinically brain-dead neonatal infants. Persistence of the clinical criteria for 2 days in term infants and 3 days in preterm infants predicts brain death in most asphyxiated newborns. Nonetheless, no universal agreement has been reached regarding the definition of neonatal brain death. Consideration of withdrawal of life support should include discussions with the family, the healthcare team, and, if there is disagreement, an ethics committee. The best interest of the infant involves judgments about the benefits and harm of continuing therapy or avoiding ongoing futile therapy.

99.6 Spine and Spinal Cord

Waldemar A. Carlo and Namasivayam Ambalavanan

Injury to the spine/spinal cord during birth is rare but can be devastating. Strong traction exerted when the spine is hyperextended or when the direction of pull is lateral, or forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis, especially when combined with flexion and torsion of the vertical axis, may produce fracture and separation of the vertebrae. Such injuries are most likely to occur when difficulty is encountered in delivering the shoulders in cephalic presentations and the head in breech presentations. The injury occurs most commonly at the level of the 4th cervical vertebra with cephalic presentations and the lower cervical–upper thoracic vertebrae with breech presentations. Transection of the cord may

occur with or without vertebral fractures; hemorrhage and edema may produce neurologic signs that are indistinguishable from those of transection except that they may not be permanent. Areflexia, loss of sensation, and complete paralysis of voluntary motion occur below the level of injury, although the persistence of a withdrawal reflex mediated through spinal centers distal to the area of injury is frequently misinterpreted as representing voluntary motion. If the injury is severe, the infant, who from birth may be in poor condition because of respiratory depression, shock, or hypothermia, may deteriorate rapidly to death within several hours before any neurologic signs are obvious. Alternatively, the course may be protracted, with symptoms and signs appearing at birth or later in the 1st wk; immobility, flaccidity, and associated brachial plexus injuries may not be recognized for several days. Constipation may also be present. Some infants survive for prolonged periods, their initial flaccidity, immobility, and areflexia being replaced after several weeks or months by rigid flexion of the extremities, increased muscle tone, and spasms. Apnea on day 1 and poor motor recovery by 3 mo are poor prognostic signs.

The **differential diagnosis** of spine/spinal cord injury includes amyotonia congenita and myelodysplasia associated with spina bifida occulta. Ultrasonography or, more often, MRI confirms the diagnosis. Treatment of the survivors is supportive, including home ventilation; patients often remain permanently disabled. When a fracture or dislocation is causing spinal compression, the prognosis is related to the time elapsed before the compression is relieved.

Bibliography is available at Expert Consult.

99.7 Peripheral Nerve Injuries

Waldemar A. Carlo and Namasivayam Ambalavanan

BRACHIAL PALSY

Brachial plexus injury is a common problem, with an incidence of 0.6-4.6/1,000 live births. Injury to the brachial plexus may cause paralysis of the upper part of the arm with or without paralysis of the forearm or hand or, more commonly, paralysis of the entire arm. These injuries occur in macrosomic infants and when lateral traction is exerted on the head and neck during delivery of the shoulder in a vertex presentation, when the arms are extended over the head in a breech presentation, or when excessive traction is placed on the shoulders. Approximately 45% of brachial plexus injuries are associated with shoulder dystocia. In **Erb-Duchenne paralysis**, the injury is limited to the 5th and 6th cervical nerves. The infant loses the power to abduct the arm from the shoulder, rotate the arm externally, and supinate the forearm. The characteristic position consists of adduction and internal rotation of the arm with pronation of the forearm. Power to extend the forearm is retained, but the biceps reflex is absent; the Moro reflex is absent on the affected side (Fig. 99-9). The outer aspect of the arm may have some sensory impairment. Power in the forearm and hand grasps is preserved unless the lower part of the plexus is also injured; the presence of hand grasp is a favorable prognostic sign. When the injury includes the phrenic nerve, alteration in diaphragmatic excursion may be observed with ultrasonography or fluoroscopy. **Klumpke paralysis** is a rare form of brachial palsy, in which injury to the 7th and 8th cervical nerves and the 1st thoracic nerve produces a paralyzed hand and ipsilateral ptosis and miosis **(Horner syndrome)** if the sympathetic fibers of the 1st thoracic root are also injured. Mild cases may not be detected immediately after birth. Differentiation must be made from cerebral injury; from fracture, dislocation, or epiphyseal separation of the humerus; and from fracture of the clavicle. MRI demonstrates nerve root rupture or avulsion.

Full recovery occurs in most patients; prognosis depends on whether the nerve was merely injured or was lacerated. If the paralysis was a result of edema and hemorrhage about the nerve fibers, function should return within a few months; if it was because of laceration, permanent damage may result. Involvement of the deltoid is usually the most serious problem and may result in shoulder drop secondary to muscle atrophy. In general, paralysis of the upper part of the arm has a better prognosis than paralysis of the lower part.

Figure 99-9 Brachial palsy of the left arm (asymmetric Moro reflex).

Treatment consists of initial conservative management with monthly follow-up and a decision for surgical intervention by 3 mo if function has not improved. Partial immobilization and appropriate positioning are used to prevent the development of contractures. In upper arm paralysis, the arm should be abducted 90 degrees with external rotation at the shoulder, full supination of the forearm, and slight extension at the wrist with the palm turned toward the face. This position may be achieved with a brace or splint during the 1st 1-2 wk. Immobilization should be intermittent throughout the day while the infant is asleep and between feedings. In lower arm or hand paralysis, the wrist should be splinted in a neutral position, and padding placed in the fist. When the entire arm is paralyzed, the same treatment principles should be followed. Gentle massage and range-of-motion exercises may be started by 7-10 days of age. Infants should be closely monitored with active and passive corrective exercises. If the paralysis persists without improvement for 3 mo, neuroplasty, neurolysis, end-to-end anastomosis, and nerve grafting offer hope for partial recovery.

The type of treatment and the prognosis depend on the mechanism of injury and the number of nerve roots involved. The mildest injury to a peripheral nerve (neurapraxia) is due to edema and heals spontaneously within a few weeks. Axonotmesis is more severe and is a consequence of nerve fiber disruption with an intact myelin sheath; function usually returns in a few months. Total disruption of nerves (neurotmesis) or root avulsion is the most severe, especially if it involves C5-T1; microsurgical repair may be indicated. Fortunately, most (75%) injuries are at the root level C5-C6, involve neurapraxia and axonotmesis, and should heal spontaneously. Botulism toxin may be used to treat biceps-triceps co-contractions.

PHRENIC NERVE PARALYSIS

Phrenic nerve injury (3rd, 4th, 5th cervical nerves) with diaphragmatic paralysis must be considered when cyanosis and irregular and labored respirations develop. Such injuries, usually unilateral, are associated with ipsilateral upper brachial palsy. Because breathing is thoracic in type, the abdomen does not bulge with inspiration. Breath

sounds are diminished on the affected side. The thrust of the diaphragm, which may often be felt just under the costal margin on the normal side, is absent on the affected side. The diagnosis is established by ultrasonographic or fluoroscopic examination, which reveals elevation of the diaphragm on the paralyzed side and seesaw movements of the 2 sides of the diaphragm during respiration.

No specific treatment is available; infants should be placed on the involved side and given oxygen if necessary. Initially, intravenous feedings may be needed; later, progressive gavage or oral feeding may be started, depending on the infant's condition. Pulmonary infections are a serious complication. Recovery usually occurs spontaneously by 1-3 mo; rarely, surgical plication of the diaphragm may be indicated.

FACIAL NERVE PALSY

Facial palsy is usually a peripheral paralysis that results from pressure over the facial nerve in utero, from efforts during labor, or from forceps use during delivery. Rarely, it may result from nuclear agenesis of the facial nerve. Peripheral paralysis is flaccid and, when complete, involves the entire side of the face, including the forehead. When the infant cries, movement occurs only on the nonparalyzed side of the face, and the mouth is drawn to that side. On the affected side the forehead is smooth, the eye cannot be closed, the nasolabial fold is absent, and the corner of the mouth droops. The forehead wrinkles on the affected side with central paralysis because only the lower 2/3 of the face is involved. The infant also usually has other manifestations of intracranial injury, most commonly 6th nerve palsy. The prognosis depends on whether the nerve was injured by pressure or the nerve fibers were torn. Improvement occurs within a few weeks in the former instance. Care of the exposed eye is essential. Neuroplasty may be indicated when the paralysis is persistent. Facial palsy may be confused with absence of the depressor muscles of the mouth, which is a benign problem.

Other peripheral nerves are seldom injured in utero or at birth except when they are involved in fractures or hemorrhage.

Chapter 100

Delivery Room Emergencies

Waldemar A. Carlo

Most infants complete the transition to extrauterine life without difficulty; however, a small percentage requires resuscitation after birth. The most common delivery room emergency for neonates is secondary to failure to initiate and maintain effective respirations. Less frequent, but of major importance, are shock (see Chapter 98), severe anemia (see Chapter 103.1), plethora (see Chapter 103.3), convulsions (see Chapter 593.7), and management of life-threatening congenital malformations (see Chapter 98). Improved perinatal care and prenatal diagnosis of fetal anomalies allow for appropriate maternal transports for high-risk deliveries.

RESPIRATORY DISTRESS AND FAILURE

Disorders of respiration in newborn infants can be categorized as either central nervous system (CNS) failure, representing depression or failure of the respiratory center, or peripheral respiratory difficulty, indicating interference with the alveolar exchange of oxygen and carbon dioxide. Cyanosis occurs in both groups (see Table 98-1). Respiratory problems encountered in the delivery room are most frequently those of airway obstruction and depression of the CNS (maternal medications, asphyxia) with an absence of adequate respiratory effort. Respiratory distress in the presence of good respiratory effort should lead to an immediate consideration of the underlying cause and is an indication for radiographic examination of the chest.

If respiratory movements are made with the mouth closed but the infant fails to move air in and out of the lungs, bilateral **choanal atresia** (see Chapter 376) or other obstruction of the upper respiratory tract should be suspected. The mouth should be opened, and the mouth and pharynx cleared of secretions with gentle suction. An oropharyngeal airway should be inserted, and the source of the obstruction sought immediately. If effective respiratory flow is not produced by opening the infant's mouth and clearing the airway, laryngoscopy is indicated. With obstructive malformations of the mandible, epiglottis, larynx, or trachea, an endotracheal tube should be inserted; prolonged endotracheal intubation or tracheostomy may be required. Respiratory failure caused by CNS depression or injury may require continuous mechanical ventilation.

Hypoplasia of the mandible (Pierre Robin, Stickler, DiGeorge, and other syndromes; see Chapters 308 and 311) with posterior displacement of the tongue may result in symptoms similar to those of choanal atresia and may be temporarily relieved by pulling the tongue or mandible forward or placing the infant in the prone position. A scaphoid abdomen suggests a **diaphragmatic hernia** or **eventration,** as does asymmetry in contour or movement of the chest or a shift of the apical impulse of the heart; these latter manifestations are also compatible with **tension pneumothorax.** A pneumothorax can be the presenting symptom in infants with pulmonary hypoplasia, renal malformations, or both.

Pulmonary causes of respiratory difficulty are discussed in Chapter 101.

FAILURE TO INITIATE OR SUSTAIN RESPIRATION

Failure to initiate or sustain respiratory effort is common at birth. Infants with **primary apnea** respond to stimulation by establishing normal breathing. Infants with secondary apnea need ventilatory assistance. **Secondary apnea** usually originates in the CNS as a result of asphyxia or peripherally because of neuromuscular disorders. Prematurity alone is seldom a causative factor, except in infants weighing <1,500 g. Intrapulmonary problems, such as respiratory distress syndrome, pulmonary hypoplasia associated with oligohydramnios as in Potter syndrome or neuromuscular diseases, bilateral pleural effusions (hydrops fetalis), pneumothorax, and severe intrauterine pneumonia, may at times result in poor ventilation despite strong respiratory efforts. The lungs in affected infants may be noncompliant, and efforts to begin respirations may be inadequate to initiate sufficient ventilation.

Respiratory depression may occur from administration of morphine, meperidine, fentanyl, barbiturates, or tranquilizers to the mother shortly before delivery or from maternal anesthesia given during the 2nd stage of labor. This sequela may be minimized by the use of appropriate analgesic and anesthetic practices. Treatment includes initial physical stimulation and securing of a patent airway. If effective ventilation is not initiated, artificial breathing with a bag and mask must be instituted. At the same time, if the respiratory depression is caused by an opiate, naloxone hydrochloride (Narcan), 0.1 mg/kg, should be given intravenously or intramuscularly. Naloxone is contraindicated in infants born to mothers with opiate addiction as it may precipitate acute neonatal withdrawal with seizures. If depression is a consequence of other anesthetics or analgesics, artificial respiration should be continued until the infant is able to sustain ventilation. CNS-stimulant drugs should not be used because they are ineffective and may be harmful. External cardiac massage, correction of acidosis, and circulatory support with drugs may be important adjuncts to ventilation in the severely asphyxiated infant.

NEONATAL RESUSCITATION

Although the majority of babies undergo a smooth physiologic transition and breathe effectively after delivery, 5-10% requires active intervention to establish normal cardiorespiratory function. The goals of neonatal resuscitation are to prevent the morbidity and mortality

associated with hypoxic–ischemic tissue (brain, heart, kidney) injury and to reestablish adequate spontaneous respiration and cardiac output. High-risk situations should be anticipated from the history of the pregnancy, labor, and delivery and identification of signs of fetal distress. Infants who are born limp, cyanotic, apneic, or pulseless require immediate resuscitation before assignment of the 1-min Apgar score. Rapid and appropriate resuscitative efforts improve the likelihood of preventing brain damage and achieving a successful outcome.

Guidelines for neonatal resuscitation propose an "integrated" assessment/response approach for the initial evaluation of an infant, consisting of simultaneous assessment of infant color, general appearance, and risk factors. The fundamental principles include evaluation of the airway, establishing effective respiration and adequate circulation; the guidelines also highlight the assessment and response to the neonatal heart rate and the management of infants with meconium-stained amniotic fluid.

Immediately after birth, an infant *in need of resuscitation* should be placed under a radiant heater and dried (to avoid passive hypothermia), positioned with the head down and slightly extended; the airway should be cleared by suctioning, and gentle tactile stimulation provided (slapping the foot, rubbing the back). Simultaneously, the infant's color, heart rate, and respiratory effort should be assessed (Fig. 100-1).

The steps in neonatal resuscitation follow the ABCs: **A,** anticipate and establish a patent airway by suctioning and, if necessary, performing endotracheal intubation; **B,** initiate breathing by using tactile stimulation or positive-pressure ventilation with a bag-and-mask or through an endotracheal tube; **C,** maintain the circulation with chest compression and medications, if needed. Figure 100-1 outlines the steps to follow for immediate neonatal evaluation and resuscitation (see also Chapter 67).

If no respirations are noted, or if the heart rate is <100 beats/min, positive-pressure ventilation is given through a tightly fitted face-bag-and-mask for 15-30 sec. In infants with severe respiratory depression that does not respond to positive-pressure ventilation via bag-and-mask, endotracheal intubation should be performed. Many authorities recommend early intubation for extremely low birthweight preterm infants. Table 100-1 lists guidelines for endotracheal tube size and depth of insertion in infants with different birthweights. If the heart rate does not improve after 30 sec with bag-and-mask (or endotracheal) ventilation and remains below 100 beats/min, ventilation is continued and chest compression should be initiated over the lower third of the sternum at a rate of 90 compressions/min. The ratio of compressions to ventilation is 3:1 (90 compressions:30 breaths). If the heart rate remains <60 beats/min despite effective compressions and ventilation, administration of epinephrine should be considered. Persistent bradycardia in neonates is usually attributable to hypoxia resulting from respiratory arrest and often responds rapidly to effective ventilation alone. Persistent bradycardia despite what appears to be adequate resuscitation suggests inadequate ventilation or more severe cardiac compromise. Poor response to ventilation may be a result of a loosely fitted mask, poor positioning of the endotracheal tube, intraesophageal intubation, airway obstruction, insufficient pressure, pleural effusions, pneumothorax, excessive air in the stomach, asystole, hypovolemia, diaphragmatic hernia, or prolonged intrauterine asphyxia.

In the past, the inspired gas for neonatal resuscitation had been 100% oxygen. *Resuscitation with room air in term infants is equally effective and may reduce the risk of hyperoxia, which is associated with decreased cerebral blood flow and generation of oxygen free radicals.* Room air is the preferred initial gas for neonatal resuscitation in term infants; if the neonate does not achieve normal oxygen saturation levels within 90 sec, increasing concentrations of oxygen should be blended in (up to 100% oxygen) until normal oxygen saturation levels are achieved. If pulmonary hypertension is suspected (meconium aspiration, diaphragmatic hernia) one may consider 100% oxygen as the initial gas for resuscitation. Particular attention is required during the resuscitation of very-low birthweight neonates, to monitor oxygen saturation and adjust oxygen concentration using an oxygen blender so as to minimize the risk of hyperoxia and hypoxia.

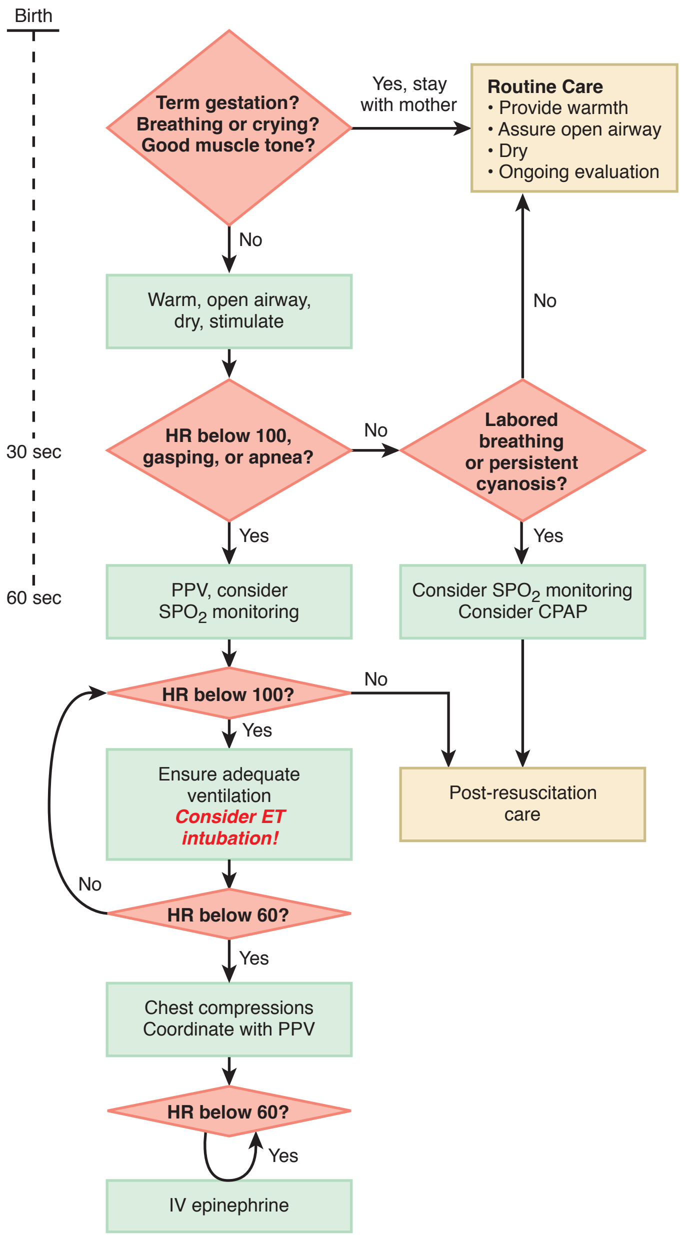

Figure 100-1 **Newborn resuscitation algorithm.** CPAP, continuous positive airway pressure; ET, endotracheal; HR, heart rate; IV, intravenous; PPV, positive pressure ventilation. *(From the American Academy of Pediatrics:* Textbook of Neonatal Resuscitation, *ed 6, Elk Grove Village, IL, 2011, AAP.)*

Although the first breath normally requires pressures as low as 15-20 cm H_2O, pressures as high as 30-40 cm H_2O may be needed. Subsequent breaths are given at a rate of 40-60/min with a pressure of 15-20 cm H_2O. Noncompliant stiff lungs secondary to respiratory distress syndrome, congenital pneumonia, pulmonary hypoplasia, or meconium aspiration may require higher pressures. Successful ventilation is signified by adequate chest rise, symmetric breath sounds, improved pink color, heart rate >100 beats/min, spontaneous respirations, presence of end-tidal CO_2, and improved tone. Various devices to detect exhaled CO_2 and to confirm accurate placement of an endotracheal tube are available commercially. A laryngeal mask airway may be an effective tool to establish an airway, especially if bag and mask ventilation is ineffective or intubation is unsuccessful.

Table 100-1 Guidelines for Tracheal Tube Size and Depth of Insertion

TUBE SIZE (MM INTERNAL DIAMETER)	DEPTH OF INSERTION FROM UPPER LIP (cm)	WEIGHT (g)	GESTATION (wk)
2.5	6.5-7	<1,000	<28
3	7-8	1,000-2,000	28-34
3/3.5	8-9	2,000-3,000	34-38
3.5/4.0	≥9	>3,000	>38

From Kattwinkel J, Niermeyer S, Nadkarni V, et al: ILCOR advisory statement: resuscitation of the newly born infant: an advisory statement from the Pediatric Working Group of the International Liaison Committee on Resuscitation, Circulation *99:1927–1938, 1999. By permission of the American Heart Association, Inc.*

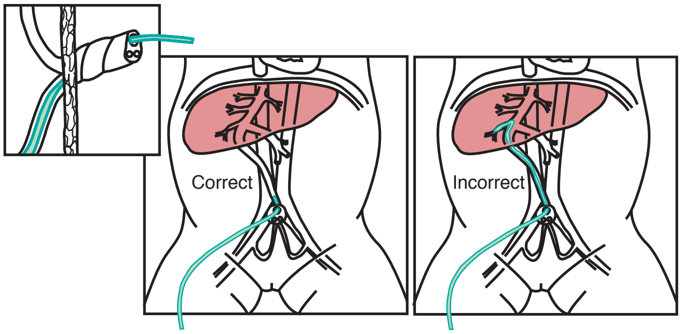

Figure 100-2 Use of the umbilical vein for administration of medications during neonatal resuscitation. *(From Kattwinkel J, Bloom RS, editors:* Neonatal resuscitation textbook, *ed 5, Elk Grove, IL, 2006, American Academy of Pediatrics, American Heart Association.)*

If the infant has respiratory depression and the mother has received an analgesic narcotic drug within 4 hr prior to delivery, naloxone hydrochloride (0.1 mg/kg) is given while adequate ventilation is maintained. Breathing in the depressed infant should be maintained until a response to naloxone is noted. Continuous observation of the infant is important because repeated doses of naloxone may be needed even after the infant has been transferred to the nursery owing to the short half-life of naloxone.

Medications are rarely required but should be administered when the heart rate is <60 beats/min after 30 sec of combined ventilation and chest compressions or during asystole. The umbilical vein can generally be readily cannulated and used for immediate administration of medications during neonatal resuscitation (Fig. 100-2). The endotracheal tube may be used for the administration of epinephrine if intravenous access is not available and/or for naloxone. Epinephrine (0.1-0.3 mL/kg of a 1 : 10,000 solution, given intravenously or intratracheally) is given for asystole or for failure to respond to 30 sec of combined resuscitation. The dose may be repeated every 3-5 min. Data in neonates are insufficient to recommend higher doses in infants who are unresponsive to the standard dose. Emergency volume expansion is accomplished with 10-20 mL/kg of an isotonic crystalloid solution or type O Rh-negative red blood cells (in acute hemorrhage). Volume infusions should be used cautiously during the resuscitation of a very-low birth-weight infant. Sodium bicarbonate (2 mEq/kg, 0.5 mEq/mL of a 4.2% solution) is sometimes given and should be administered slowly (1 mEq/kg/min) if metabolic acidosis has been documented and the resuscitation is prolonged. Sodium bicarbonate should be given only after effective ventilation has been established, because such therapy may increase the blood CO_2 concentration and produce respiratory acidosis, complicating an existing metabolic acidosis. Restoration of oxygenation and tissue perfusion is the main treatment of metabolic acidosis associated with asphyxia.

Severe asphyxia may also depress myocardial function and cause cardiogenic shock despite the recovery of heart and respiratory rates. Dopamine or dobutamine administered as a continuous infusion (5-20 μg/kg/min) and fluids should be started after the initial resuscitation effort, to improve cardiac output in an infant with poor peripheral perfusion, weak pulses, hypotension, tachycardia, and poor urine output. Epinephrine (0.1-1.0 μg/kg/min) may be indicated for infants in severe shock that does not respond to dopamine or dobutamine (see Chapter 67).

Less-severe degrees of poor cardiopulmonary transition in the delivery room can usually be managed by brief periods of bag-and-mask ventilation. Chest compression and medications are not needed for most neonates who have mild to moderate birth depression. Regardless of the severity of asphyxia or the response to resuscitation, asphyxiated infants should be monitored closely for signs of multiorgan hypoxic–ischemic tissue injury (see Table 99-1 in Chapter 99).

MECONIUM

Meconium staining of the amniotic fluid may be an indication of fetal stress; therefore, personnel skilled at endotracheal intubation and resuscitation should be present at the delivery. Previously the decision to intubate a neonate was based on the presence and thickness/consistency of the meconium-stained fluid; *current evidence no longer supports this practice*. If the infant is vigorous with good respiratory effort and a heart rate >100 beats/min, tracheal intubation to aspirate meconium **should not be attempted**; the mouth and nose may be suctioned with a bulb or suction catheter. If the infant is depressed with poor muscle tone and/or a heart rate <100 beats/min, tracheal intubation and suctioning should be performed. The endotracheal tube should be attached to a suction device, and free-flow oxygen should be provided throughout the procedure.

SHOCK

Circulatory insufficiency may be present at birth as a result of severe asphyxia or hemorrhage during gestation, labor, or delivery. Causes of blood loss include hemolysis; placental abruption or tear, placenta previa; traumatic injury to the umbilical cord or internal organs; and intracranial bleeding. Clinical manifestations include signs of respiratory distress, cyanosis, pallor, flaccidity, cold mottled skin, tachycardia or bradycardia, hepatosplenomegaly, and, rarely, convulsions. Edema and hepatosplenomegaly suggest hydrops fetalis or heart failure without shock. Shock from overwhelming infection may be present immediately after birth.

Supportive treatment with type O Rh-negative blood or normal saline is indicated for hemorrhage or hypovolemia, respectively. Oxygen should be administered and the metabolic acidosis corrected with sodium bicarbonate. A sympathomimetic agent such as dopamine or dobutamine may be needed to support cardiac output and blood pressure. The diagnosis and treatment of erythroblastosis fetalis are discussed in Chapter 103.2. If infection is present, appropriate antibiotics must be started as soon as possible.

After supportive measures have stabilized the infant's condition, a specific diagnosis should be established, and appropriate continuing treatment instituted.

PNEUMOTHORAX

Infants may experience pneumothorax in the delivery room, resulting in respiratory distress and hypoxia. Approximately 1-2% of infants have pneumothorax after birth; only 0.05-0.07% have symptoms (see Chapter 101.12). The risk is higher in infants requiring positive pressure ventilation or those with meconium-stained amniotic fluid. Rarely, an infant has a congenital malformation that results in lung hypoplasia, such as congenital diaphragmatic hernia or renal agenesis. Clinically, the infant demonstrates respiratory distress and has diminished breath sounds on the affected side. Transillumination may be helpful to confirm the diagnosis, particularly in the low birth-weight infant. Emergency evacuation of a pneumothorax without

radiographic confirmation is indicated in an infant who is unresponsive to resuscitation efforts, and has asymmetric breath sounds, bradycardia, and cyanosis. A 23-gauge butterfly needle or angiocatheter attached to a stopcock and syringe should be inserted perpendicular to the chest wall above the rib in the 4th intercostal space at the level of the nipple (Fig. 100-3). The air is evacuated. The catheter is then inserted with constant negative pressure, and the air evacuated.

AIRWAY OBSTRUCTION

Critical fetal and then neonatal airway obstruction represents an emergency in the delivery room. The **ex utero intrapartum treatment (EXIT) procedure** allows time to secure the airway in an infant known to have airway obstruction for a variety of causes, including laryngeal atresia or stenosis, teratomas, hygromas, and oral tumors, before the infant is separated from the placenta. Uteroplacental gas exchange is maintained throughout the procedure. High-risk perinatal care has led to more frequent prenatal diagnosis of many disorders known to cause the **critical high airway obstruction syndrome (CHAOS)** (Fig. 100-4).

ABDOMINAL WALL DEFECTS

Appropriate management of patients with abdominal wall defects (omphalocele, gastroschisis) in the delivery room prevents excessive fluid loss and minimizes the risk for injury to the exposed viscera.

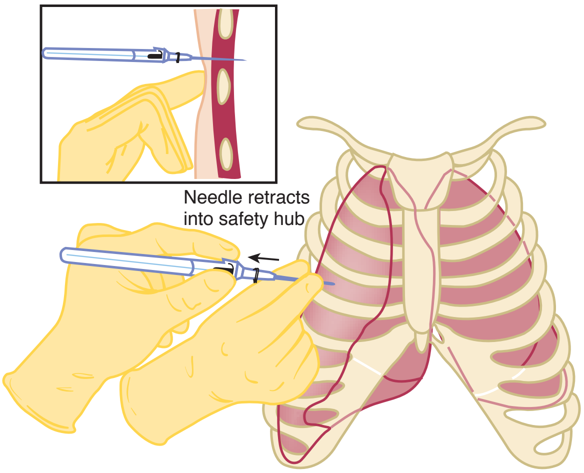

Figure 100-3 Decompression of a pneumothorax. *(From Kattwinkel J, Bloom RS, editors:* Neonatal resuscitation textbook, *ed 5, Elk Grove, IL, 2006, American Academy of Pediatrics, American Heart Association.)*

Gastroschisis is the more common defect and typically the intestines are not covered by a membrane. The exposed intestines should be gently placed in a sterile clear plastic bag after delivery. A membrane often covers an omphalocele, and care should be taken to prevent its rupture. The infant should be transferred to a tertiary referral center for surgical consultation and evaluation for other associated anomalies (see Chapter 105).

INJURY DURING DELIVERY

Central Nervous System

See Chapter 99.

Viscera

The **liver** is the only internal organ other than the brain that is injured with any frequency during the delivery process. Damage usually results from pressure on the liver during delivery of the head in breech presentations. Large infant size, intrauterine asphyxia, coagulation disorders, extreme prematurity, and hepatomegaly are contributing factors. Incorrect cardiac massage is a less-frequent cause. Hepatic rupture may result in the formation of a **subcapsular hematoma,** but the capsule may tamponade further bleeding. Affected infants may appear normal for the 1st 1-3 days. Nonspecific signs related to loss of blood into the hematoma may appear early and include poor feeding, listlessness, pallor, jaundice, tachypnea, and tachycardia. A mass may be palpable in the right upper quadrant, and the abdomen or inguinal area may appear blue. The hematoma may be large enough to cause anemia. Shock and death may occur if the hematoma ruptures into the peritoneal cavity, where the reduced pressure may allow fresh hemorrhage. Early suspicion, ultrasonographic diagnosis, and prompt supportive therapy can decrease the mortality associated with this disorder. Surgical repair of a laceration may be required. Rupture of the spleen may occur alone or in connection with rupture of the liver. The causes, complications, treatment, and prevention are similar.

Although **adrenal hemorrhage** occurs with some frequency, especially after breech delivery, in infants who are large for gestational age or have diabetic mothers, its cause is often undetermined; it may be due to trauma, anoxia, or severe stress, as in overwhelming infection. Ninety percent of adrenal hemorrhages are unilateral; 75% are right-sided. Calcified central hematomas of the adrenal, identified on radiographs or at autopsy in older infants and children, suggest that not all adrenal hemorrhages are immediately fatal. In severe cases, the diagnosis is usually made at postmortem examination. The symptoms are profound shock and cyanosis. A mass may be present in the flank along with overlying skin discoloration; jaundice may also develop. If adrenal hemorrhage is suspected, abdominal ultrasonography may be helpful, and treatment of acute adrenal failure may be indicated (see Chapter 569).

Figure 100-4 EXIT procedure. Baby with teratoma and critical high airway obstruction syndrome (CHAOS). Trachea is displaced to the lateral neck. *(Courtesy of Dr. Mark Wulkan, Pediatric Surgery, Emory University.)*

Fractures

Clavicle

The clavicle is fractured during labor and delivery more frequently than any other bone; it is particularly vulnerable with difficult delivery of the shoulder in vertex presentations and the extended arms in breech deliveries. The infant characteristically does not move the arm freely on the affected side; crepitus and bony irregularity may be palpated, and discoloration is occasionally visible over the fracture site. The Moro reflex is absent on the affected side, and spasm of the sternocleidomastoid muscle with obliteration of the supraclavicular depression at the site of the fracture can be noted. Infants with greenstick clavicle fractures may not have any limitation of movement, and the Moro reflex may be present. The prognosis for this fracture is excellent. **Treatment,** if any, consists of immobilization of the arm and shoulder on the affected side. A remarkable degree of palpable callus develops at the site within a week and may be the initial evidence of the fracture. Fracture of the humerus or brachial palsy may also be responsible for limitation of movement of an arm and absence of a Moro reflex on the affected side.

Extremities

In fractures of the long bones, spontaneous movement of the extremity is usually absent (**pseudoparalysis**). The Moro reflex is often absent from the involved extremity. Associated nerve involvement may occur. Satisfactory results of treatment of a fractured humerus are obtained with 2-4 wk of immobilization, during which the arm is strapped to the chest, a triangular splint and a Velpeau bandage are applied, or a cast is applied. For fracture of the femur, good results are achieved with traction-suspension of both lower extremities, even if the fracture is unilateral; the legs are immobilized in a spica cast. Splints are effective for treatment of fractures of the forearm or leg. Healing is usually accompanied by excess callus formation. The prognosis is excellent for fractures of the extremities. Fractures in very-low birthweight infants may be related to osteopenia of prematurity (see Chapter 106).

Dislocations and epiphyseal separations rarely result from birth trauma. The upper femoral epiphysis may be separated by forcible manipulation of the infant's leg as, for example, in breech extraction or after version. The affected leg shows swelling, slight shortening, limitation of active motion, painful passive motion, and external rotation. The diagnosis is established radiographically. The prognosis is good for milder injuries, but coxa vara frequently results from extensive displacement.

Nose

The most prevalent injury to the nose is dislocation of the cartilaginous portion of the septum from the vomerine groove and the columella. The affected infant may have difficulty nursing and some impairment of nasal respiration. On physical examination, the nares appear asymmetric and the nose is flattened. An oral airway is rarely needed, and surgical consultation should be obtained for definitive treatment.

Chapter 101

Respiratory Tract Disorders

Waldemar A. Carlo and Namasivayam Ambalavanan

Respiratory disorders are the most frequent cause of admission for neonatal intensive care in both term and preterm infants. Signs and symptoms of respiratory distress include cyanosis, grunting, nasal flaring, retractions, tachypnea, decreased breath sounds with or without rales and/or rhonchi, and pallor. A wide variety of pathologic lesions may be responsible for respiratory disturbances, including pulmonary, airway, cardiovascular, central nervous, infection, and other disorders (Fig. 101-1).

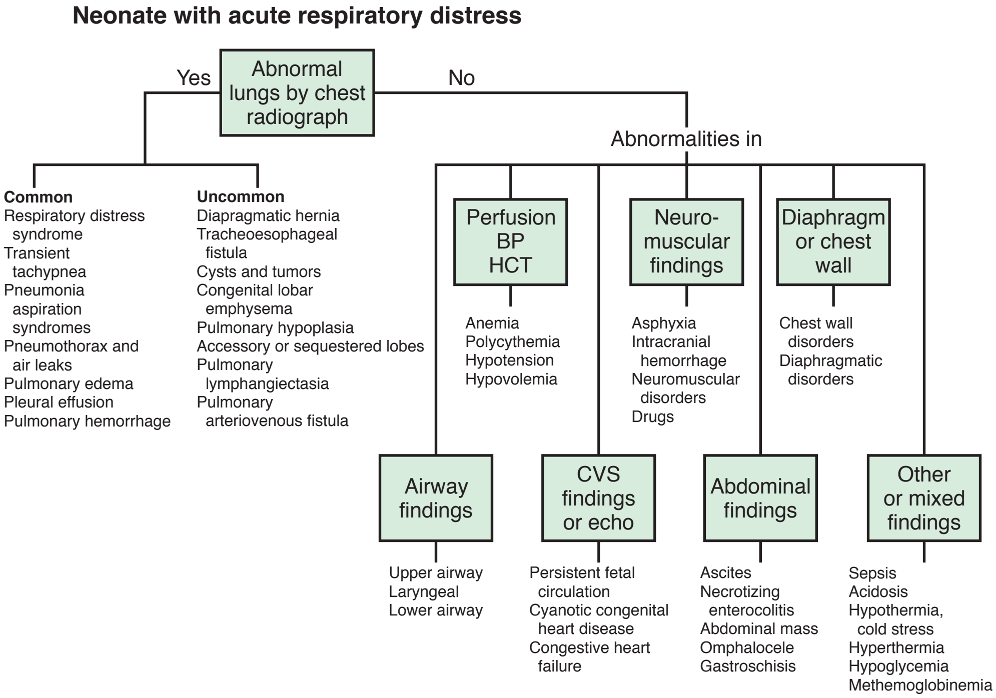

Figure 101-1 **Neonate with acute respiratory distress.** BP, blood pressure; CVS, cardiovascular system; HCT, hematocrit. *(From Battista MA, Carlo WA: Differential diagnosis of acute respiratory distress in the neonate. In Frantz ID, editor:* Tufts University of School of Medicine and Floating Hospital for Children reports on neonatal respiratory diseases, *vol 2, issue 3, Newtown, PA, 1992, Associates in Medical Marketing Co.)*

It is occasionally difficult to distinguish respiratory from nonrespiratory etiologies on the basis of clinical signs alone. Signs of respiratory distress are an indication for a physical examination and diagnostic evaluation, including a blood gas or pulse oximetry determination and chest x-ray. Timely and appropriate therapy is essential to improve outcome.

101.1 Transition to Pulmonary Respiration

Waldemar A. Carlo

Successful establishment of adequate lung function at birth depends on airway patency, functional lung development, and maturity of respiratory control. Fetal lung fluid must be removed and replaced with gas. This process begins before birth as active sodium transport across the pulmonary epithelium drives liquid from the lung lumen into the interstitium with subsequent absorption into the vasculature. Increased levels of circulating catecholamines, vasopressin, prolactin, and glucocorticoids enhance lung fluid adsorption and trigger the change in lung epithelia from a chloride-secretory to a sodium-reabsorptive mode. Functional residual capacity (FRC) must be established and maintained in order to develop a ventilation–perfusion relationship that will provide optimal exchange of oxygen and carbon dioxide between alveoli and blood (see Chapter 421).

THE FIRST BREATH

During vaginal delivery, intermittent compression of the thorax facilitates removal of lung fluid. Surfactant lining the alveoli enhances the aeration of gas-free lungs by reducing surface tension, thereby lowering the pressure required to open alveoli. Although spontaneously breathing infants do not need to generate an opening pressure to create airflow, infants requiring positive-pressure ventilation at birth need an opening pressure of 13-32 cm H_2O and are more likely to establish FRC if they generate a spontaneous, negative pressure breath. Expiratory esophageal pressures associated with the first few spontaneous breaths in term newborns range from 45-90 cm H_2O. This high pressure, due to expiration against a partially closed glottis, may aid in the establishment of FRC but would be difficult to mimic safely with use of artificial ventilation. The higher pressures needed to initiate respiration are required to overcome the opposing forces of surface tension (particularly in small airways) and the viscosity of liquid remaining in the airways, as well as to introduce about 50 mL/kg of air into the lungs, 20-30 mL/kg of which remains after the first breath to establish FRC. Air entry into the lungs displaces fluid, decreases hydrostatic pressure in the pulmonary vasculature, and increases pulmonary blood flow. The greater blood flow, in turn, increases the blood volume of the lung and the effective vascular surface area available for fluid uptake. The remaining fluid is removed via the pulmonary lymphatics, upper airway, mediastinum, and pleural space. Fluid removal may be impaired after cesarean section or as a result of surfactant deficiency, endothelial cell damage, hypoalbuminemia, high pulmonary venous pressure, or neonatal sedation.

Initiation of the first breath is caused by a decline in Pa_{O_2} and pH and a rise in Pa_{CO_2} as a result of interruption of the placental circulation, a redistribution of cardiac output, a decrease in body temperature, and various tactile and sensory inputs. The relative contributions of these stimuli to the onset of respiration are uncertain.

When compared with term infants, preterm infants have a very compliant chest wall and may be at a disadvantage in establishing FRC. The FRC is lowest in the most immature infants because of the decrease in alveolar number. Abnormalities in ventilation : perfusion ratio are greater and persist for longer periods in preterm infants and may lead to hypoxemia and hypercarbia as a result of atelectasis, intrapulmonary shunting, hypoventilation, and gas trapping. The smallest immature infants have the most profound disturbances as a consequence of respiratory distress syndrome (RDS). However, even in healthy term infants, oxygenation is impaired immediately after birth, and oxygen saturation improves to exceed 90% only around 5 min. In addition, right-to-left shunting is common soon after birth; if pulse oximetry is performed soon after birth, the recommendation is to measure oxygen saturation in the right upper extremity.

BREATHING PATTERNS IN NEWBORNS

During sleep in the 1st few mo after birth, normal full-term infants may have episodes when regular breathing is interrupted by short pauses. This **periodic breathing** pattern, which shifts from a regular rhythmicity to cyclic brief episodes of intermittent apnea, is more common in preterm infants, who may have apneic pauses of 5-10 sec followed by a burst of rapid respirations at a rate of 50-60 breaths/min for 10-15 sec. They rarely have an associated change in color or heart rate, and periodic breathing often stops without apparent reason. Periodic breathing, a normal characteristic of neonatal respiration, has no prognostic significance.

101.2 Apnea

Waldemar A. Carlo

Apnea is a common problem in preterm infants that may be the result of prematurity or an associated illness. In term infants, apnea is always worrisome and demands prompt diagnostic evaluation. Periodic breathing must be distinguished from prolonged apneic pauses, because the latter may be associated with serious illnesses. Apnea is a feature of many primary diseases that affect neonates (Table 101-1). These disorders produce apnea by direct depression of the central nervous system's control of respiration (hypoglycemia, meningitis, drugs, hemorrhage, seizures), disturbances in oxygen delivery (shock, sepsis, anemia), or ventilation defects (obstruction of the airway, pneumonia, muscle weakness).

Idiopathic apnea of prematurity occurs in the absence of identifiable predisposing diseases. Apnea is a disorder of respiratory control and may be obstructive, central, or mixed. **Obstructive apnea** (pharyngeal instability, neck flexion) is characterized by absence of airflow but persistent chest wall motion. Pharyngeal collapse may follow the negative airway pressures generated during inspiration or it may result from incoordination of the tongue and other upper airway muscles

Table 101-1 Potential Causes of Neonatal Apnea and Bradycardia

Central nervous system	Intraventricular hemorrhage, drugs, seizures, hypoxic injury, herniation, neuromuscular disorders, Leigh syndrome, brainstem infarction or anomalies (e.g., olivopontocerebellar atrophy), spinal cord injury after general anesthesia
Respiratory	Pneumonia, obstructive airway lesions, upper airway collapse, atelectasis, extreme prematurity, laryngeal reflex, phrenic nerve paralysis, pneumothorax, hypoxia
Infectious	Sepsis, meningitis (bacterial, fungal, viral), respiratory syncytial virus, pertussis
Gastrointestinal	Oral feeding, bowel movement, necrotizing enterocolitis, intestinal perforation
Metabolic	↓ Glucose, ↓ calcium, ↓/↑ sodium, ↑ ammonia, ↑ organic acids, ↑ ambient temperature, hypothermia
Cardiovascular	Hypotension, hypertension, heart failure, anemia, hypovolemia, vagal tone
Other	Immaturity of respiratory center, sleep state

involved in maintaining airway patency. In **central apnea,** which is caused by decreased central nervous system (CNS) stimuli to respiratory muscles, both airflow and chest wall motion are absent. Gestational age is the most important determinant of respiratory control, with the frequency of apnea being inversely related to gestational age. The immaturity of the brainstem respiratory centers is manifested by an attenuated response to carbon dioxide and a paradoxical response to hypoxia that results in apnea rather than the hyperventilation observed after the 1st few mo of life. The most common pattern of idiopathic apnea in preterm neonates is **mixed apnea** (50-75% of cases), with obstructive apnea preceding (usually) or following central apnea. Short episodes of apnea are usually central, whereas prolonged ones are often mixed. Apnea depends on the sleep state; its frequency increases during active (rapid eye movement) sleep.

CLINICAL MANIFESTATIONS

The incidence of idiopathic apnea of prematurity varies inversely with gestational age. The onset of idiopathic apnea can be during the 1st 1-2 wk after birth but is often delayed if there is RDS or other causes of respiratory distress. Apneic episodes have been noted to be as frequent on day 1 as throughout the 1st wk in premature infants without respiratory disease. In preterm infants, **serious apnea** is defined as cessation of breathing for longer than 20 sec or for any duration if accompanied by cyanosis and bradycardia. The incidence of associated bradycardia increases with the length of the preceding apnea and correlates with the severity of hypoxia. Short apnea episodes (10 sec) are rarely associated with bradycardia, whereas longer episodes (>20 sec) have a higher incidence of bradycardia. Bradycardia follows the apnea by 1-2 sec in more than 95% of cases and is most often sinus, but on occasion it can be nodal. Vagal responses and, rarely, heart block are causes of bradycardia without apnea. Short oxygen desaturation episodes noted with oxygen saturation monitoring are normal in neonates, and treatment is not necessary.

TREATMENT

Infants at risk for apnea should get cardiorespiratory monitoring. Gentle tactile stimulation is often adequate therapy for mild and intermittent episodes. The onset of apnea in a previously well preterm neonate after the 2nd wk of life or in a term infant at any time is a critical event that warrants prompt investigation. Recurrent apnea of prematurity may be treated with caffeine or theophylline. Methylxanthines increase central respiratory drive by lowering the threshold of response to hypercapnia as well as enhancing contractility of the diaphragm and preventing diaphragmatic fatigue. Caffeine and theophylline are as effective, *but caffeine has fewer side effects (less tachycardia and feeding intolerance)*. Loading doses of 5-7 mg/kg of theophylline (orally) or aminophylline (intravenously) should be followed by doses of 1-2 mg/kg given every 6-12 hr by the oral or intravenous route. Loading doses of 20 mg/kg of **caffeine citrate** are followed 24 hr later by maintenance doses of 5 mg/kg/24 hr qd, either orally or intravenously. These doses should be monitored through observation of vital signs and clinical response. Serum drug determinations (therapeutic levels: theophylline, 6-10 µg/mL; caffeine, 8-20 µg/mL) are optional because important side effects of these medications are rare. Higher doses of methylxanthines may be more effective, do not necessarily result in more frequent side effects, and may reduce major neurodevelopmental disabilities. Withholding respiratory stimulants in infants with RDS may result in ventilator dependency, increased bronchopulmonary dysplasia (BPD), and death. Doxapram, known to be a potent respiratory stimulant, acts predominantly on peripheral chemoreceptors and is effective in neonates with apnea of prematurity that is unresponsive to methylxanthines. Transfusion of packed red blood cells to reduce the incidence of idiopathic apnea is reserved for severely anemic infants. Gastroesophageal reflux is common in neonates, but data do not support a causal relationship between gastroesophageal reflux and apneic events or the use of antireflux medications to reduce the frequency of apnea in preterm infants.

Nasal continuous positive airway pressure (continuous positive airway pressure [CPAP], 3-5 cm H_2O) and high-flow humidification using nasal cannula (1-2.5 L/min) are therapies for mixed or obstructive apnea, but CPAP is preferred because of its proven efficacy and safety. The efficacy of CPAP is related to its ability to splint the upper airway and prevent airway obstruction.

PROGNOSIS

Apnea of prematurity does not alter an infant's prognosis unless it is severe, recurrent, and refractory to therapy. The associated problems of intraventricular hemorrhage (IVH), BPD, and retinopathy of prematurity are critical in determining the prognosis for apneic infants. Apnea of prematurity usually resolves by 37 wk of postconceptional age, although it may persist beyond term gestation, particularly in extremely preterm infants born at <28 wk of gestation, and does not predict future episodes of sudden infant death syndrome (SIDS). Some infants with persistent apnea are discharged with cardiorespiratory monitoring performed at home. In the absence of significant events, home monitoring can be safely discontinued after 44 wk postconceptional age.

APNEA AND SUDDEN INFANT DEATH SYNDROME

Although preterm infants are at higher risk for SIDS, apnea of prematurity is not a risk factor for SIDS. The epidemiologic evidence that positioning the babies to sleep on their backs reduces the rate of SIDS deaths by more than 50% suggests that position, and not prematurity, has been the primary cause of SIDS. Avoidance of cigarette smoke exposure and of overheating the infant are also important in the prevention of SIDS.

Bibliography is available at Expert Consult.

101.3 Respiratory Distress Syndrome (Hyaline Membrane Disease)

Waldemar A. Carlo and Namasivayam Ambalavanan

INCIDENCE

Respiratory distress syndrome occurs primarily in premature infants; its incidence is inversely related to gestational age and birthweight. It occurs in 60-80% of infants <28 wk of gestational age, in 15-30% of those between 32 and 36 wk of gestational age, and rarely in those >37 wk of gestational age. The risk for development of RDS increases with maternal diabetes, multiple births, cesarean delivery, precipitous delivery, asphyxia, cold stress, and a maternal history of previously affected infants. The incidence is highest in preterm male or white infants. The risk of RDS is reduced in pregnancies with chronic or pregnancy-associated hypertension, maternal heroin use, prolonged rupture of membranes, and antenatal corticosteroid prophylaxis.

ETIOLOGY AND PATHOPHYSIOLOGY

Surfactant deficiency (decreased production and secretion) is the primary cause of RDS. The failure to attain an adequate FRC and the tendency of affected lungs to become atelectatic correlate with high surface tension and the absence of pulmonary surfactant. The major constituents of surfactant are dipalmitoyl phosphatidylcholine (lecithin), phosphatidylglycerol, apoproteins (surfactant proteins SP-A, SP-B, SP-C, and SP-D), and cholesterol (Fig. 101-2). With advancing gestational age, increasing amounts of phospholipids are synthesized and stored in type II alveolar cells (Fig. 101-3). These surface-active agents are released into the alveoli, where they reduce surface tension and help maintain alveolar stability by preventing the collapse of small air spaces at end-expiration. Because of immaturity, the amounts produced or released may be insufficient to meet postnatal demands. Surfactant is present in high concentrations in fetal lung homogenates by 20 wk of gestation, but it does not reach the surface of the lungs until later. It appears in amniotic fluid between 28 and 32 wk of gestation. Mature levels of pulmonary surfactant are present usually after 35 wk of gestation.

Although rare, genetic disorders may contribute to respiratory distress. Abnormalities in surfactant protein B and C genes as well as a gene responsible for transporting surfactant across membranes (ABC transporter 3 *[ABCA3]*) are associated with severe and often lethal familial respiratory disease. Other familial causes of neonatal respiratory distress (not RDS) include alveolar capillary dysplasia, acinar dysplasia, pulmonary lymphangiectasia, and mucopolysaccharidosis.

Synthesis of surfactant depends in part on normal pH, temperature, and perfusion. Asphyxia, hypoxemia, and pulmonary ischemia, particularly in association with hypovolemia, hypotension, and cold stress, may suppress surfactant synthesis. The epithelial lining of the lungs may also be injured by high oxygen concentrations and the effects of respirator management, thereby resulting in a further reduction in surfactant.

Alveolar atelectasis, hyaline membrane formation, and interstitial edema make the lungs less compliant in RDS, so greater pressure is required to expand the alveoli and small airways. The chest wall of the preterm infant, which is highly compliant, offers less resistance than that of the mature infant to the natural tendency of the lungs to collapse. Thus, at end-expiration, the volume of the thorax and lungs tends to approach residual volume, and atelectasis may develop.

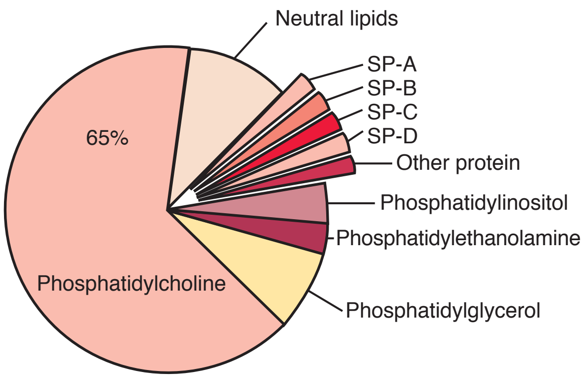

Figure 101-2 Composition of surfactant recovered by alveolar wash. The quantities of the different components are similar for surfactant from the mature lungs of mammals. SP, surfactant protein. *(From Jobe AH: Fetal lung development, tests for maturation, induction of maturation, and treatment. In Creasy RK, Resnick R, editors:* Maternal-fetal medicine: principles and practice, *ed 3, Philadelphia, 1994, WB Saunders.)*

Deficient synthesis or release of surfactant, together with small respiratory units and a compliant chest wall, produces atelectasis and results in perfused but not ventilated alveoli, causing **hypoxia.** Decreased lung compliance, small tidal volumes, increased physiologic dead space, and insufficient alveolar ventilation eventually result in **hypercapnia.** The combination of hypercapnia, hypoxia, and acidosis produces pulmonary arterial vasoconstriction with increased right-to-left shunting through the foramen ovale and ductus arteriosus and within the lung itself. Progressive injury to epithelial and endothelial cells from atelectasis (atelectrauma), volutrauma, ischemic injury, and oxygen toxicity results in effusion of proteinaceous material into the alveolar spaces (Fig. 101-4).

CLINICAL MANIFESTATIONS

Signs of RDS usually appear within minutes of birth, although they may not be recognized for several hours in larger premature infants until rapid, shallow respirations become more obvious. A later onset of tachypnea should suggest other conditions. Some patients require resuscitation at birth because of intrapartum asphyxia or initial severe respiratory distress (especially with a birthweight <1,000 g). Characteristically, tachypnea, prominent (often audible) grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis are noted. Breath sounds may be normal or diminished with a harsh tubular quality, and on deep inspiration, fine crackles may be heard. The natural course of untreated RDS is characterized by progressive worsening of cyanosis and dyspnea. If the condition is inadequately treated, blood pressure may fall; cyanosis and pallor increase, and grunting decreases or disappears, as the condition worsens. Apnea and irregular respirations are ominous signs requiring immediate intervention. Untreated patients may also have a mixed respiratory-metabolic acidosis, edema, ileus, and oliguria. Respiratory failure may occur in infants with rapid progression of the disease. In most cases, the signs reach a peak within 3 days, after which improvement is gradual. Improvement is often heralded by spontaneous diuresis and improved blood gas values at lower inspired oxygen levels and/or lower ventilator support. Death can result from severe impairment of gas exchange, alveolar air leaks (interstitial emphysema, pneumothorax), pulmonary hemorrhage, or IVH. BPD is a form of chronic lung disease that often develops in infants with severe RDS.

DIAGNOSIS

The clinical course, chest x-ray findings, and blood gas and acid–base values help establish the clinical diagnosis. On x-ray, the lungs may have a characteristic but not pathognomonic appearance that includes

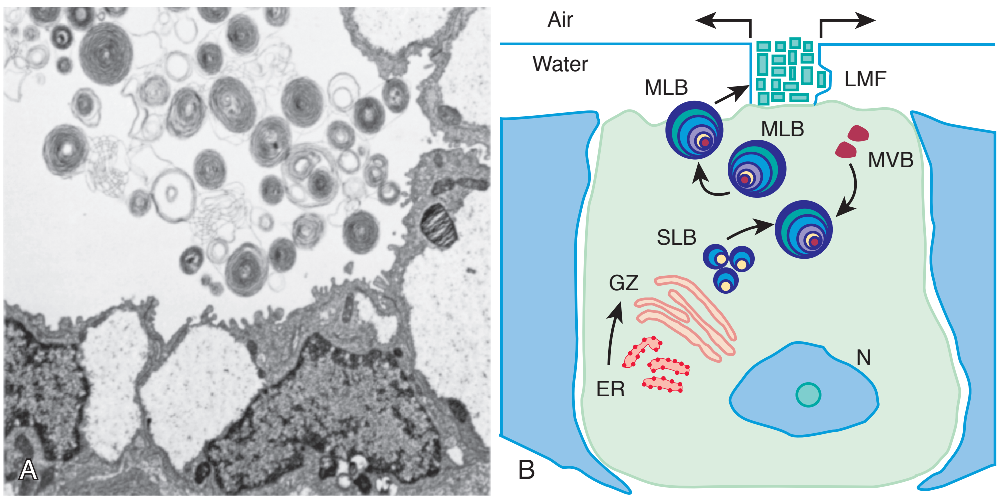

Figure 101-3 A, Fetal rat lung (low magnification), day 20 (term: day 22) showing developing type II cells, stored glycogen *(pale areas),* secreted lamellar bodies, and tubular myelin. **B,** Possible pathway for transport, secretion, and reuptake of surfactant. a fine reticular granularity of the parenchyma and air bronchograms, which are often more prominent early in the left lower lobe because of superimposition of the cardiac shadow (Fig. 101-5). The initial x-ray appearance is occasionally normal, with the typical pattern developing during the first day. Considerable variation in radiographic findings may be seen, depending on the phase of respiration (inspiratory vs. expiratory radiograph) and the use of CPAP or positive end-expiratory pressure (PEEP); this variation often results in poor correlation between radiographic findings and the clinical course. Laboratory findings are characterized initially by hypoxemia and later by progressive hypoxemia, hypercapnia, and variable metabolic acidosis.

In the differential diagnosis**, early-onset sepsis** may be indistinguishable from RDS. In neonates with **pneumonia**, the chest radiograph may be identical to that for RDS. Maternal group B streptococcal colonization, identification of organisms on Gram staining of gastric or tracheal aspirates or a buffy coat smear, and/or the presence of marked neutropenia may suggest the diagnosis of early-onset sepsis. **Cyanotic heart disease** (in particular, total anomalous pulmonary venous return) can also mimic RDS both clinically and radiographically. Echocardiography with color-flow imaging should be performed in infants who show no response to surfactant replacement to rule out cyanotic congenital heart disease as well as ascertain patency of the ductus arteriosus and assess pulmonary vascular resistance (PVR). **Persistent pulmonary hypertension, aspiration (meconium, amniotic fluid) syndromes, spontaneous pneumothorax, pleural effusions**, and **congenital anomalies,** such as cystic adenomatoid malformation, pulmonary lymphangiectasia, diaphragmatic hernia, and lobar emphysema, must be considered in patients with an atypical clinical course, but can generally be differentiated from RDS through radiographic and other evaluations. **Transient tachypnea** may be distinguished by its shorter and milder clinical course and is characterized by low or no need for oxygen supplementation. Congenital alveolar proteinosis (congenital surfactant protein B deficiency) is a rare familial disease that manifests as severe and lethal RDS in predominantly term and near-term infants (see Chapter 405). In atypical cases of RDS, a lung profile (lecithin : sphingomyelin ratio and phosphatidylglycerol determination) performed on a tracheal aspirate can be helpful in establishing a diagnosis of surfactant deficiency.

PREVENTION

Avoidance of unnecessary or poorly timed early cesarean section (<39 wk) or induction of labor, appropriate management of high-risk pregnancy and labor (including administration of antenatal corticosteroids), and prediction of pulmonary immaturity with possible in utero acceleration of maturation (see Chapter 98) are important preventive strategies. Antenatal and intrapartum fetal monitoring may decrease the risk of fetal asphyxia; asphyxia is associated with an increased incidence and severity of RDS.

Administration of antenatal corticosteroids to women before 34 wk of gestation significantly reduces the incidence and mortality of RDS as well as overall neonatal mortality. Antenatal steroids also reduce (1) overall mortality, (2) the need for and duration of ventilatory support and admission to a neonatal ICU, and (3) the incidence of severe IVH, necrotizing enterocolitis, and neurodevelopmental impairment. Postnatal growth is not adversely affected. Antenatal steroids do not increase the risk of maternal death, chorioamnionitis, or puerperal sepsis. Steroid administration is recommended for all women in preterm labor who are likely to deliver a fetus within 1 wk. Antenatal steroids act synergistically with postnatal exogenous surfactant therapy so they should be given even though surfactant therapy is effective. Betamethasone and dexamethasone have both been used antenatally. Betamethasone may reduce neonatal death to a greater extent as compared to dexamethasone.

In the past administration of surfactant into the trachea of symptomatic premature infants immediately after birth (prophylactic) or during the 1st few hr of life (early rescue) showed reduced air leak and mortality from RDS. *CPAP started at birth is as effective as prophylactic or early surfactant and is the approach of choice for the delivery room management of a preterm neonate at risk for RDS.*

TREATMENT

The basic defect requiring treatment in RDS is inadequate pulmonary exchange of oxygen and carbon dioxide; metabolic acidosis and circulatory insufficiency are secondary manifestations. Early supportive care of premature infants, especially in the treatment of acidosis, hypoxia, hypotension (see Chapter 98), and hypothermia, may lessen the severity of RDS. Therapy requires careful and frequent monitoring
